#### Abstract

Quantitative languages are an extension of boolean languages that assign to each word a real number. Mean-payoff automata are finite automata with numerical weights on transitions that assign to each infinite path the long-run average of the transition weights. When the mode of branching of the automaton is deterministic, nondeterministic, or alternating, the corresponding class of quantitative languages is not robust as it is not closed under the pointwise operations of max, min, sum, and numerical complement. Nondeterministic and alternating mean-payoff automata are not decidable either, as the quantitative generalization of the problems of universality and language inclusion is undecidable. We introduce a new class of quantitative languages, defined by mean-payoff automaton expressions, which is robust and decidable: it is closed under the four pointwise operations, and we show that all decision problems are decidable for this class. Mean-payoff automaton expressions subsume deterministic meanpayoff automata, and we show that they have expressive power incomparable to nondeterministic and alternating mean-payoff automata. We also present for the first time an algorithm to compute distance between two quantitative languages, and in our case the quantitative languages are given as mean-payoff automaton expressions.

## 1 Introduction

Quantitative languages $L$ are a natural generalization of boolean languages that assign to every word $w$ a real number $L(w) \in \mathbb{R}$ instead of a boolean value. For instance, the value of a word (or behavior) can be interpreted as the amount of some resource (e.g., memory consumption, or power consumption) needed to produce it, or bound the long-run average available use of the resource. Thus quantitative languages can specify properties related to resource-constrained programs, and an implementation $L_{A}$ satisfies (or refines) a specification $L_{B}$ if $L_{A}(w) \leq L_{B}(w)$ for all words $w$. This notion of refinement is a quantitative generalization of language inclusion, and it can be used to check for example if for each behavior, the long-run average response time of the system lies below the specified average response requirement. Hence it is crucial to identify some relevant class of quantitative languages for which this question is decidable. The other classical decision questions such as emptiness, universality, and language equivalence have also a natural quantitative extension. For example, the quantitative emptiness problem asks, given a quantitative language $L$ and a threshold $\nu \in \mathbb{Q}$, whether there exists some word $w$ such that $L(w) \geq \nu$, and the quantitative universality problem asks
whether $L(w) \geq \nu$ for all words $w$. Note that universality is a special case of language inclusion (where $L_{A}(w)=\nu$ is constant).

Weighted mean-payoff automata present a nice framework to express such quantitative properties [3]. A weighted mean-payoff automaton is a finite automaton with numerical weights on transitions. The value of a word $w$ is the maximal value of all runs over $w$ (if the automaton is nondeterministic, then there may be many runs over $w$ ), and the value of a run $r$ is the long-run average of the weights that appear along $r$. A mean-payoff extension to alternating automata has been studied in [4]. Deterministic, nondeterministic and alternating mean-payoff automata are three classes of meanpayoff automata with increasing expressive power. However, none of these classes is closed under the four pointwise operations of max, min (which generalize union and intersection respectively), numerical complement ${ }^{4}$, and sum (see Table 1). Deterministic mean-payoff automata are not closed under max, min, and sum [5]; nondeterministic mean-payoff automata are not closed under min, sum and complement [5]; and alternating mean-payoff automata are not closed under sum [4]. Hence none of the above classes is robust with respect to closure properties.

Moreover, while deterministic mean-payoff automata enjoy decidability of all quantitative decision problems [3], the quantitative language-inclusion problem is undecidable for nondeterministic and alternating mean-payoff automata [9], and thus also all decision problems are undecidable for alternating mean-payoff automata. Hence although mean-payoff automata provide a nice framework to express quantitative properties, there is no known class which is both robust and decidable (see Table 1).

In this paper, we introduce a new class of quantitative languages that are defined by mean-payoff automaton expressions. An expression is either a deterministic meanpayoff automaton, or it is the max, min, or sum of two mean-payoff automaton expressions. Since deterministic mean-payoff automata are closed under complement, mean-payoff automaton expressions form a robust class that is closed under max, min, sum and complement. We show that (a) all decision problems (quantitative emptiness, universality, inclusion, and equivalence) are decidable for mean-payoff automaton expressions; (b) mean-payoff automaton expressions are incomparable in expressive power with both the nondeterministic and alternating mean-payoff automata (i.e., there are quantitative languages expressible by mean-payoff automaton expressions that are not expressible by alternating mean-payoff automata, and there are quantitative languages expressible by nondeterministic mean-payoff automata that are not expressible by mean-payoff automata expressions); and (c) the properties of cut-point languages (i.e., the sets of words with value above a certain threshold) for deterministic automata carry over to mean-payoff automaton expressions, mainly the cut-point language is $\omega$ regular when the threshold is isolated (i.e., some neeighborhood around the threshold contains no word). Moreover, mean-payoff automaton expressions can express all examples in the literature of quantitative properties using mean-payoff measure [1,5,6]. Along with the quantitative generalization of the classical decision problems, we also consider the notion of distance between two quantitative languages $L_{A}$ and $L_{B}$, defined as $\sup _{w}\left|L_{A}(w)-L_{B}(w)\right|$. When quantitative language inclusion does not hold between an implementation $L_{A}$ and a specification $L_{B}$, the distance is a relevant information to

Table 1. Closure properties and decidability of the various classes of mean-payoff automata. Mean-payoff automaton expressions enjoy fully positive closure and decidability properties.
evaluate how close they are, as we may accept implementations that overspend the resource but we would prefer the least expensive ones. We present the first algorithm to compute the distance between two quantitative languages: we show that the distance can be computed for mean-payoff automaton expressions.

Our approach to show decidability of mean-payoff automaton expressions relies on the characterization and algorithmic computation of the values set $\left\{L_{E}(w) \mid w \in \Sigma^{\omega}\right\}$ of an expression $E$, i.e. the set of all values of words according to $E$. The value set can be viewed as an abstract representation of the quantitative language $L_{E}$, and we show that all decision problems, cut-point language and distance computation can be solved efficiently once we have this set.

First, we present a precise characterization of the value set for quantitative languages defined by mean-payoff automaton expressions. In particular, we show that it is not sufficient to construct the convex hull $\operatorname{conv}\left(S_{E}\right)$ of the set of the values of simple cycles in the mean-payoff automata occurring in $E$, but we need essentially to apply an operator $F_{\min }(\cdot)$ which given a set $Z \subseteq \mathbb{R}^{n}$ computes the set of points $y \in \mathbb{R}^{n}$ that can be obtained by taking pointwise minimum of each coordinate of points of a set $X \subseteq Z$. We show that while we need to compute the set $V_{E}=F_{\min }\left(\operatorname{conv}\left(S_{E}\right)\right)$ to obtain the value set, and while this set is always convex, it is not always the case that $F_{\min }\left(\operatorname{conv}\left(S_{E}\right)\right)=\operatorname{conv}\left(F_{\min }\left(S_{E}\right)\right)$ (which would immediately give an algorithm to compute $V_{E}$ ). This may appear counter-intuitive because the equality holds in $\mathbb{R}^{2}$ but we show that the equality does not hold in $\mathbb{R}^{3}$ (Example 2).

Second, we provide algorithmic solutions to compute $F_{\min }(\operatorname{conv}(S))$, for a finite set $S$. We first present a constructive procedure that given $S$ constructs a finite set of points $S^{\prime}$ such that $\operatorname{conv}\left(S^{\prime}\right)=F_{\min }(\operatorname{conv}(S))$. The explicit construction presents interesting properties about the set $F_{\min }(\operatorname{conv}(S))$, however the procedure itself is computationally expensive. We then present an elegant and geometric construction of $F_{\min }(\operatorname{conv}(S))$ as a set of linear constraints. The computation of $F_{\min }(\operatorname{conv}(S))$ is a new problem in computational geometry and the solutions we present could be of independent interest. Using the algorithm to compute $F_{\min }(\operatorname{conv}(S))$, we show that all decision problems for mean-payoff automaton expressions are decidable. Due to lack of space, most proofs are given in the appendix.

[^1]Related works. Quantitative languages have been first studied over finite words in the context of probabilistic automata [16] and weighted automata [17]. Several works have generalized the theory of weighted automata to infinite words (see [13, 11, 15, 2] and [12] for a survey), but none of those have considered mean-payoff conditions. Examples where the mean-payoff measure has been used to specify long-run behaviours of systems can be found in game theory [14, 19] and in Markov decision processes [7]. The mean-payoff automata as a specification language have been first investigated in $[3,5$, 4], and extended in [1] to construct a new class of (non-quantitative) languages of infinite words (the multi-threshold mean-payoff languages), obtained by applying a query to a mean-payoff language, and for which emptiness is decidable. It turns out that a richer language of queries can be expressed using mean-payoff automaton expressions (together with decidability of the emptiness problem). A detailed comparison with the results of [1] is given in Section 5. Moreover, we provide algorithmic solutions to the quantitative language inclusion and equivalence problems and to distance computation which have no counterpart for non-quantitative languages. Related notions of metrics have been addressed in stochastic games [8] and probabilistic processes [10, 18].

## 2 Mean-Payoff Automaton Expressions

Quantitative languages. A quantitative language $L$ over a finite alphabet $\Sigma$ is a function $L: \Sigma^{\omega} \rightarrow \mathbb{R}$. Given two quantitative languages $L_{1}$ and $L_{2}$ over $\Sigma$, we denote by $\max \left(L_{1}, L_{2}\right)$ (resp., $\min \left(L_{1}, L_{2}\right), \operatorname{sum}\left(L_{1}, L_{2}\right)$ and $\left.-L_{1}\right)$ the quantitative language that assigns $\max \left(L_{1}(w), L_{2}(w)\right)$ (resp., $\min \left(L_{1}(w), L_{2}(w)\right), L_{1}(w)+L_{2}(w)$, and $-L_{1}(w)$ ) to each word $w \in \Sigma^{\omega}$. The quantitative language $-L$ is called the complement of $L$. The max and min operators for quantitative languages correspond respectively to the least upper bound and greatest lower bound for the pointwise order $\preceq$ such that $L_{1} \preceq L_{2}$ if $L_{1}(w) \leq L_{2}(w)$ for all $w \in \Sigma^{\omega}$. Thus, they generalize respectively the union and intersection operators for classical boolean languages.
Weighted automata. A $\mathbb{Q}$-weighted automaton is a tuple $A=\left\langle Q, q_{I}, \Sigma, \delta\right.$, wt $\rangle$, where

- $Q$ is a finite set of states, $q_{I} \in Q$ is the initial state, and $\Sigma$ is a finite alphabet;
- $\delta \subseteq Q \times \Sigma \times Q$ is a finite set of labelled transitions. We assume that $\delta$ is total, i.e., for all $q \in Q$ and $\sigma \in \Sigma$, there exists $q^{\prime}$ such that $\left(q, \sigma, q^{\prime}\right) \in \delta$;
- wt : $\delta \rightarrow \mathbb{Q}$ is a weight function, where $\mathbb{Q}$ is the set of rational numbers. We assume that rational numbers are encoded as pairs of integers in binary.

