ABSTRACT

The purpose of this study was to evaluate the radioprotective effect of carnosine (β -alanyl-1-histidine) on the wound healing in rats. Therefore, 48 male rats were submitted to a surgical procedure to perform a rectangular wound in the anterior-dorsal region. The animals were divided into 4 experimental groups randomly chosen: control; irradiated; carnosine irradiated and carnosine group. The irradiated and carnosine irradiated group were exposed to a dose (6Gy) of gamma irradiation, in the whole body, 72 hours after surgery. The carnosine and carnosine irradiated groups, in addition to the surgical procedure and the irradiation, received two doses of carnosine aqueous solution, the first one being injected 48 hours after surgery, and the second one 1 hour and 30 minutes before irradiation. The tissue repair of the 4 groups was evaluated at 4, 7, 14, and 21 days after inflicting the wound, by morphological, histochemical and histophysical methods. At all examined periods, it could be observed that the animals from the carnosine irradiated group presented a better developed granulation tissue than the irradiated group and closely similar to that of the control group. Thus, under the experimental conditions used, it was possible to conclude that carnosine is an effective radioprotective substance.

Uniterms: Radiation, ionizing; Radiation-protective agents; Carnosine; Wound healing.

RESUMO

O objetivo deste estudo foi avaliar o efeito radioprotetor da carnosina (β -alanil-1-histidina) no processo de cicatrização em ratos. Para isto, 48 ratos machos foram submetidos a um procedimento cirúrgico para realização de uma ferida retangular na região dorsal anterior. Os animais foram divididos aleatoriamente em 4 grupos experimentais: controle, irradiado, carnosina irradiado e carnosina. Os grupos carnosina e carnosina irradiado foram expostos a uma dose de corpo todo de 6 Gy de radiação gama, 72 horas após a cirurgia para confecção da ferida. O grupo carnosina e carnosina irradiado, adicionalmente, ao procedimento cirúrgico e a irradiação, receberam duas doses de solução aquosa de carnosina, a primeira sendo injetada 48 horas após a cirurgia, e a segunda 1 hora e 30 minutos antes da irradiação. A reparação tecidual nos 4 grupos foi avaliada 4, 7, 14 e 21 dias após a realização da ferida, por métodos morfológicos, histoquímicos e histofísicos. Em todos os períodos examinados, pode ser observado que os animais do grupo carnosina irradiado apresentaram um melhor desenvolvimento do tecido de granulação do que o grupo irradiado e muito similar ao do grupo controle. Logo, de acordo com as condições experimentais usadas, foi possível concluir que a carnosina é uma substância radioprotetora efetiva.

Unitermos: Radiação ionizante; Protetores contra radiação; Carnosina; Cicatrização de feridas.

INTRODUCTION

Wound healing is a complex process, which is commonly divided into three phases, including invasion of inflammatory cells, proliferation of tissue repairing cells and tissue remodeling. Any alteration in some of these phases will inevitably cause an abnormal tissue repair process²². Any of these phases will be altered or retarded when radiation is involved. The effects of ionizing radiation are mediated by the formation of free radicals, which are highly reactive, removing hydrogen atoms from fatty acids, causing lipid peroxidation and consequently cell death⁹. These modifications could be caused by vessel or fibroblast alterations, including: hypoxia, inefficient collagen production and reduction of proliferation capacity of local tissues, which become less capable of reacting to the inflammatory stimulation^{15,19,28}.

The fibroblasts, vascular endothelial cells, keratinocytes and granulation tissue formation are fundamental to the wound healing process¹⁷. Radiation causes an irregular proliferation of endothelial cells, originating capillaries with different forms and diameters, leading to a transitory increase of permeability². The reduction of granulation tissue thickness, which becomes less cellular in open wounds, thus delaying the formation and maturation of the collagen, was observed when it was submitted to radio-therapeutic doses¹⁶. The main histomorphological alterations caused in wound healing by postoperative irradiation, were retarded fibroblast growth, alterations in their development with production of atypical cells, formation of fibrin which persisted for a longer than normal time and reduction of the number of vessels^{12,24}.

The role of antioxidants in reducing the deleterious effects of ionizing radiations on the tissue repair process has already been studied³². The radio-protective effect of substances, such as vitamin E, on wound healing in irradiated rats was also demonstrated on the tissue repair process after 6 Gy of electron irradiation¹⁴. The action of carnosine in stimulating the normal tissue repair process was reported and its affinity for hydroxyl and capacity to reduce the intermediate products of oxidative free radicals in wound tissues and blood serum was also pointed out^{1,5,11,18,26,27}.

This study aimed to evaluate the possible protective effect of carnosine on the wound healing in rats' whole body exposed to gamma radiation, observing the development of granulation tissue by morphologic, histochemistry and histophysical methods.

MATERIAL AND METHODS

Animals. Forty-eight male rats (*Rattus norvegicus*, albinus Wistar) aged between 60 - 90 days and weighing approximately 300 grams were used. The animals were kept in polycarbonate cages under an alternating 12h light/dark cycle and maintained on laboratory chow and water ad libitum.

Experimental design. The experimental procedures

consisted of six phases: anesthesia; surgical procedure; irradiation; achievement of the specimen and slide preparations.

The animals were divided into four experimental groups as follows:

Control group (CG): these animals were only submitted to the surgical procedure. **Irradiated (IG):** these animals were submitted to a surgical procedure and to a whole-body irradiation, 72 hours after the wound was made.

Carnosine Irradiated group (CaIG): these animals received two i.p. doses of aqueous carnosine solution (L-Carnosine Sigma-Aldrich) 150mg/Kg. The first one was administered 48 hours after the wound and the second one, 1 hour and 30 minutes before the whole-body irradiation;

Carnosine group (CaG): the animals from this group were submitted to the wounding surgery and received two doses of aqueous carnosine solutions, administered in the same way as in group CaIG. These animals were not irradiated.

Surgical procedure. Rats were i.p. anesthetized with thiazine hydrochloride (10mg/kg) and ketamine hydrochloride (100mg/Kg) and a wound of 2.0 x 1.0 cm in size was made in the anterior dorsal region of each animal and at a distance of approximately 1.0cm to the right of the spine. The depth of each incision was approximately 0.2cm, having as a reference the muscular tissue at the base of the wound and the presence of the dermis at its edges.

Irradiation. Rats were i.p. anesthetized with thiazine hydrochloride (10mg/kg), and ketamine hydrochloride (100mg/Kg) and the whole-body irradiated, 72 hours after the surgical procedure, with a single exposure of 6Gy delivered by a Cobalt therapy tube (Alcyon II) with an output of 84cGy/min. The distance to target was 80cm. Irradiation was done on the 3rd day of tissue repair, because this period is related to the cell proliferation phase of healing, characterized by the fibroblasts and endothelial cells migration.

The tissue repair process was evaluated at 4, 7, 14 and 21 days after the surgical procedure. Each part of tissue contents, the wound or the scar surrounded by normal tissue was removed, correctly fixed and paraffin-embedded. Sections of 5mm thickness were obtained and stained with hematoxylin-eosin, in order to evaluate the development of the newly formed tissue. Mallory fibroglia method according to Edwards⁸ and Picosirius staining to evaluate collagen birefringence under polarized light microscopy were also performed.

Sections were also submitted to the toluidine blue pH 4 reaction, which allows the macromolecular organization of granulation tissue to be evaluated, using the observations through linear dichroism by means of polarization microscopy³. This phenomenon is essential for detecting the presence or absence of macromolecular orientation of the tissue evolution. The observations under light and polarized microscopy were done through a Zeiss-Pol 01 photomicroscope.

The objective of histophysical methods is the quantitative analysis of collagen fiber birefringence. For this purpose, Zeiss Axiolab microscopy connected to a micro

camera (Sony CCD IRIS/RGB Collor- Japan) was used, and the slides stained with picosirius were analyzed. The fields of the sections were measured in five regions each. The evaluation was done on the 4th and 7th days and based on these measurements, the relative means of each group were obtained for submission to statistical analysis.

The morphometric study for counting the fibroblast number was performed under light microscopy, ZEISS Germany, to high-power view (x400) by means of an ocular containing reticule lens PK 8 x mn, Zeiss, West Germany. The fibroblast count was carried out in all the groups on the 4th and 7th day, 10 fields having been evaluated in each slide. From the results of these measurements, the relative means of each group were calculated by statistical analysis.

For statistical analysis, data were initially evaluated using ANOVA. Significant differences were resolved with the Tukey test, with significant p-value < 0.05.

RESULTS

Morphological Analysis

The morphological analysis of CG performed by HE staining was able to demonstrate that on the 4th day the wound was very large, completely covered by a necrotic crust, containing remaining cellular portions, fibrin and coagulated blood, whose function is to protect the subjacent tissue. The inflammatory infiltrate was composed mainly of neutrophils and lymphocytes. In the IG the wound area was also large; the crust was thicker when compared to the control group, with a larger amount of accumulated necrotic material. The granulation tissue presented little organization, with few fibroblasts and a smaller number of vessels and newly formed collagen fibers. In the CaIG, the tissue analyzed was similar to the control group, with a thin superficial necrotic layer and immediately below it, an inflamed zone. The CaG showed very similar aspects to the control group.