We say that $A$ is deterministic if for all $q \in Q$ and $\sigma \in \Sigma$, there exists $\left(q, \sigma, q^{\prime}\right) \in \delta$ for exactly one $q^{\prime} \in Q$. We sometimes call automata nondeterministic to emphasize that they are not necessarily deterministic.
Words and runs. A word $w \in \Sigma^{\omega}$ is an infinite sequence of letters from $\Sigma$. A lassoword $w$ in $\Sigma^{\omega}$ is an ultimately periodic word of the form $w_{1} \cdot w_{2}^{\omega}$ where $w_{1} \in \Sigma^{*}$ is a finite prefix, and $w_{2} \in \Sigma^{+}$is nonempty. A run of $A$ over an infinite word $w=\sigma_{1} \sigma_{2} \ldots$ is an infinite sequence $r=q_{0} \sigma_{1} q_{1} \sigma_{2} \ldots$ of states and letters such that (i) $q_{0}=q_{I}$, and (ii) $\left(q_{i}, \sigma_{i+1}, q_{i+1}\right) \in \delta$ for all $i \geq 0$. We denote by $\operatorname{wt}(r)=v_{0} v_{1} \ldots$ the sequence of weights that occur in $r$ where $v_{i}=\mathrm{wt}\left(q_{i}, \sigma_{i+1}, q_{i+1}\right)$ for all $i \geq 0$.

Quantitative language of mean-payoff automata. The mean-payoff value (or limitaverage) of a sequence $\bar{v}=v_{0} v_{1} \ldots$ of real numbers is either

$$
\operatorname{Lim} \operatorname{InfA} \operatorname{Avg}(\bar{v})=\liminf _{n \rightarrow \infty} \frac{1}{n} \cdot \sum_{i=0}^{n-1} v_{i}, \text { or } \quad \operatorname{LimSupAvg}(\bar{v})=\limsup _{n \rightarrow \infty} \frac{1}{n} \cdot \sum_{i=0}^{n-1} v_{i} .
$$

Note that if we delete or insert finitely many values in an infinite sequence of numbers, its limit-average does not change, and if the sequence is ultimately periodic, then the LimInfAvg and LimSupAvg values coincide (and correspond to the mean of the weights on the periodic part of the sequence).

For Val $\in\{\operatorname{Lim} \operatorname{lnf} A v g, \operatorname{LimSupAvg}\}$, the quantitative language $L_{A}$ of $A$ is defined by $L_{A}(w)=\sup \{\operatorname{Val}(\operatorname{wt}(r)) \mid r$ is a run of $A$ over $w\}$ for all $w \in \Sigma^{\omega}$. Accordingly, the automaton $A$ and its quantitative language $L_{A}$ are called LimInfAvg or LimSupAvg. Note that for deterministic automata, we have $L_{A}(w)=\operatorname{Val}(\mathrm{wt}(r))$ where $r$ is the unique run of $A$ over $w$.

We omit the weight function wt when it is clear from the context, and we write LimAvg when the value according to LimInfAvg and LimSupAvg coincide (e.g., for runs with a lasso shape).
Decision problems and distance. We consider the following classical decision problems for quantitative languages, assuming an effective presentation of quantitative languages (such as mean-payoff automata, or automaton expressions defined later). Given a quantitative language $L$ and a threshold $\nu \in \mathbb{Q}$, the quantitative emptiness problem asks whether there exists a word $w \in \Sigma^{\omega}$ such that $L(w) \geq \nu$, and the quantitative universality problem asks whether $L(w) \geq \nu$ for all words $w \in \Sigma^{\omega}$.

Given two quantitative languages $L_{1}$ and $L_{2}$, the quantitative language-inclusion problem asks whether $L_{1}(w) \leq L_{2}(w)$ for all words $w \in \Sigma^{\omega}$, and the quantitative language-equivalence problem asks whether $L_{1}(w)=L_{2}(w)$ for all words $w \in \Sigma^{\omega}$. Note that universality is a special case of language inclusion where $L_{1}$ is constant. Finally, the distance between $L_{1}$ and $L_{2}$ is $D_{\sup }\left(L_{1}, L_{2}\right)=\sup _{w \in \Sigma^{\omega}}\left|L_{1}(w)-L_{2}(w)\right|$. It measures how close is an implementation $L_{1}$ as compared to a specification $L_{2}$.

It is known that quantitative emptiness is decidable for nondeterministic meanpayoff automata [3], while decidability was open for alternating mean-payoff automata, as well as for the quantitative language-inclusion problem of nondeterministic meanpayoff automata. Recent undecidability results on games with imperfect information and mean-payoff objective [9] entail that these problems are undecidable (see Theorem 5).
Robust quantitative languages. A class $\mathcal{Q}$ of quantitative languages is robust if the class is closed under max, min, sum and complementation operations. The closure properties allow quantitative languages from a robust class to be described compositionally. While nondeterministic LimInfAvg- and LimSupAvg-automata are closed under the max operation, they are not closed under min and complement [5]. Alternating LimInfAvg- and LimSupAvg-automata ${ }^{6}$ are closed under max and min, but are not closed under complementation and sum [4] We define a robust class of quantitative

[^2]languages for mean-payoff automata which is closed under max, min, sum, and complement, and which can express all natural examples of quantitative languages defined using the mean-payoff measure $[1,5,6]$.
Mean-payoff automaton expressions. A mean-payoff automaton expression $E$ is obtained by the following grammar rule:
$$
E::=A|\max (E, E)| \min (E, E) \mid \operatorname{sum}(E, E)
$$
where $A$ is a deterministic LimInfAvg- or LimSupAvg-automaton. The quantitative language $L_{E}$ of a mean-payoff automaton expression $E$ is $L_{E}=L_{A}$ if $E=A$ is a deterministic automaton, and $L_{E}=\mathrm{op}\left(L_{E_{1}}, L_{E_{2}}\right)$ if $E=\mathrm{op}\left(E_{1}, E_{2}\right)$ for op $\in$ $\{\max , \min , \operatorname{sum}\}$. By definition, the class of mean-payoff automaton expression is closed under max, min and sum. Closure under complement follows from the fact that the complement of $\max \left(E_{1}, E_{2}\right)$ is $\min \left(-E_{1},-E_{2}\right)$, the complement of $\min \left(E_{1}, E_{2}\right)$ is $\max \left(-E_{1},-E_{2}\right)$, the complement of $\operatorname{sum}\left(E_{1}, E_{2}\right)$ is $\operatorname{sum}\left(-E_{1},-E_{2}\right)$, and the complement of a deterministic LimInfAvg-automaton can be defined by the same automaton with opposite weights and interpreted as a LimSupAvg-automaton, and vice versa, since $-\lim \sup \left(v_{0}, v_{1}, \ldots\right)=\lim \inf \left(-v_{0},-v_{1}, \ldots\right)$. Note that arbitrary linear combinations of deterministic mean-payoff automaton expressions (expressions such as $c_{1} E_{1}+c_{2} E_{2}$ where $c_{1}, c_{2} \in \mathbb{Q}$ are rational constants) can be obtained for free since scaling the weights of a mean-payoff automaton by a positive factor $|c|$ results in a quantitative language scaled by the same factor.

## 3 The Vector Set of Mean-Payoff Automaton Expressions

Given a mean-payoff automaton expression $E$, let $A_{1}, \ldots, A_{n}$ be the deterministic weighted automata occurring in $E$. The vector set of $E$ is the set $V_{E}=$ $\left\{\left\langle L_{A_{1}}(w), \ldots, L_{A_{n}}(w)\right\rangle \in \mathbb{R}^{n} \mid w \in \Sigma^{\omega}\right\}$ of tuples of values of words according to each automaton $A_{i}$. In this section, we characterize the vector set of mean-payoff automaton expressions, and in Section 4 we give an algorithmic procedure to compute this set. This will be useful to establish the decidability of all decision problems, and to compute the distance between mean-payoff automaton expressions. Given a vector $v \in \mathbb{R}^{n}$, we denote by $\|v\|=\max _{i}\left|v_{i}\right|$ the $\infty$-norm of $v$.

The synchronized product of $A_{1}, \ldots, A_{n}$ such that $A_{i}=\left\langle Q_{i}, q_{I}^{i}, \Sigma, \delta_{i}\right.$, wt $\left._{i}\right\rangle$ is the $\mathbb{Q}^{n}$-weighted automaton $A_{E}=A_{1} \times \cdots \times A_{n}=\left\langle Q_{1} \times \cdots \times Q_{n},\left(q_{I}^{1}, \ldots, q_{I}^{n}\right), \Sigma, \delta\right.$, wt $\rangle$ such that $t=\left(\left(q_{1}, \ldots, q_{n}\right), \sigma,\left(q_{1}^{\prime}, \ldots, q_{n}^{\prime}\right)\right) \in \delta$ if $t_{i}:=\left(q_{i}, \sigma, q_{i}^{\prime}\right) \in \delta_{i}$ for all $1 \leq i \leq n$, and $w t(t)=\left(\mathrm{wt}_{1}\left(t_{1}\right), \ldots, \mathrm{wt}_{n}\left(t_{n}\right)\right)$. In the sequel, we assume that all $A_{i}$ 's are deterministic LimInfAvg-automata (hence, $A_{E}$ is deterministic) and that the underlying graph of the automaton $A_{E}$ has only one strongly connected component (scc). We show later how to obtain the vector set without these restrictions.

For each (simple) cycle $\rho$ in $A_{E}$, let the vector value of $\rho$ be the mean of the tuples labelling the edges of $\rho$, denoted $\operatorname{Avg}(\rho)$. To each simple cycle $\rho$ in $A_{E}$ corresponds a (not necessarily simple) cycle in each $A_{i}$, and the vector value $\left(v_{1}, \ldots, v_{n}\right)$ of $\rho$ contains the mean value $v_{i}$ of $\rho$ in each $A_{i}$. We denote by $S_{E}$ the (finite) set of vector values of simple cycles in $A_{E}$. Let conv $\left(S_{E}\right)$ be the convex hull of $S_{E}$.

Fig. 1. The vector set of $E=\max \left(A_{1}, A_{2}\right)$ is $F_{\min }\left(\operatorname{conv}\left(S_{E}\right)\right) \supsetneq \operatorname{conv}\left(S_{E}\right)$.

Lemma 1. Let $E$ be a mean-payoff automaton expression. The set $\operatorname{conv}\left(S_{E}\right)$ is the closure of the set $\left\{L_{E}(w) \mid w\right.$ is a lasso-word $\}$.

The vector set of $E$ contains more values than the convex hull $\operatorname{conv}\left(S_{E}\right)$, as shown by the following example.

Example 1. Consider the expression $E=\max \left(A_{1}, A_{2}\right)$ where $A_{1}$ and $A_{2}$ are deterministic LimInfAvg-automata (see Fig. 1). The product $A_{E}=A_{1} \times A_{2}$ has two simple cycles with respective vector values $(1,0)$ (on letter ' $a$ ') and $(0,1)$ (on letter ' $b$ '). The set $H=\operatorname{conv}\left(S_{E}\right)$ is the solid segment on Fig. 1 and contains the vector values of all lasso-words. However, other vector values can be obtained: consider the word $w=a^{n_{1}} b^{n_{2}} a^{n_{3}} b^{n_{4}} \ldots$ where $n_{1}=1$ and $n_{i+1}=\left(n_{1}+\cdots+n_{i}\right)^{2}$ for all $i \geq 1$. It is easy to see that the value of $w$ according to $A_{1}$ is 0 because the average number of $a$ 's in the prefixes $a^{n_{1}} b^{n_{2}} \ldots a^{n_{i}} b^{n_{i+1}}$ for $i$ odd is smaller than $\frac{n_{1}+\cdots+n_{i}}{n_{1}+\cdots+n_{i}+n_{i+1}}=\frac{1}{1+n_{1}+\cdots+n_{i}}$ which tends to 0 when $i \rightarrow \infty$. Since $A_{1}$ is a LimInfAvg-automaton, the value of $w$ is 0 in $A_{1}$, and by a symmetric argument the value of $w$ is also 0 in $A_{2}$. Therefore the vector $(0,0)$ is in the vector set of $E$. Note that $z=(0,0)$ is the pointwise minimum of $x=(1,0)$ and $y=(0,1)$, i.e. $(0,0)=f_{\min }((1,0),(0,1))$ where $z=f_{\min }(x, y)$ if $z_{1}=\min \left(x_{1}, y_{1}\right)$ and $z_{2}=\min \left(y_{1}, y_{2}\right)$. In fact, the vector set is the whole triangular region in Fig. 1, i.e. $V_{E}=\left\{f_{\min }(x, y) \mid x, y \in \operatorname{conv}\left(S_{E}\right)\right\}$.