On the 7th day, the CG presented a reduction in the size of the wound area, with no crust, which was replaced by a thin superficial necrotic layer. The granulation tissue below presented fibroblastic and angioblastic proliferation, showing newly formed capillary vessels corresponding to the surface. In the IG the wound area had also diminished, however the necrotic crust was still present to the full extent. Below the crust, an acute inflammatory infiltrate still remained. The granulation tissue showed a delayed aspect, showing no capillary vessel organization, and fibroblastic proliferation was poor when compared to the control group (Figure 1A). In the CaIG, the granulation tissue presented evidence of better development than the IG, but slightly less than the control group. The functional capillaries were shown to be present in number and degree of evolution similar to that of the CG. In the CaIG, the analyzed tissue was similar to the control group, both in granulation tissue evolution and in epithelial proliferation (Figure 1B).

Around the 14th day, the wound area in the CG was already totally covered by epithelium, with a keratin layer

formation, which demonstrates epithelial tissue maturation. The granulation tissue showed few fibroblastic cells and blood capillaries, becoming fibrous. In the IG, the granulation tissue was shown to be still delayed in relation to the control group. The CaIG was observed to present a slower development process when compared to the control, but more developed than IG. The CaG showed similar aspects to the control group, both in epithelial and granulation tissue maturation and rate of development.

On the 21st day, CG presented a completely healed wound, sufficiently covered by a functional epithelium, almost reaching the normal tissue appearance, also with the presence of cutaneous appendices. The IG presented the tissue repair process still delayed in relation to all groups, with minor retraction and fibrousness. In the CaIG, the tissue development was similar to the CG. The CaG also presented similar aspects to the control group.

Quantitative Analysis of Fibroblasts

The relative means for each group after being submitted to statistical analysis may be seen in Figure 2.

Mallory Method for Fibroglia

Fibroglia is evident in granulation tissues with high rate of proliferation before they become fibrous. Therefore, this method was used only on the 4th day of tissue evolution. In the CG, CaG and CaIG (Figure 1C) it could be seen that there was a large fibroglia proliferation. Contrarily, IG has shown almost total absence of fibroglia development (Figure 1D).

Qualitative Evaluation of Birefringence of Collagen Fibers – Picosirius Staining

On the 4th day, the CG and CaG presented a small amount of birefringent collagen fibers, still slim and moderately bright. In the IG the amount of fibers was lower when compared to the control. In the CaIG the collagen fibers showed aspect very similar to the control (Figure 3).

On the 7th day of repair, all groups showed similar aspects in their birefringence, with exception of the IG, which presented fewer collagen fibers with less brightness. On the 14th and 21st days the conditions observed on the 7th day of evolution remained the same, with the IG displaying less birefringence than the other groups.

Quantitative Evaluation of Collagen Fiber Birefringence

The relative means for each group after being submitted to statistical analysis may be seen in graphs (Figure 3).

Evaluation of Linear Dicroism

On the 4th day of development none of the groups presented linear dicroism, indicating that at this time, there was still not a sufficient degree of macromolecular

orientation to induce the phenomenon. When the 7th day of development was analyzed, the CG, CaIG and CaG showed evident microism. By contrast, the IG did not show microism, which only became evident for this group, on the 14th day of development.

DISCUSSION

The deleterious effects of ionizing radiation on the tissue repair process were evident when comparing the CG to the IG ^{4, 6,12,14-16,19, 21, 23- 25, 28,32}.