We generalize $f_{\min }$ to finite sets of points $P \subseteq \mathbb{R}^{n}$ in $n$ dimensions as follows: $f_{\min }(P) \in \mathbb{R}^{n}$ is the point $p=\left(p_{1}, p_{2}, \ldots, p_{n}\right)$ such that $p_{i}$ is the minimum $i^{\text {th }}$ coordinate of the points in $P$, for $1 \leq i \leq n$. For arbitrary $S \subseteq \mathbb{R}^{n}$, define $F_{\min }(S)=\left\{f_{\min }(P) \mid P\right.$ is a finite subset of $\left.S\right\}$. As illustrated in Example 1, the next lemma shows that the vector set $V_{E}$ is equal to $F_{\min }\left(\operatorname{conv}\left(S_{E}\right)\right)$.

Lemma 2. Let $E$ be a mean-payoff automaton expression built from deterministic LimInfAvg-automata, and such that $A_{E}$ has only one strongly connected component. Then, the vector set of $E$ is $V_{E}=F_{\min }\left(\operatorname{conv}\left(S_{E}\right)\right)$.

For a general mean-payoff automaton expression $E$ (with both deterministic LimInfAvg- and LimSupAvg automata, and with multi-scc underlying graph), we can use the result of Lemma 2 as follows. We replace each LimSupAvg automaton $A_{i}$ occurring in $E$ by the LimlnfAvg automaton $A_{i}^{\prime}$ obtained from $A_{i}$ by replacing every weight wt by $-w t$. The duality of liminf and $\limsup$ yields $L_{A_{i}^{\prime}}=-L_{A_{i}}$. In
each strongly connected component $\mathcal{C}$ of the underlying graph of $A_{E}$, we compute $V_{\mathcal{C}}=F_{\min }\left(\operatorname{conv}\left(S_{\mathcal{C}}\right)\right)\left(\right.$ where $S_{\mathcal{C}}$ is the set of vector values of the simple cycles in $\left.\mathcal{C}\right)$ and apply the transformation $x_{i} \rightarrow-x_{i}$ on every coordinate $i$ where the automaton $A_{i}$ was originally a LimSupAvg automaton. The union of the sets $\bigcup_{\mathcal{C}} V_{\mathcal{C}}$ where $\mathcal{C}$ ranges over the strongly connected components of $A_{E}$ gives the vector set of $E$.

Theorem 1. Let $E$ be a mean-payoff automaton expression built from deterministic LimInfAvg-automata, and let $\mathcal{Z}$ be the set of strongly connected components in $A_{E}$. For a strongly connected component $\mathcal{C}$ let $S_{\mathcal{C}}$ denote the set of vector values of the simple cycles in $\mathcal{C}$. The vector set of $E$ is $V_{E}=\bigcup_{\mathcal{C} \in \mathcal{Z}} F_{\min }\left(\operatorname{conv}\left(S_{\mathcal{C}}\right)\right)$.

## 4 Computation of $F_{\min }(\operatorname{conv}(S))$ for a Finite Set $S$

It follows from Theorem 1 that the vector set $V_{E}$ of a mean-payoff automaton expression $E$ can be obtained as a union of sets $F_{\min }(\operatorname{conv}(S))$, where $S \subseteq \mathbb{R}^{n}$ is a finite set. However, the set $\operatorname{conv}(S)$ being in general infinite, it is not immediate that $F_{\min }(\operatorname{conv}(S))$ is computable. In this section we consider the problem of computing $F_{\min }(\operatorname{conv}(S))$ for a finite set $S$. In subsection 4.1 we present an explicit construction and in subsection 4.2 we give a geometric construction of the set as a set of linear constraints. We first present some properties of the set $F_{\min }(\operatorname{conv}(S))$.

Lemma 3. If $X$ is a convex set, then $F_{\min }(X)$ is convex.
By Lemma 3, the set $F_{\min }(\operatorname{conv}(S))$ is convex, and since $F_{\min }$ is a monotone operator and $S \subseteq \operatorname{conv}(S)$, we have $F_{\min }(S) \subseteq F_{\min }(\operatorname{conv}(S))$ and thus conv $\left(F_{\min }(S)\right) \subseteq$ $F_{\min }(\operatorname{conv}(S))$. The following proposition states that in two dimensions the above sets coincide.

Proposition 1. Let $S \subseteq \mathbb{R}^{2}$ be a finite set. Then, $\operatorname{conv}\left(F_{\min }(S)\right)=F_{\min }(\operatorname{conv}(S))$.
We show in the following example that in three dimensions the above proposition does not hold, i.e., we show that $F_{\min }\left(\operatorname{conv}\left(S_{E}\right)\right) \neq \operatorname{conv}\left(F_{\min }\left(S_{E}\right)\right)$ in $\mathbb{R}^{3}$.

Example 2. We show that in three dimension there is a finite set $S$ such that $F_{\min }(\operatorname{conv}(S)) \nsubseteq \operatorname{conv}\left(F_{\min }(S)\right)$. Let $S=\{q, r, s\}$ with $q=(0,1,0), r=$ $(-1,-1,1)$, and $s=(1,1,1)$. Then $f_{\min }(r, s)=r, f_{\min }(q, r, s)=f_{\min }(q, r)=$ $t=(-1,-1,0)$, and $f_{\min }(q, s)=q$. Therefore $F_{\min }(S)=\{q, r, s, t\}$. Consider $p=(r+s) / 2=(0,0,1)$. We have $p \in \operatorname{conv}(S)$ and $f_{\min }(p, q)=(0,0,0)$. Hence $(0,0,0) \in F_{\min }(\operatorname{conv}(S))$. We now show that $(0,0,0)$ does not belong to $\operatorname{conv}\left(F_{\min }(S)\right)$. Consider $u=\alpha_{q} \cdot q+\alpha_{r} \cdot r+\alpha_{s} \cdot s+\alpha_{t} \cdot t$ such that $u$ in $\operatorname{conv}\left(F_{\min }(S)\right)$. Since the third coordinate is non-negative for $q, r, s$, and $t$, it follows that if $\alpha_{r}>0$ or $\alpha_{s}>0$, then the third coordinate of $u$ is positive. If $\alpha_{s}=0$ and $\alpha_{r}=0$, then we have two cases: (a) if $\alpha_{t}>0$, then the first coordinate of $u$ is negative; and (b) if $\alpha_{t}=0$, then the second coordinate of $u$ is 1 . It follows $(0,0,0)$ is not in $\operatorname{conv}\left(F_{\min }(S)\right)$.

### 4.1 Explicit construction

Example 2 shows that in general $F_{\min }(\operatorname{conv}(S)) \nsubseteq \operatorname{conv}\left(F_{\min }(S)\right)$. In this section we present an explicit construction that given a finite set $S$ constructs a finite set $S^{\prime}$ such that (a) $S \subseteq S^{\prime} \subseteq \operatorname{conv}(S)$ and (b) $F_{\min }(\operatorname{conv}(S)) \subseteq \operatorname{conv}\left(F_{\min }\left(S^{\prime}\right)\right)$. It would follow that $F_{\min }(\operatorname{conv}(S))=\operatorname{conv}\left(F_{\min }\left(S^{\prime}\right)\right)$. Since convex hull of a finite set is computable and $F_{\min }\left(S^{\prime}\right)$ is finite, this would give us an algorithm to compute $F_{\min }(\operatorname{conv}(S))$. For simplicity, for the rest of the section we write $F$ for $F_{\min }$ and $f$ for $f_{\text {min }}$ (i.e., we drop the min from subscript). Recall that $F(S)=\{f(P) \mid P$ finite subset of $S\}$ and let $F_{i}(S)=\{f(P) \mid P$ finite subset of $S$ and $|P| \leq i\}$. We consider $S \subseteq \mathbb{R}^{n}$.

Lemma 4. Let $S \subseteq \mathbb{R}^{n}$. Then, $F(S)=F_{n}(S)$ and $F_{n}(S) \subseteq F_{2}^{n-1}(S)$.

Iteration of a construction $\gamma$. We will present a construction $\gamma$ with the following properties: input to the construction is a finite set $Y$ of points, and the output $\gamma(Y)$ satisfies the following properties

1. (Condition C1). $\gamma(Y)$ is finite and subset of $\operatorname{conv}(Y)$.
2. $\left(\right.$ Condition C2). $F_{2}(\operatorname{conv}(Y)) \subseteq \operatorname{conv}(F(\gamma(Y)))$.

Before presenting the construction $\gamma$ we first show how to iterate the construction to obtain the following result: given a finite set of points $X$ we construct a finite set of points $X^{\prime}$ such that $F(\operatorname{conv}(X))=\operatorname{conv}\left(F\left(X^{\prime}\right)\right)$.
Iterating $\gamma$. Consider a finite set of points $X$, and let $X_{0}=X$ and $X_{1}=\gamma\left(X_{0}\right)$. Then we have

$$
\operatorname{conv}\left(X_{1}\right) \subseteq \operatorname{conv}\left(\operatorname{conv}\left(X_{0}\right)\right) \quad\left(\text { since by Condition } \mathbf{C 1} \text { we have } X_{1} \subseteq \operatorname{conv}\left(X_{0}\right)\right)
$$

and hence $\operatorname{conv}\left(X_{1}\right) \subseteq \operatorname{conv}\left(X_{0}\right)$; and

$$
F_{2}\left(\operatorname{conv}\left(X_{0}\right)\right) \subseteq \operatorname{conv}\left(F\left(X_{1}\right)\right) \quad \text { (by Condition C2) }
$$

By iteration we obtain that $X_{i}=\gamma\left(X_{i-1}\right)$ for $i \geq 2$ and as above we have

$$
\text { (1) } \operatorname{conv}\left(X_{i}\right) \subseteq \operatorname{conv}\left(X_{0}\right) \quad \text { (2) } F_{2}^{i}\left(\operatorname{conv}\left(X_{0}\right)\right) \subseteq \operatorname{conv}\left(F\left(X_{i}\right)\right)
$$

Thus for $X_{n-1}$ we have

$$
\text { (1) } \operatorname{conv}\left(X_{n-1}\right) \subseteq \operatorname{conv}\left(X_{0}\right) \quad \text { (2) } F_{2}^{n-1}\left(\operatorname{conv}\left(X_{0}\right)\right) \subseteq \operatorname{conv}\left(F\left(X_{n-1}\right)\right)
$$

By (2) above and Lemma 4, we obtain

$$
(A) F\left(\operatorname{conv}\left(X_{0}\right)\right)=F_{n}\left(\operatorname{conv}\left(X_{0}\right)\right) \subseteq F_{2}^{n-1}\left(\operatorname{conv}\left(X_{0}\right)\right) \subseteq \operatorname{conv}\left(F\left(X_{n-1}\right)\right)
$$

By (1) above we have $\operatorname{conv}\left(X_{n-1}\right) \subseteq \operatorname{conv}\left(X_{0}\right)$ and hence $F\left(\operatorname{conv}\left(X_{n-1}\right)\right) \subseteq$ $F\left(\operatorname{conv}\left(X_{0}\right)\right)$. Thus we have

$$
\operatorname{conv}\left(F\left(\operatorname{conv}\left(X_{n-1}\right)\right)\right) \subseteq \operatorname{conv}\left(F\left(\operatorname{conv}\left(X_{0}\right)\right)\right)=F\left(\operatorname{conv}\left(X_{0}\right)\right)
$$

where the last equality follows since by Lemma 3 we have $F\left(\operatorname{conv}\left(X_{0}\right)\right)$ is convex. Since $X_{n-1} \subseteq \operatorname{conv}\left(X_{n-1}\right)$ we have

$$
(B) \operatorname{conv}\left(F\left(X_{n-1}\right)\right) \subseteq \operatorname{conv}\left(F\left(\operatorname{conv}\left(X_{n-1}\right)\right)\right) \subseteq F\left(\operatorname{conv}\left(X_{0}\right)\right)
$$

Thus by (A) and (B) above we have $F\left(\operatorname{conv}\left(X_{0}\right)\right)=\operatorname{conv}\left(F\left(X_{n-1}\right)\right)$. Thus given the finite set $X$, we have the finite set $X_{n-1}$ such that (a) $X \subseteq X_{n-1} \subseteq \operatorname{conv}(X)$ and (b) $F(\operatorname{conv}(X))=\operatorname{conv}\left(F\left(X_{n-1}\right)\right)$. We now present the construction $\gamma$ to complete the result.
The construction $\gamma$. Given a finite set $Y$ of points $Y^{\prime}=\gamma(Y)$ is obtained by adding points to $Y$ in the following way:

- For all $1 \leq k \leq n$, we consider all $k$-dimensional coordinate planes $\Pi$ supported by a point in $Y$;
- Intersect each coordinate plane $\Pi$ with $\operatorname{conv}(Y)$ and the result is a convex polytope $Y_{\Pi}$;
- We add the corners (or extreme points) of each polytope $Y_{\Pi}$ to $Y$.

The proof that the above construction satisfies condition $\mathbf{C 1}$ and $\mathbf{C 2}$ is given in the appendix, and thus we have the following result.

Theorem 2. Given a finite set $S \subseteq \mathbb{R}^{n}$ such that $|S|=m$, the following assertion holds: a finite set $S^{\prime}$ with $\left|S^{\prime}\right| \leq m^{2^{n}} \cdot 2^{n^{2}+n}$ can be computed in $m^{O\left(n \cdot 2^{n}\right)} \cdot 2^{O\left(n^{3}\right)}$ time such that (a) $S \subseteq S^{\prime} \subseteq \operatorname{conv}(S)$ and $(b) F_{\min }(\operatorname{conv}(S))=\operatorname{conv}\left(F_{\min }\left(S^{\prime}\right)\right)$.

### 4.2 Linear constraint construction

In the previous section we presented an explicit construction of a finite set of points whose convex hull gives us $F_{\min }(\operatorname{conv}(S))$. The explicit construction illuminates properties of the set $F_{\min }(\operatorname{conv}(S))$, however, the construction is inefficient computationally. In this subsection we present an efficient geometric construction for the computation of $F_{\min }(\operatorname{conv}(S))$ for a finite set $S$. Instead of constructing a finite set $S^{\prime} \subseteq \operatorname{conv}(S)$ such that $\operatorname{conv}\left(S^{\prime}\right)=F_{\min }(\operatorname{conv}(S))$, we represent $F_{\min }(\operatorname{conv}(S))$ as a finite set of linear constraints.

Consider the positive orthant anchored at the origin in $\mathbb{R}^{n}$, that is, the set of points with non-negative coordinates: $\mathbb{R}_{+}^{n}=\left\{\left(z_{1}, z_{2}, \ldots, z_{n}\right) \mid z_{i} \geq 0, \forall i\right\}$. Similarly, the negative orthant is the set of points with non-positive coordinates, denoted as $\mathbb{R}_{-}^{n}=$ $-\mathbb{R}_{+}^{n}$. Using vector addition, we write $y+\mathbb{R}_{+}^{n}$ for the positive orthant anchored at $y$. Similarly, we write $x+\mathbb{R}_{-}^{n}=x-\mathbb{R}_{+}^{n}$ for the negative orthant anchored at $x$. The positive and negative orthants satisfy the following simple duality relation: $x \in y+\mathbb{R}_{+}^{n}$ iff $y \in x-\mathbb{R}_{+}^{n}$.

Note that $\mathbb{R}_{+}^{n}$ is an $n$-dimensional convex polyhedron. For each $1 \leq j \leq n$, we consider the $(n-1)$-dimensional face $\mathbb{L}_{j}$ spanned by the coordinate axes except the $j^{\text {th }}$ one, that is, $\mathbb{L}_{j}=\left\{\left(z_{1}, z_{2}, \ldots, z_{n}\right) \in \mathbb{R}_{+}^{n} \mid z_{j}=0\right\}$.

We say that $y+\mathbb{R}_{+}^{n}$ is supported by $X$ if $\left(y+\mathbb{L}_{j}\right) \cap X \neq \varnothing$ for every $1 \leq j \leq n$. Assuming $y+\mathbb{R}_{+}^{n}$ is supported by $X$, we can construct a set $Y \subseteq X$ by collecting one point per $(n-1)$-dimensional face of the orthant and get $y=f(Y)$. It is also
allowed that two faces contribute the same point to $Y$. Similarly, if $y=f(Y)$ for a subset $Y \subseteq X$, then the positive orthant anchored at $y$ is supported by $X$. Hence, we get the following lemma.

Lemma 5 (Orthant Lemma). $y \in F_{\min }(X)$ iff $y+\mathbb{R}_{+}^{n}$ is supported by $X$.

Construction. We use the Orthant Lemma to construct $F_{\min }(X)$. We begin by describing the set of points $y$ for which the $j^{\text {th }}$ face of the positive orthant anchored at $y$ has a non-empty intersection with $X$. Define $F_{j}=X-\mathbb{L}_{j}$, the set of points of the form $x-z$, where $x \in X$ and $z \in \mathbb{L}_{j}$.

Lemma 6 (Face Lemma). $\left(y+\mathbb{L}_{j}\right) \cap X \neq \varnothing$ iff $y \in F_{j}$.
Proof. Let $x \in X$ be a point in the intersection, that is, $x \in y+\mathbb{L}_{j}$. Using the duality relation for the $(n-1)$-dimensional orthant, we get $y \in x-\mathbb{L}_{j}$. By definition, $x-\mathbb{L}_{j}$ is a subset of $X-\mathbb{L}_{j}$, and hence $y \in F_{j}$.

It is now easy to describe the set defined in our problem statement.

Lemma 7 (Characterization). $F_{\min }(X)=\bigcap_{j=1}^{n} F_{j}$.
Proof. By the Orthant Lemma, $y \in F_{\min }(X)$ iff $y+\mathbb{R}_{+}^{n}$ is supported by $X$. Equivalently, $\left(y+\mathbb{L}_{j}\right) \cap X \neq \varnothing$ for all $1 \leq j \leq n$. By the Face Lemma, this is equivalent to $y$ belonging to the common intersection of the sets $F_{j}=X-\mathbb{L}_{j}$.

Algorithm for computation of $F_{\min }(\operatorname{conv}(S))$. Following the construction, we get an algorithm that computes $F_{\min }(\operatorname{conv}(S))$ for a finite set $S$ of points in $\mathbb{R}^{n}$. Let $|S|=m$. We first represent $X=\operatorname{conv}(S)$ as intersection of half-spaces: we require at most $m^{n}$ half-spaces (linear constraints). It follows that $F_{j}=X-\mathbb{L}_{j}$ can be expressed as $m^{n}$ linear constraints, and hence $F_{\min }(X)=\bigcap_{j=1}^{n} F_{j}$ can be expressed as $n \cdot m^{n}$ linear constraints. This gives us the following result.

Theorem 3. Given a finite set $S$ of moints in $\mathbb{R}^{n}$, we can construct in $O\left(n \cdot m^{n}\right)$ time $n \cdot m^{n}$ linear constraints that represent $F_{\min }(\operatorname{conv}(S))$.

## 5 Mean-Payoff Automaton Expressions are Decidable

Several problems on quantitative languages can be solved for the class of mean-payoff automaton expressions using the vector set. The decision problems of quantitative emptiness and universality, and quantitative language inclusion and equivalence are all decidable, as well as questions related to cut-point languages, and computing distance between mean-payoff languages.

Decision problems and distance. From the vector set $V_{E}=\left\{\left\langle L_{A_{1}}(w), \ldots, L_{A_{n}}(w)\right\rangle \in\right.$ $\left.\mathbb{R}^{n} \mid w \in \Sigma^{\omega}\right\}$, we can compute the value set $L_{E}\left(\Sigma^{\omega}\right)=\left\{L_{E}(w) \mid w \in \Sigma^{\omega}\right\}$ of values of words according to the quantitative language of $E$ as follows. The set $L_{E}\left(\Sigma^{\omega}\right)$ is obtained by successive application of min-, max- and sum-projections $p_{i j}^{\text {min }}, p_{i j}^{\text {max }}, p_{i j}^{\text {sum }}: \mathbb{R}^{k} \rightarrow \mathbb{R}^{k-1}$ where $i<j \leq k$, defined by

$$
\begin{aligned}
& p_{i j}^{\min }\left(\left(x_{1}, \ldots, x_{k}\right)\right)=\left(x_{1}, \ldots, x_{i-1}, \min \left(x_{i}, x_{j}\right), x_{i+1}, \ldots, x_{j-1}, x_{j+1}, \ldots x_{k}\right), \\
& p_{i j}^{\text {sum }}\left(\left(x_{1}, \ldots, x_{k}\right)\right)=\left(x_{1}, \ldots, x_{i-1}, \quad x_{i}+x_{j}, x_{i+1}, \ldots, x_{j-1}, x_{j+1}, \ldots x_{k}\right),
\end{aligned}
$$

and analogously for $p_{i j}^{\max }$. For example, $p_{12}^{\max }\left(p_{23}^{\min }\left(V_{E}\right)\right)$ gives the set $L_{E}\left(\Sigma^{\omega}\right)$ of word values of the mean-payoff automaton expression $E=\max \left(A_{1}, \min \left(A_{2}, A_{3}\right)\right)$.

Assuming a representation of the polytopes of $V_{E}$ as a boolean combination $\varphi_{E}$ of linear constraints, the projection $p_{i j}^{\min }\left(V_{E}\right)$ is represented by the formula

$$
\psi=\left(\exists x_{j}: \varphi_{E} \wedge x_{i} \leq x_{j}\right) \vee\left(\exists x_{i}: \varphi_{E} \wedge x_{j} \leq x_{i}\right)\left[x_{j} \leftarrow x_{i}\right]
$$

where $[x \leftarrow e]$ is a substitution that replaces every occurrence of $x$ by the expression $e$. Since linear constraints over the reals admit effective elimination of existential quantification, the formula $\psi$ can be transformed into an equivalent boolean combination of linear constraints without existential quantification. The same applies to max- and sum-projections.