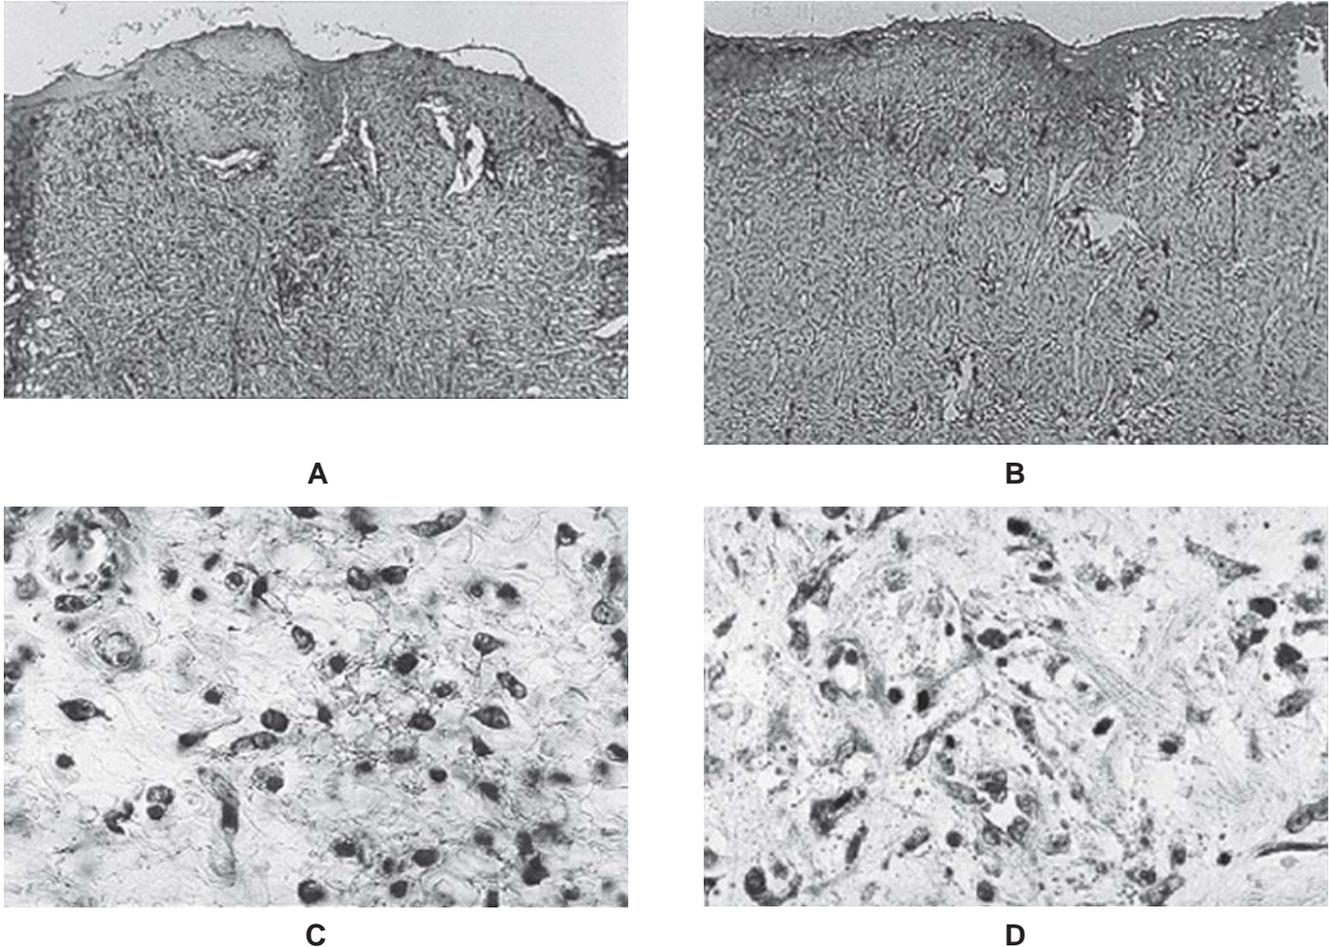

FIGURE 1- A- In the IG, on the 7th day, note that granulation tissue showed poor cellular organization; B- CaIG, on the 7th day, functional capillaries were shown to be present in higher number and degree of differentiation and the granulation tissue showed more development than the IG (HE, original magnification x250); C- CaIG, on the 4th day, showed great fibroglia proliferation; D- IG, on the 4th day, showed almost total absence of fibroglia development (Mallory method, original magnification x250)

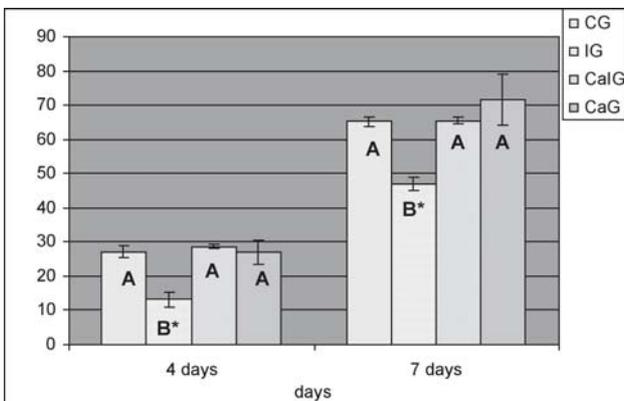

FIGURE 2- Means and standard deviation of the fibroblasts morphometry on the 4th and 7th of tissue evolution. Letters differ statistically between them, with significant p-value of 5%, by the Tukey test

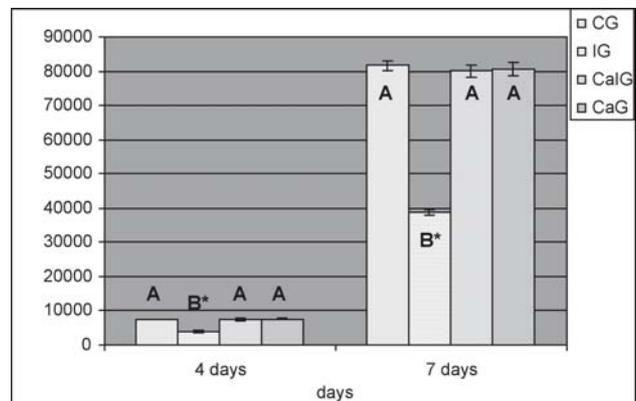

FIGURE 3- Means and standard deviation of the birefringence of collagen fibers (im²) on the 4th and 7th day of tissue evolution. Letters differ statistically between them, with significant p-value of 5%, by the Tukey test

In the present study, the morphometry of fibroblasts was analyzed on the 4th and 7th days and significant differences were observed when comparing the IG to the CG and CaIG. Evident modifications could be seen in the IG, such as the diminished number of fibroblasts in the granulation tissue. Thus, the effect of ionizing radiation on damaging tissue repair could be related to the reduction in the number of fibroblasts.

The deleterious effects of ionizing radiation on tissues during healing have been extensively studied. Some authors believe that the damage is related to both fibroblast modifications and vessel complications^{15,16,25}. Delay in fibroblast growth has been reported²⁵. Functional modification of fibroblasts could influence the production of deficient collagen, which requires a longer maturation time^{4,7,28,31}. Other authors^{12,19} observed a reduction in the amount of new vessel formation. It is believed that fibroblasts play a fundamental role in the healing process, because they are responsible for collagen producing protein synthesis. It is accepted that a reduction in the number of fibroblasts decreases collagen synthesis, delaying macromolecular orientation and collagen fiber production, thus retarding the tissue repair process.

Fibroglia is evident in granulation tissue with a high rate of proliferation. In this study, the effect of radiation on delaying this proliferation rate could be observed, when comparing the CG and CaIG to the IG. The IG showed a complete absence of fibroglia development, however the group pre treated with carnosine and irradiated (CaIG) presented a high rate of proliferation similar to CG. The deleterious effect also modified the molecular orientation of collagen, and through picrosirius staining and polarized light microscopy, it could be shown that the IG showed a decrease in birefringence for all evaluation periods, while CaIG presented more organized and shiny collagen fibers, similar to the control group.

Linear dichroism was analyzed and it could be concluded that on the 7th day of IG development, there was no evidence of tissue organization, while the other groups already showed the presence of macromolecular orientation. According to some authors^{14,29} the macromolecular orientation of granulation tissue begins at approximately the 7th day of the tissue repairing process; so, with exception of the IG, all groups presented tissue organization similar to that of the control repair tissue. Thus, a protection given by this antioxidant substance may be advocated.

The action of carnosine in irradiated tissues is related to its affinity for free radicals, mainly for hydroxyl, and its ability to interact with the products of lipid peroxidation, preventing cell membrane damage^{4,5,13}. Carnosine acts as a great hydroxyl radical scavenger, protecting biological structures and playing an important role in the anti-oxidative process^{1,27}. The action of carnosine and b alanyl in wound healing in rats treated with hydrocortisone was tested. The exogenous carnosine is degraded through carnosine tissue into histidine and b alanyl. The histidine plays a role in histamine production through hydrocortisone, stimulating the healing process and b alanyl promotes collagen

synthesis, accelerating the repair process²⁰. As seen in this study, the irradiation process prolongs the inflammatory phase; considering that carnosine administration enables a greater production of histamine, the chemistry mediator responsible for the increase of vascular permeability, its radio-protective effect could be related to the acceleration of the inflammatory phase.

Carnosine promotes the stimulation of the repair process, accelerating granulation tissue development^{10,11,18,30}. In this experimental study this was not observed. The CaG was similar to the CG, probably because of the amount and period of dose administration. Carnosine was administered twice before the animals were submitted to irradiation and the tissue repair process was already at the end of the inflammatory phase and at the beginning of the proliferation phase. It was observed that the daily administration of carnosine accelerated the production of scar tissue^{10,20,30}.

The CaIG presented similar aspects when compared to the control, therefore, carnosine helped to inhibit the deleterious effects of gamma radiation. No effect related to acceleration of tissue repair process was observed, and in comparison to the control, similar aspects were maintained.