Successive applications of min-, max- and sum-projections (following the structure of the mean-payoff automaton expression $E$ ) gives the value set $L_{E}\left(\Sigma^{\omega}\right) \subseteq \mathbb{R}$ as a boolean combination of linear constraints, hence it is a union of intervals. From this set, it is easy to decide the quantitative emptiness problem and the quantitative universality problem: there exists a word $w \in \Sigma^{\omega}$ such that $L_{E}(w) \geq \nu$ if and only if $L_{E}\left(\Sigma^{\omega}\right) \cap$ $\left[\nu,+\infty\left[\neq \varnothing\right.\right.$, and $L_{E}(w) \geq \nu$ for all words $w \in \Sigma^{\omega}$ if and only if $\left.L_{E}\left(\Sigma^{\omega}\right) \cap\right]-$ $\infty, \nu[=\varnothing$.

In the same way, we can decide the quantitative language inclusion problem "is $L_{E}(w) \leq L_{F}(w)$ for all words $w \in \Sigma^{\omega}$ ?" by a reduction to the universality problem for the expression $F-E$ and threshold 0 since mean-payoff automaton expressions are closed under sum and complement. The quantitative language equivalence problem is then obviously also decidable.

Finally, the distance between the quantitative languages of $E$ and $F$ can be computed as the largest number (in absolute value) in the value set of $F-E$. As a corollary, this distance is always a rational number.

Comparison with [1]. The work in [1] considers deterministic mean-payoff automata with multiple payoffs. The weight function in such an automaton is of the form wt : $\delta \rightarrow \mathbb{Q}^{d}$. The value of a finite sequence $\left(v_{i}\right)_{1 \leq i \leq n}\left(\right.$ where $\left.v_{i} \in \mathbb{Q}^{d}\right)$ is the mean of the tuples $v_{i}$, that is a $d$-dimensional vector $\operatorname{Avg}_{n}=\frac{1}{n} \cdot \sum_{i=0}^{n-1} v_{i}$. The "value" associated to an infinite run (and thus also to the corresponding word, since the automaton is deterministic) is the set $A c c \subseteq \mathbb{R}^{d}$ of accumulation points of the sequence $\left(\operatorname{Avg}_{n}\right)_{n \geq 1}$.

In [1], a query language on the set of accumulation points is used to define multithreshold mean-payoff languages. For $1 \leq i \leq n$, let $p_{i}: \mathbb{R}^{n} \rightarrow \mathbb{R}$ be the usual projection along the $i^{\text {th }}$ coordinate. A query is a boolean combination of atomic threshold conditions of the form $\min \left(p_{i}(A c c)\right) \sim \nu$ or $\max \left(p_{i}(A c c)\right) \sim \nu$ where $\sim \in\{<, \leq, \geq,>\}$
and $\nu \in \mathbb{Q}$. A word is accepted if the set of accumulation points of its (unique) run satisfies the query. Emptiness is decidable for such multi-threshold mean-payoff languages, by an argument based on the computation of the convex hull of the vector values of the simple cycles in the automaton [1] (see also Lemma 1). We have shown that this convex hull $\operatorname{conv}\left(S_{E}\right)$ is not sufficient to analyze quantitative languages of mean-payoff automaton expressions. It turns out that a richer query language can also be defined using our construction of $F_{\min }\left(\operatorname{conv}\left(S_{E}\right)\right)$.

In our setting, we can view a $d$-dimensional mean-payoff automaton $A$ as a product $P_{A}$ of 2 d copies $A_{t}^{i}$ of $A$ (where $1 \leq i \leq d$ and $t \in\{\operatorname{LimlnfAvg}$, LimSupAvg $\}$ ), where $A_{t}^{i}$ assigns to each transition the $i^{\text {th }}$ coordinate of the payoff vector in $A$, and the automaton is interpreted as a $t$-automaton. Intuitively, the set $A c c$ of accumulation points of a word $w$ satisfies $\min \left(p_{i}(A c c)\right) \sim \nu\left(\right.$ resp. $\max \left(p_{i}(A c c) \sim \nu\right)$ if and only if the value of $w$ according to the automaton $A_{t}^{i}$ for $t=\operatorname{Lim} \operatorname{lnfAvg}$ (resp. $t=\operatorname{LimSupAvg}$ ) is $\sim \nu$. Therefore, atomic threshold conditions can be encoded as threshold conditions on single variables of the vector set for $P_{A}$. Therefore, the vector set computed in Section 4 allows to decide the emptiness problem for multi-threshold mean-payoff languages, by checking emptiness of the intersection of the vector set with the constraint corresponding to the query.

Furthermore, we can solve more expressive queries in our framework, namely where atomic conditions are linear constraints on LimInfAvg- and LimSupAvg-values. For example, the constraint $\operatorname{Lim} \operatorname{lnf} \operatorname{Avg}\left(w_{1}\right)+\operatorname{LimSupAvg}\left(w t_{2}\right) \sim \nu$ is simply encoded as $x_{k}+x_{l} \sim \nu$ where $k, l$ are the indices corresponding to $A_{\text {LimlnfAvg }}^{1}$ and $A_{\text {LimSupAvg }}^{2}$ respectively. Note that the trick of extending the dimension of the $d$-payoff vector with, say $w t_{d+1}=w_{1}+w_{2}$, is not equivalent because $\left.\operatorname{Lim}\left\{{ }^{\{ }{ }^{\text {sup }}\right\}\right\} \operatorname{Avg}\left(w t_{1}\right) \pm \operatorname{Lim}\left\{{ }^{\text {Sup }}\right\}$ is not equal to $\operatorname{Lim}\left\{\right.$ hnf $\left.^{\text {un }\}}\right\} \operatorname{Avg}\left(w_{1} \pm \mathrm{wt}_{2}\right)$ in general (no matter the choice of $\left\{\begin{array}{l}\text { Sup }\}\end{array}\right.$ and $\pm$ ). Hence, in the context of non-quantitative languages our results also provide a richer query language for the deterministic mean-payoff automata with multiple payoffs.

Complexity. All problems studied in this section can be solved easily (in polynomial time) once the value set is constructed, which can be done in quadruple exponential time. The quadruple exponential blow-up is caused by $(a)$ the synchronized product construction for $E,(b)$ the computation of the vector values of all simple cycles in $A_{E}$, (c) the construction of the vector set $F_{\min }\left(\operatorname{conv}\left(S_{E}\right)\right)$, and $(d)$ the successive projections of the vector set to obtain the value set. Therefore, all the above problems can be solved in 4EXPTIME.

Theorem 4. For the class of mean-payoff automaton expressions, the quantitative emptiness, universality, language inclusion, and equivalence problems, as well as distance computation can be solved in 4EXPTIME.

Theorem 4 is in sharp contrast with the nondeterministic and alternating meanpayoff automata for which language inclusion is undecidable (see also Table 1). The following theorem presents the undecidability result that is derived from the results of [9].

Theorem 5. The quantitative universality, language inclusion, and language equivalence problems are undecidable for nondeterministic mean-payoff automata; and the
quantitative emptiness, universality, language inclusion, and language equivalence problems are undecidable for alternating mean-payoff automata.

## 6 Expressive Power and Cut-point Languages

We study the expressive power of mean-payoff automaton expressions $(i)$ according to the class of quantitative languages that they define, and (ii) according to their cut-point languages.

Expressive power comparison. We compare the expressive power of mean-payoff automaton expressions with nondeterministic and alternating mean-payoff automata. The results of [5] show that there exist deterministic mean-payoff automata $A_{1}$ and $A_{2}$ such that $\min \left(A_{1}, A_{2}\right)$ cannot be expressed by nondeterministic mean-payoff automata. The results of [4] shows that there exists deterministic mean-payoff automata $A_{1}$ and $A_{2}$ such that $\operatorname{sum}\left(A_{1}, A_{2}\right)$ cannot be expressed by alternating mean-payoff automata. It follows that there exist languages expressible by mean-payoff automaton expression that cannot be expressed by nondeterministic and alternating mean-payoff automata. In Theorem 6 we show the converse, that is, we show that there exist languages expressible by nondeterministic mean-payoff automata that cannot be expressed by mean-payoff automaton expression. It may be noted that the subclass of mean-payoff automaton expressions that only uses min and max operators (and no sum operator) is a strict subclass of alternating mean-payoff automata, and when only the max operator is used we get a strict subclass of the nondeterministic mean-payoff automata.

Theorem 6. Mean-payoff automaton expressions are incomparable in expressive power with nondeterministic and alternating mean-payoff automata: (a) there exists a quantitative language that is expressible by mean-payoff automaton expressions, but cannot be expressed by alternating mean-payoff automata; and (b) there exists a quantitative language that is expressible by a nondeterministic mean-payoff automaton, but cannot be expressed by a mean-payoff automaton expression.

Cut-point languages. Let $L$ be a quantitative language over $\Sigma$. Given a threshold $\eta \in$ $\mathbb{R}$, the cut-point language defined by $(L, \eta)$ is the language (i.e., the set of words) $L^{\geq \eta}=\left\{w \in \Sigma^{\omega} \mid L(w) \geq \eta\right\}$. It is known for deterministic mean-payoff automata that the cut-point language may not be $\omega$-regular, while it is $\omega$-regular if the threshold $\eta$ is isolated, i.e. if there exists $\epsilon>0$ such that $|L(w)-\eta|>\epsilon$ for all words $w \in \Sigma^{\omega}$ [5].

We present the following results about cut-point languages of mean-payoff automaton expressions. First, we note that it is decidable whether a rational threshold $\eta$ is an isolated cut-point of a mean-payoff automaton expression, using the value set (it suffices to check that $\eta$ is not in the value set since this set is closed). Second, isolated cut-point languages of mean-payoff automaton expressions are robust as they remain unchanged under sufficiently small perturbations of the transition weights. This result follows from a more general robustness property of weighted automata [5] that extends to mean-payoff automaton expressions: if the weights in the automata occurring in $E$ are changed by at most $\epsilon$, then the value of every word changes by at most
$\max (k, 1) \cdot \epsilon$ where $k$ is the number of occurrences of the sum operator in $E$. Therefore $D_{\text {sup }}\left(L_{E}, L_{F^{\epsilon}}\right) \rightarrow 0$ when $\epsilon \rightarrow 0$ where $F^{\epsilon}$ is any mean-payoff automaton expression obtained from $E$ by changing the weights by at most $\epsilon$. As a consequence, isolated cutpoint languages of mean-payoff automaton expressions are robust. Third, the isolated cut-point language of mean-payoff automaton expressions is $\omega$-regular. To see this, note that every strongly connected component of the product automaton $A_{E}$ contributes with a closed convex set to the value set of $E$. Since the max-, min- and sum-projections are continuous functions, they preserve connectedness of sets and therefore each scc $C$ contributes with an interval $\left[m_{C}, M_{C}\right]$ to the value set of $E$. An isolated cut-point $\eta$ cannot belong to any of these intervals, and therefore we obtain a Büchi-automaton for the cut-point language by declaring to be accepting the states of the product automaton $A_{E}$ that belong to an scc $C$ such that $m_{C}>\eta$. Hence, we get the following result.

Theorem 7. Let $L$ be the quantitative language of a mean-payoff automaton expression. If $\eta$ is an isolated cut-point of $L$, then the cut-point language $L \geq \eta$ is $\omega$-regular.

## 7 Conclusion and Future Works

We have presented a new class of quantitative languages, the mean-payoff automaton expressions which are both robust and decidable (see Table 1), and for which the distance between quantitative languages can be computed. The decidability results come with a high worst-case complexity, and it is a natural question for future works to either improve the algorithmic solution, or present a matching lower bound. Another question of interest is to find a robust and decidable class of quantitative languages based on the discounted sum measure [3].

## A Proofs of Section 3

Proof (of Lemma 1). Let $A_{1}, \ldots, A_{n}$ be the deterministic weighted automata occurring in $E$.

First, let $x \in \operatorname{conv}\left(S_{E}\right)$. Then, $x=\sum_{i=1}^{p} \lambda_{i} v_{i}$ where $v_{1}, v_{2}, \ldots, v_{p}$ are the vector values of simple cycles $\rho_{1}, \rho_{2}, \ldots, \rho_{p}$ in $A_{E}=A_{1} \times \cdots \times A_{n}$, and $\sum_{i=1}^{p} \lambda_{i}=1$ with $\lambda_{i} \geq 0$ for all $1 \leq i \leq p$.

For each of the above cycles $\rho_{i}$, let $q_{i}$ be a state occurring in $\rho_{i}$, and let $\rho_{i \rightarrow j}$ be a simple path in $A_{E}$ connecting $q_{i}$ and $q_{j}$ (such paths exist for each $1 \leq i, j \leq p$ because $A_{E}$ has a unique strongly connected component). Let $\rho_{0 \rightarrow i}$ be a simple path in $A_{E}$ from the initial state $q_{I}$ to $q_{i}$. Note that the length of $\rho_{i}$ and $\rho_{i \rightarrow j}$ is at most $m=\left|A_{E}\right|$ the number of states in $A_{E}$. We consider the following sequence of ultimately periodic paths, parameterized by $N \in \mathbb{N}$ :

$$
\hat{\rho}_{N}=\rho_{0 \rightarrow 1} \cdot\left(\rho_{1}^{k_{1}^{N}} \cdot \rho_{1 \rightarrow 2} \cdot \ldots \cdot \rho_{p}^{k_{p}^{N}} \cdot \rho_{p \rightarrow 1}\right)^{\omega}
$$

where $k_{i}^{N}=\left\lfloor\frac{N \cdot \lambda_{i}}{\left|\rho_{i}\right|}\right\rfloor$ for all $1 \leq i \leq p$. Note that $\hat{\rho}_{N}$ is the run of a lasso-word $w_{N}$ in $A_{E}$, and that $N \cdot \lambda_{i}-\left|\rho_{i}\right| \leq\left|\rho_{i}\right| \cdot k_{i}^{N} \leq N \cdot \lambda_{i}$.

Because $\hat{\rho}_{N}$ is ultimately periodic, the vector value of $\hat{\rho}_{N}$ gives the value of $w_{N}$ in each $A_{i}$. It can be computed as

$$
\operatorname{LimAvg}\left(\hat{\rho}_{N}\right)=\operatorname{Avg}\left(\rho_{1}^{k_{1}^{N}} \cdot \rho_{1 \rightarrow 2} \cdot \ldots \cdot \rho_{p}^{k_{p}^{N}} \cdot \rho_{p \rightarrow 1}\right)
$$

and it can be bounded along each coordinate $j=1, \ldots, n$ as follows (we denote by $W$ the largest weight in $A_{E}$ in absolute value):

$$
\begin{aligned}
\operatorname{LimAvg}_{j}\left(\hat{\rho}_{N}\right) & \leq \frac{\sum_{i=1}^{p} k_{i}^{N} \cdot\left|\rho_{i}\right| \cdot \operatorname{Avg}_{j}\left(\rho_{i}\right)+\sum_{i=1}^{p}\left|A_{E}\right| \cdot W}{\sum_{i=1}^{p} k_{i}^{N} \cdot\left|\rho_{i}\right|+\sum_{i=1}^{p}\left|A_{E}\right|} \\
& \leq \frac{\sum_{i=1}^{p} N \cdot \lambda_{i} \cdot \operatorname{Avg}_{j}\left(\rho_{i}\right)+p \cdot m \cdot W}{\sum_{i=1}^{p} N \cdot \lambda_{i}-\left|\rho_{i}\right|+\left|A_{E}\right|} \\
& \leq \frac{N \cdot x_{j}+p \cdot m \cdot W}{N}=x_{j}+\frac{p \cdot m \cdot W}{N}
\end{aligned}
$$

Analogously, we have

$$
\begin{aligned}
\operatorname{LimAvg}_{j}\left(\hat{\rho}_{N}\right) & \geq \frac{\sum_{i=1}^{p} k_{i}^{N} \cdot\left|\rho_{i}\right| \cdot \operatorname{Avg}_{j}\left(\rho_{i}\right)-\sum_{i=1}^{p}\left|A_{E}\right| \cdot W}{\sum_{i=1}^{p} k_{i}^{N} \cdot\left|\rho_{i}\right|+\sum_{i=1}^{p}\left|A_{E}\right|} \\
& \geq \frac{\sum_{i=1}^{p}\left(N \cdot \lambda_{i}-\left|\rho_{i}\right|\right) \cdot \operatorname{Avg}_{j}\left(\rho_{i}\right)-p \cdot m \cdot W}{\sum_{i=1}^{p} N \cdot \lambda_{i}+\left|A_{E}\right|} \\
& \geq \frac{N \cdot x_{j}-2 p \cdot m \cdot W}{N+p \cdot m}=x_{j}-\frac{p \cdot m \cdot\left(2 W-x_{j}\right)}{N+p \cdot m}
\end{aligned}
$$

Therefore $\operatorname{LimAvg}_{j}\left(\hat{\rho}_{N}\right) \rightarrow x_{j}$ when $N \rightarrow \infty$. This shows that $x$ is in the closure of the vector set of lasso-words.

Second, we show that the value of lasso words according to each automaton $A_{i}$ form a vector which belong to $\operatorname{conv}\left(S_{E}\right)$ (which is equal to its closure). Let $w=w_{1}\left(w_{2}\right)^{\omega}$ be a lasso-word. It is easy to see that there exists $p_{1}, p_{2}$ such that $p=p_{1}+p_{2} \leq m=\left|A_{E}\right|$ and the run of $A_{E}$ on $w_{1} w_{2}^{p}$ has the shape of a lasso (i.e., the automaton $A_{E}$ is in the same state after reading $w_{1} w_{2}^{p_{1}}$ and after reading $w_{1} w_{2}^{p}$ ), and thus the cyclic part of the lasso can be decomposed into simple cycles in $A_{E}$. The vector value of $w$ in each $A_{i}$ is the mean of the vector values of the simple cycles in the decomposition, and therefore it belongs to the convex hull $\operatorname{conv}\left(S_{E}\right)$.

Proof (of Lemma 2). First, show that $V_{E} \subseteq F_{\min }\left(\operatorname{conv}\left(S_{E}\right)\right)$. Let $x \in V_{E}$ be a tuple of values of some word $w$ according to each automaton $A_{i}$ occurring in $E$ (i.e., $x_{i}=$ $L_{A_{i}}(w)$ for all $\left.1 \leq i \leq n\right)$. For $\epsilon>0$ and $1 \leq k \leq n$, we construct a lasso-word $w_{\epsilon}^{k}$ such that $\left|L_{A_{k}}\left(w_{\epsilon}\right)-x_{k}\right| \leq \epsilon$ and $L_{A_{i}}\left(w_{\epsilon}\right) \geq x_{i}-\epsilon$ for all $1 \leq i \leq n$ with $i \neq k$. If we denote by $y_{\epsilon}^{k}$ the vector value of $w_{\epsilon}^{k}$, then the value $y=f_{\min }\left(\left\{y_{\epsilon}^{\bar{k}} \mid 1 \leq k \leq n\right\}\right)$ is such that $\left|y_{i}-x_{i}\right| \leq \epsilon$ for all $1 \leq k \leq n$. By Lemma 1, the limit of the vector value $y_{\epsilon}^{k}$ when $\epsilon \rightarrow 0$ is $\operatorname{in} \operatorname{conv}\left(S_{E}\right)$, and thus $x \in F_{\min }\left(\operatorname{conv}\left(S_{E}\right)\right)$.

We give the construction of $w_{\epsilon}^{k}$ for $k=1$. The construction is similar for $k \geq 2$. Consider the word $w$ and let $\rho$ be the suffix of the (unique) run of $A_{E}$ on $w$ which visits only states in the strongly connected component of $A_{E}$. The value of $\rho$ and the value of $w$ coincide (according to each $A_{i}$ ) since the mean-payoff value is prefix-independent. Since $L_{A_{i}}(w)=x_{i}$ for all $1 \leq i \leq n$, there exists a position $p \in \mathbb{N}$ such that the mean value of all prefixes of $\rho$ of length greater than $p$ is at least $x_{i}-\epsilon$ according to each $A_{i}$ (since each $A_{i}$ is a LimInfAvg-automata). Since $L_{A_{1}}(w)=x_{1}$, there exist infinitely many prefixes $\rho^{\prime}$ of $\rho$ with mean value according to $A_{1}$ close to $x_{1}$, more precisely such that $\left|\operatorname{Avg}_{1}\left(\rho^{\prime}\right)-x_{1}\right| \leq \epsilon$. Pick such a prefix $\rho^{\prime}$ of length at least $\max \left(p, \frac{1}{\epsilon}\right)$. Since $\rho^{\prime}$ is in the strongly connected component of $A_{E}$, we can extend $\rho^{\prime}$ to loop back to its first state. This requires at most $m$ additional steps and gives $\rho^{\prime \prime}$. Note also that $\rho^{\prime \prime}$ can be reached from the initial state of $A_{E}$ since it was the case of $\rho$, and thus it defines a
lasso-shaped run whose value can be bounded along the first coordinate as follows:

Hence, the value along the first coordinate of the word $w_{\epsilon}^{1}$ corresponding to the run $\rho^{\prime \prime}$ tends to $x_{1}$ when when $\epsilon \rightarrow 0$. We show similarly that the value of $w_{\epsilon}^{1}$ along the other coordinates $i \geq 2$ is bounded from below by $x_{i}-\epsilon \cdot(1+2 m \cdot W)$. The result follows.

Now, we show that $F_{\min }\left(\operatorname{conv}\left(S_{E}\right)\right) \subseteq V_{E}$. In this proof, we use the notation $\odot$ for iterated concatenation defined as follows. Given nonempty words $w_{1}, w_{2} \in \Sigma^{+}$, the finite word $w_{1} \odot w_{2}$ is $w_{1} \cdot\left(w_{2}\right)^{k}$ where $k=\left|w_{1}\right|^{2}$. We assume that $\odot$ (iterated concatenation) and (usual concatenation) have the same precedence and that they are left-associative. For example, the expression $a b \odot a \cdot b$ is parsed as $(a b \odot a) \cdot b$ and denotes the word $a b a a a a b$, while the expression $a b \cdot a \odot b$ is parsed as $(a b \cdot a) \odot b$ and denotes the word $a b a b^{9}$. We use this notation for the purpose of simplifying the proof presentation, and some care needs to be taken. For example, explicit use of concatenation (i.e., $a \cdot b$ vs. $a b$ ) makes a difference since $a b \odot a b=(a b)^{5}$ while $a b \odot a \cdot b=a b a^{4} b$. Finally, we use notations such as $\left(w_{1} \cdot w_{2} \odot\right)^{\omega}$ to denote the infinite word $w_{1} \cdot w_{2} \odot w_{1} \cdot w_{2} \odot \ldots$

Usually we use the notation $w_{1} \odot w_{2}$ when the run of $A_{E}$ on $w_{1} \cdot w_{2}$ can be decomposed as $\rho_{1} \cdot \rho_{2}$ where $\rho_{i}$ corresponds to $w_{i}(i=1,2)$ and $\rho_{2}$ is a cycle in the automaton. Then, the mean value of the run on $w_{1} \odot w_{2}$ is

$$
\begin{aligned}
& \frac{\left|\rho_{1}\right| \cdot \operatorname{Avg}\left(\rho_{1}\right)+\left|\rho_{1}\right|^{2} \cdot\left|\rho_{2}\right| \cdot \operatorname{Avg}\left(\rho_{2}\right)}{\left|\rho_{1}\right|+\left|\rho_{1}\right|^{2} \cdot\left|\rho_{2}\right|} \\
= & \frac{\operatorname{Avg}\left(\rho_{1}\right)+\left|\rho_{1}\right| \cdot\left|\rho_{2}\right| \cdot \operatorname{Avg}\left(\rho_{2}\right)}{1+\left|\rho_{1}\right| \cdot\left|\rho_{2}\right|} \\
= & \operatorname{Avg}\left(\rho_{2}\right)+\frac{\operatorname{Avg}\left(\rho_{1}\right)-\operatorname{Avg}\left(\rho_{2}\right)}{1+\left|\rho_{1}\right| \cdot\left|\rho_{2}\right|}
\end{aligned}
$$

Therefore, since $\left|\operatorname{Avg}\left(\rho_{1}\right)-\operatorname{Avg}\left(\rho_{2}\right)\right| \leq 2 W$ independently of $w_{1}$ and $w_{2}$, a key property of $\odot$ is that the mean value of $w_{1} \odot w_{2}$ can be made arbitrarily close to $\operatorname{Avg}\left(\rho_{2}\right)$ by taking $w_{1}$ sufficiently long (since $\left|w_{1}\right|=\left|\rho_{1}\right|$ ).

We proceed with the proof of the lemma. Let $x \in F_{\min }\left(\operatorname{conv}\left(S_{E}\right)\right)$ and let $y_{1}, \ldots, y_{n}$ be $n$ points in $\operatorname{conv}\left(S_{E}\right)$ such that the $i^{\text {th }}$ coordinate of $x$ and $y_{i}$ coincide for all $1 \leq i \leq n$, and the $j^{\text {th }}$ coordinate of $x$ is smaller than the $j^{\text {th }}$ coordinate of $y_{i}$ for all $j \neq i$. Such $y_{i}$ 's exist by definition of $F_{\min }$ though they may not be distinct.

By Lemma 1, for all $\epsilon>0$ there exist lasso-words $w_{1}, \ldots, w_{n}$ such that $\left\|v_{k}-y_{k}\right\| \leq$ $\epsilon$ where $v_{k}=\left\langle L_{A_{1}}\left(w_{k}\right), \ldots, L_{A_{n}}\left(w_{k}\right)\right\rangle$ for each $1 \leq k \leq n$. For each $1 \leq i \leq n$, let
$\rho_{i}$ be the cyclic part of the (lasso-shaped) run of $A_{E}$ on $w_{i}$, and let $q_{i}$ be the first state in $\rho_{i}$. For each $1 \leq i, j \leq n$, define $\rho_{i \rightarrow j}$ the shortest path in $A_{E}$ from $q_{i}$ to $q_{j}$, and let $\rho_{0 \rightarrow j}$ be a simple path in $A_{E}$ from the initial state $q_{I}$ to $q_{j}$ (such paths exist because $A_{E}$ is strongly connected). Note that $\operatorname{Avg}_{j}\left(\rho_{i}\right)=L_{A_{j}}\left(w_{i}\right)$. We construct the following infinite run in $A_{E}$ :

$$
\hat{\rho}=\rho_{0 \rightarrow 1} \odot\left(\rho_{1} \cdot \rho_{1 \rightarrow 2} \odot \rho_{2} \cdot \rho_{2 \rightarrow 3} \odot \ldots \rho_{n} \cdot \rho_{n \rightarrow 1} \odot\right)^{\omega}
$$

It is routine to show that $\hat{\rho}$ is a run of $A_{E}$, and we have $\operatorname{LimAvg}{ }_{j}(\hat{\rho})=v_{j j}$ because (i) the cycles $\rho_{1}, \ldots, \rho_{n}$ are asymptotically prevailing over the cycle $\rho_{1 \rightarrow 2} \rho_{2 \rightarrow 3} \dot{\rho}_{n \rightarrow 1}$, (ii) by the key property of $\odot$, there exist infinitely many prefixes in $\hat{\rho}$ such that the average of the weight along the $j^{\text {th }}$ coordinate converges to $v_{j j}$, and (iii) all cycles $\rho_{i}$ have average value greater than $v_{j j}$ along the $j^{\text {th }}$ coordinate. Therefore, the liminf of the averages along the $j^{\text {th }}$ coordinate (i.e., $\operatorname{LimAvg}_{j}(\hat{\rho})$ ) is $v_{j j}$, and the vector of values of $\hat{\rho}$ is thus at distance $\epsilon$ of $x$, that is $\|\operatorname{LimAvg}(\hat{\rho})-x\| \leq \epsilon$. The construction of $\hat{\rho}$ can be adapted to obtain $\operatorname{Lim} \operatorname{Avg}(\hat{\rho})=x$ by changing the $k^{\text {th }}$ occurrence of $\rho_{i}$ in $\hat{\rho}$ by a cycle corresponding to a lasso-word $w_{i}$ obtained as above for $\epsilon<\frac{1}{n}$.

## B Proofs of Section 4

Proof (of Lemma 3). Let $x=f_{\min }\left(u^{1}, u^{2}, \ldots, u^{n}\right)$ and $y=f_{\min }\left(v^{1}, v^{2}, \ldots, v^{n}\right)$ where $u^{1}, \ldots, u^{n}, v^{1}, \ldots, v^{n} \in X$. Let $z=\lambda x+(1-\lambda) y$ where $0 \leq \lambda \leq 1$ and we prove that $z \in F_{\min }(X)$. Without loss of generality, assume that $x_{i}=u_{i}^{i}$ and $y_{i}=v_{i}^{i}$ for all $1 \leq i \leq n$. Then $z_{i}=\lambda u_{i}^{i}+(1-\lambda) v_{i}^{i}$ for all $1 \leq i \leq n$.

To show that $z \in F_{\min }(X)$, we give for each $1 \leq j \leq n$ a point $p \in X$ such that $p_{j}=z_{j}$ and $p_{k} \geq z_{k}$ for all $k \neq j$. Take $p=\lambda u^{j}+(1-\lambda) v^{j}$. Clearly $p \in X$ since $u^{j}, v^{j} \in X$ and $X$ is convex, and $(i) w_{j}=\lambda u_{j}^{j}+(1-\lambda) v_{j}^{j}=z_{j}$, and (ii) for all $k \neq j$, we have $w_{k}=\lambda u_{k}^{j}+(1-\lambda) v_{k}^{j} \geq \lambda u_{k}^{k}+(1-\lambda) v_{k}^{k}=z_{k}$ (since $u^{k}$ has the minimal value on $k^{\text {th }}$ coordinate among $u^{1}, \ldots, u^{n}$, similarly for $v^{k}$ ).

Proof (of Proposition 1). By Lemma 3, we already know that $\operatorname{conv}\left(F_{\min }(S)\right) \subseteq$ $F_{\min }(\operatorname{conv}(S))$ (the set $F_{\min }(\operatorname{conv}(S))$ is convex, and since $F_{\min }$ is a monotone operator and $S \subseteq \operatorname{conv}(S)$, we have $F_{\min }(S) \subseteq F_{\min }(\operatorname{conv}(S))$ and thus conv $\left(F_{\min }(S)\right) \subseteq$ $\left.F_{\text {min }}(\operatorname{conv}(S))\right)$.

We prove that $F_{\min }(\operatorname{conv}(S)) \subseteq \operatorname{conv}\left(F_{\min }(S)\right)$ if $S \subseteq \mathbb{R}^{2}$. Let $x \in$ $F_{\min }(\operatorname{conv}(S))$ and show that $x \in \operatorname{conv}\left(F_{\min }(S)\right)$. Since $x \in F_{\min }(\operatorname{conv}(S))$, there exist $p, q \in \operatorname{conv}(S)$ such that $x=f_{\min }(p, q)$, and assume that $p_{1}<q_{1}$ and $p_{2}>q_{2}$ (other cases are symmetrical, or imply that $x=p$ or $x=q$ for which the result is trivial as then $x \in \operatorname{conv}(S)$ ). We show that $x=\left(p_{1}, q_{2}\right)$ is in the convex hull of $\{p, q, r\}$ where $r=f_{\min }(u, v)$ and $u \in S$ is the point in $S$ with smallest first coordinate, and $v \in S$ is the point in $S$ with smallest second coordinate, so that $r_{1}=u_{1} \leq p_{1}$ and $r_{2}=v_{2} \leq q_{2}$. Simple computations show that the equation $x=\lambda p+\mu q+(1-\lambda-\mu) r$ has a solution with $0 \leq \lambda, \mu \leq 1$ and the result follows.

Proof (of Lemma 4). By definition, we have $F_{n}(S) \subseteq F(S)$. For a point $x=f(P)$ for a finite subset $P \subseteq S$, choose one point each that contributes to a coordinate and
obtain a finite set $P^{\prime} \subseteq P$ of at most $n$ points such that $x=f(P)$. This shows that $F(S) \subseteq F_{n}(S)$.

For the second part, let $P=\left\{p_{1}, p_{2}, \ldots, p_{k}\right\}$ with $k \leq n$, and let $x=f(P)$. Let $x_{1}=f\left(p_{1}, p_{2}\right)$, and for $i>1$ we define $x_{i}=f\left(x_{i-1}, p_{i+1}\right)$. We have $x=x_{n-1}$ (e.g., $f\left(p_{1}, p_{2}, p_{3}\right)=f\left(f\left(p_{1}, p_{2}\right), p_{3}\right)$ ). Thus we have obtained $x$ by applying $f$ on two points for $n-1$ times, and it follows that $F_{n}(S) \subseteq F_{2}^{n-1}(S)$.

Proof (of Theorem 2). We show that the construction $\gamma$ satisfies condition $\mathbf{C 1}$ and $\mathbf{C 2}$. Let $Y^{\prime}=\gamma(Y)$. Clearly the set $Y^{\prime}$ is a finite subset of $\operatorname{conv}(Y)$ and thus Condition C1 holds and we now show that Condition $\mathbf{C} 2$ is satisfied.

Since $F_{2}(\operatorname{conv}(Y))$ is convex (by Lemma 3), it suffices to show that all corners of $F_{2}(\operatorname{conv}(Y))$ belong to $\operatorname{conv}\left(F\left(Y^{\prime}\right)\right)$. Consider a point $x=f(p, q)$ where $p, q \in$ $\operatorname{conv}(Y)$. We will show that either $p, q \in Y^{\prime}$ or $x$ cannot be a corner of $\operatorname{conv}\left(F_{2}(Y)\right)$. It will follow that $F_{2}(\operatorname{conv}(Y)) \subseteq \operatorname{conv}\left(F\left(Y^{\prime}\right)\right)$. Our proof will be an induction on the number of coordinates such that there is a tie (tie is the case where the value of a coordinate of $p$ and $q$ coincide). If there are $n$ ties, then the points $p$ and $q$ are equal and we have $x=p=q$, and this case is trivial since $Y \subseteq Y^{\prime}$. So the base case is done. By inductive hypothesis, we assume that $k+1$-ties yield the result and we consider the case for $k$-ties. Without loss of generality we consider the following case:

$$
\begin{gathered}
p_{1}=q_{1} ; p_{2}=q_{2} ; \cdots ; p_{k}=q_{k} \\
p_{k+1}<q_{k+1} ; p_{k+2}<q_{k+2} ; \cdots ; p_{\ell}<q_{\ell} ; \\
p_{\ell+1}>q_{\ell+1} ; p_{\ell+2}>q_{\ell+2} ; \cdots ; p_{n}>q_{n} ;
\end{gathered}
$$

i.e, the first $k$ coordinates are ties, then $p$ is the sole contributor to the coordinates $k+1$ to $\ell$, and for the rest of the coordinates $q$ is the sole contributor. Below we will use the expression infinitesimal change to mean change smaller than $\eta=\min _{k<i \leq n}\left|p_{i}-q_{i}\right|$ (note $\eta>0$ ). Consider the plane $\Pi$ with first $k$ coordinates constant (given by $x_{1}=$ $\left.p_{1}=q_{1} ; x_{2}=p_{2}=q_{2} ; \cdots ; x_{k}=p_{k}=q_{k}\right)$. We intersect the plane $\Pi$ with $\operatorname{conv}(Y)$ and we obtain a polytope. First we consider the case when $p$ and $q$ are not a corner of the polytope and then we consider when $p$ and $q$ are corners of the polytope.

1. Case 1: $p$ is not a corner of the polytope $\Pi \cap \operatorname{conv}(Y)$. We draw a line in $\Pi$ with $p$ as midpoint such that the line is contained in $\Pi \cap \operatorname{conv}(Y)$. This ensures that the coordinates 1 to $k$ remain fixed along the line.
(a) If any one of coordinates from $k+1$ to $\ell$ changes along the line, then by infinitesimal change of $p$ along the line, we ensure that $x$ moves along a line.
(b) Otherwise coordinates $k+1$ to $\ell$ remain constant; and we move $p$ along the line in a direction such that at least one of the remaining coordinates (say $j$ ) decreases, and decreasing $j$ we have one of the following three cases:
i. we go down to $q_{j}$ and then we have one more tie and we are fine by inductive hypothesis;
ii. we hit a face of the polytope $\Pi \cap \operatorname{conv}(Y)$ and then we change direction of the line (while staying in the hit face) and continue;
iii. we hit a corner of the polytope $\Pi \cap \operatorname{conv}(Y)$ and then $p$ becomes a corner which will be handled in Case 3.
2. Case 2: $q$ is not a corner of the polytope $\Pi \cap \operatorname{conv}(Y)$. By symmetric analysis to Case 1 either we are done or $q$ becomes a corner of the polytope $\Pi \cap \operatorname{conv}(Y)$.
3. Case 3: $p$ and $q$ are corners of the polytope $\Pi \cap \operatorname{conv}(Y)$. If $\Pi$ is supported by $Y$, then both $p, q \in Y^{\prime}$ and we are done. Otherwise $\Pi$ is not supported by $Y$, and now we move along lines with $p$ and $q$ as midpoints and slide the plane $\Pi$. In other words we move $p$ and $q$ alone lines and move such that the ties remain the same. We also ensure infinitesimal changes along the line so that the contributor of each coordinate is the same as original. Let

$$
p(\lambda)=p+\lambda \cdot \boldsymbol{v} ; \quad q(\mu)=q+\mu \cdot \boldsymbol{w}
$$

be the lines where $\boldsymbol{v}$ and $\boldsymbol{w}$ are directions. By ties for $1 \leq i \leq k$ we have $\lambda \cdot v_{i}=$ $\mu \cdot w_{i}$. Then for infinitesimal change the point $x$ moves as follows:

$$
\begin{aligned}
& x(\lambda, \mu)=f(p(\lambda), q(\mu))) \\
& =\left(p_{1}+\lambda \cdot v_{1}, p_{2}+\lambda \cdot v_{2}, \cdots p_{\ell}+\lambda \cdot v_{\ell}, q_{\ell+1}+\mu \cdot w_{\ell+1}, \cdots, q_{n}+\mu \cdot w_{n}\right) \\
& =\left(p_{1}+\lambda \cdot v_{1}, p_{2}+\lambda \cdot v_{2}, \cdots p_{\ell}+\lambda \cdot v_{\ell}, q_{\ell+1}+\lambda \cdot \frac{v_{1}}{w_{1}} \cdot w_{\ell+1}, \cdots, q_{n}+\lambda \cdot \frac{v_{1}}{w_{1}} \cdot w_{n}\right)
\end{aligned}
$$

It follows that $x$ moves along the line $x+\lambda \cdot \boldsymbol{z}$ where for $1 \leq i \leq \ell$ we have $z_{i}=v_{i}$ and for $\ell<i \leq n$ we have $z_{i}=\frac{v_{1}}{w_{1}} \cdot w_{i}$; note that $w_{1}>0$ since the plane slides. Since $x$ moves along a line it cannot be an extreme point.

This completes the proof. Also note that in the special case when there is no tie at all then we do not need to consider Case 3 as then $\Pi=\mathbb{R}^{n}$ and thus $p$ and $q$ are corners of conv $(Y)$ and hence in $Y^{\prime}$.
Analysis. Given a set of $m$ points, the construction $\gamma$ yield at most $m^{2} \cdot 2^{n}$ points. The argument is as follows: consider a point $p$, and then we consider all $k$-dimensional coordinates planes through $p$. There are $\binom{n}{k}$ possible $k$-dimensional coordinate plane through $p$, and summing over all $k$ we get that there are at most $2^{n}$ coordinate planes that we consider through $p$. The interesection of a coordinate plane through $p$ with the convex hull of $m$ points gives at most $m$ new corner points, and this claim is as proved follows: the new corner points can be constructed as the shadow of the convex hull on the plane, and since the convex hull has $m$ corner points the claim follows. Thus it follows that the construction yield at most $m^{2} \cdot 2^{n}$ new points, and thus we have at most $m+m^{2} \cdot 2^{n} \leq 2 \cdot m^{2} \cdot 2^{n}$ points. If the set $S$ has $m$ points, applying the construction iteratively for $n$ times we obtain the desired set $S^{\prime}$ that has at most $m^{2^{n}} \cdot 2^{n^{2}+n}$ points. Since convex hull of a set of $\ell$ points in $n$ dimension can be constructed in $\ell^{O(n)}$ time, it follows that the set $S^{\prime}$ can be constructed in $m^{O\left(n \cdot 2^{n}\right)} \cdot 2^{O\left(n^{3}\right)}$ time.

Proof (Theorem 5 (Sketch)). We will show the undecidability for the quantitative universality problem for nondeterministic mean-payoff automata. It will follow that the quantitative language inclusion and quantitative language equivalence problem are undecidable for both nondeterministic and alternating automata. The quantitative universality for nondeterministic automata can be reduced to the quantitative emptiness as well as the quantitative universality problem for alternating mean-payoff automata. Hence to complete the proof we derive the undecidability of quantitative universality for nondeterministic mean-payoff automata from the recent results of [9].

The results of [9] show that in two-player blind imperfect-information mean-payoff games whether there is a player 1 blind-strategy $\sigma$ such that against all player 2 strategies $\tau$ the mean-payoff value $P(\sigma, \tau)$ of the play given $\sigma$ and $\tau$ is greater than $\nu$ is undecidable. The result is a reduction from the halting problem of two-counter machines, and we observe that the reduction has the following property: for threshold value $\nu=0$, if the two-counter machine halts then player 1 has a blind-strategy to ensure payoff greater than $\nu$, and otherwise against every blind-strategy for player 1, player 2 can ensure that the payoff for player 1 is at most $\nu=0$. Thus from the above observation about the reduction of [9] it follows that in two-player blind imperfect-information mean-payoff games, given a threshold $\nu$, the decision problem whether

$$
\exists \sigma . \inf _{\tau} P(\sigma, \tau)>\nu
$$

where $\sigma$ ranges over player 1 blind-strategies, and $\tau$ over player 2 strategies, is undecidable and dually the following decision problem whether

$$
\forall \sigma \cdot \sup _{\tau} P(\sigma, \tau) \geq \nu
$$

is also undecidable. The universality problem for nondeterministic mean-payoff automata is equivalent to two-player blind imperfect information mean-payoff games where the choice of words represents the blind-strategies for player 1 and resolving nondeterminism corresponds to strategies of player 2. It follows that for nondeterministic mean-payoff automata $A$, given a threshold $\nu$, the decision problem whether

$$
\text { for all words } w . L_{A}(w) \geq \nu
$$

is undecidable.

## C Proofs of Section 6

Proof (of Theorem 6). We prove the two assertions.

1. The results of [4] shows that there exists deterministic mean-payoff automata $A_{1}$ and $A_{2}$ such that $\operatorname{sum}\left(A_{1}, A_{2}\right)$ cannot be expressed by alternating mean-payoff automata. Hence the result follows.
2. We now show that there exist quantitative languages expressible by nondeterministic mean-payoff automata that cannot be expressed by mean-payoff automaton expressions. Consider the language $L_{F}$ of finitely many $a$ 's, i.e., for an infinite word $w$ we have $L_{F}(w)=1$ if $w$ contains finitely many $a$ 's, and $L_{F}(w)=0$ otherwise. It is easy to see that the nondeterministic mean-payoff automaton (shown in Fig. 2) defines $L_{F}$.
We now show that $L_{F}$ is not expressible by a mean-payoff automaton expression. Towards contradiction, assume that the expression $E$ defines the language $L_{F}$, and let $A_{E}$ be the synchronized product of the deterministic automata occurring in $E$ (assume $A_{E}$ has $n$ states). Consider a reachable bottom strongly connected component $V$ of the underlying graph of $A_{E}$, and let $C$ be a $b$-cycle in $V$. We construct

Fig. 2. A nondeterministic limit-average automaton.
an infinite word $w$ with infinitely many $a$ 's as follows: $(i)$ start with a prefix $w_{1}$ of length at most $n$ to reach $C$, (ii) loop $k$ times through the b-cycle $C$ (initially $k=1$ ), (iii) read an ' $a$ ' and then a finite word of length at most $n$ to reach $C$ again (this is possible since $C$ is in a bottom s.c.c.), and proceed to step (ii) with increased value of $k$.
The cycle $C$ corresponds to a cycle in each automaton of $E$, and since the value of $k$ is increasing unboundedly, the value of $w$ in each automaton of $E$ is given by the average of the weights along their $b$-cycle after reading $w_{1}$. Therefore, the value of $w$ and the value of $w_{1} b^{\omega}$ coincide in each deterministic automaton of $E$. As a consequence, their value coincide in $E$ itself. This is a contradiction since $L_{F}(w)=0$ while $L_{F}\left(w_{1} b^{\omega}\right)=1$.

[^0]:    ${ }^{4}$ The numerical complement of a quantitative languages $L$ is $-L$.

[^1]:    ${ }^{5}$ Closure under complementation holds because LimInfAvg-automata and LimSupAvgautomata are dual. It would not hold if only LimlnfAvg-automata (or only LimSupAvgautomata) were allowed.

[^2]:    ${ }^{6}$ See [4] for the definition of alternating LimInfAvg- and LimSupAvg-automata that generalize nondeterministic automata.
