ABSTRACT:

Deliveries from Indian and Chinese mothers present a higher than expected male:female ratio in their own countries, in northern Europe, EEUU and Canada. No studies have been carried out in southern European countries. We explored whether the high male-to-female ratio common in Indian and Chinese communities, also exists among families from those regions who live in Spain. For that purpose we designed a cross-sectional population-based study containing data on 3,133,908 singleton live births registered in the Spanish Vital Statistics Registry during the period 2007-2015. The ratio of male:female births by area of origin was calculated using binary intercept-only logistic regression models without reference category for the whole sample of births and taking into account a possible effect modification of birth order and sex of the previous males. Interaction effects of sociodemographic mothers' and fathers' characteristics was also assessed. In Spain, the ratio male:female is higher than expected for Indian-born mothers, especially for deliveries from mothers with no previous male births and, to a lesser extent, for Chinese-born women, specifically for third or higher order births and slightly influenced by the sex of the previous births. Therefore, the increased sex male:female ratio observed in other countries among Indian and Chinese mothers is also observed in Spain. This reinforces the notion that culture and values of the country of origin are more influential than the country of residence.

Keywords: Sex ratio; Male:Female ratio; Missing girls; Chinese mothers; Indian Mothers.

Introduction

The Sex Ratio, a demographic indicator consistent across populations, usually varies between 1.03 and 1.07 males per female, is largely independent of birth order and the sex of previous siblings, and may fluctuate somewhat among different ethnic groups [1-15].

The association of altered sex ratio with many epidemiological and biological factors such as father's occupation [16], hepatitis B virus [17], parental periconceptional smoking [18], parental hormonal levels [19], time to pregnancy [20] and caloric availability [21] has been vaguely explored in the last years. Even if some results claim a possible association [17-21], their strength and reproducibility are weak. Additionally, whether or not these factors are taken into account, the sharp decrease in female births in countries from South and East Asia regions such as India [22] and China [23] is too pronounced to arise only from biological variation. In these countries, where there is a traditional preference for sons [1-7, 14, 15, 24-26], sex selection through selective abortions or female infanticides has been proposed as possible explanation for this imbalance [12, 27, 28].

The incentives for gender selection depend not only on gender preferences but also on the number and sex of children already born [7]. The use of higher parity and conditional-upon-previous-gender boy-birth percentages has been considered in some previous studies of Asian countries [22, 29]. In India, a large study showed a sharp increase in the male:female ratio among second order births when the firstborn was a girl, and no substantial increase when the firstborn[13] was a boy [28].

There is some evidence that these patterns are also present among Asian immigrants in developed countries such as US, Canada, England and Norway [5, 7-9, 13, 27, 30], even for second generation Asian migrants [31]. A relatively recent study [27]

found that the likelihood of male births to India-born mothers in the United Kingdom had an overall upward trend since the 1980s and was considerably higher at third and later births after 1990.

Not all studies have taken into account the possible modification effect of mother's characteristics such as age, educational level, profession or parity and most of the studies conducted in developed countries have taken place in Anglo-Saxon countries. However, to our knowledge, no studies have addressed the imbalance in the sex ratio among Asian immigrants in countries of Southern Europe where the reception of immigrants is recent and have experienced a more difficult economic situation than the US, Canada and Northern Europe through the period 2007-2015 [30]. There may also be different self-selection. Those heading to English-speaking countries might be different (more traditional, many having relatives from previous generations – a more mature diaspora) than those going to Southern Europe.

Thus, the aim of the present study was to determine whether the high male-to-female ratio common in Indian and Chinese communities, also exists among families from those regions who live in Spain, and whether the imbalance increases with parity and sex of the previous children.

MATERIALS AND METHODS:

Study population

In Spain, registration of newborns is mandatory for all births occurring in the country, regardless of the mother's nationality. For the present study data on all births registered in the Spanish Vital Statistics Registry during the period 2005-2015 were used. Data included: mothers identification number, sex of the newborn (male, female), number of previous live births and mother's nationality for the period 2005-2006 or mother area

of birth from 2007 onwards (Native, East Europe, Rest of Europe, Latin America, North Africa, Sub-Saharan Africa, North America and Oceania, India, China and Rest of Asia) among other information. Some other variables that were used to describe the sample and assess possible confounding effects and interactions were year of delivery (2005-2015), birth weight (≤1500grs, 1501-2499grs, ≥2500grs), gestational age (≤32, 33-36, >36), mother's and father's age (<20, 20-34, ≥35), educational level (primary, secondary, university or more) and occupation (non-manual, manual, does not work, non-classified), mother's marital status (married, non-married) and father's nationality/area of birth. Initially all singleton live births over 23 weeks of gestational age that survived more than 24 hours and reported the information on the mother's nationality/area of birth were selected (*Figure 1*).

Statistical analyses

Data on the number of previous live births for these deliveries was used to calculate the birth order that was grouped afterwards in three categories: 1st delivery; 2nd delivery; and ≥3rd delivery. The sex of the previous deliveries was obtained by linking the mothers' registries of previous years and grouped in three categories: 1st delivery, >1st delivery with no previous males; and >1st delivery with, at least, one previous male.

As indicated before, birth records collected different information on mother's origin for the period 2005-2006 (mother's nationality) than for the period 2007 onwards (mother area of birth). In order to have a uniform and precise definition of mother's area of origin, only mothers that gave birth from 2007 onwards were kept for the subsequent analyses. Characteristics of births and mothers of selected singleton live births over 23 weeks of gestational age that survived more than 24 hours, occurred between 2007 and 2015 and with information on the mother's nationality were described using number of births and percentage of males in each of their categories for the whole sample and by

mother's area of origin (*Table 1***)**. The ratio of male:female births is a specific example of the odds [$P_{male}/(1 - P_{male})$] since it represents the proportion of males divided by the proportion of females. This ratio can be calculated with this very same formula within groups of mothers' area of origin by restricting the calculations to the data on sex from the births occurred in these groups. The 95% confidence intervals can be calculated using the formula of the 95%CI for a proportion. However, a more straight forward method to carry out these calculations will be, as some authors previously did [12, 13], to adjust a binary logistic regression model, including sex as the dependent variable and the area of mothers' origin as the main exposure keeping all levels of the variable (no basal category) and dropping the constant (see supplementary material I for more information on this method). Additionally, this modelling also allows to explore a possible modification effect of multiple external variables in a regression model (see supplementary material I). We did not consider mother's marital status, mother's and father's age, educational level and profession, and father's area of origin as potential confounders because their association with the male to female ratio has not been proved in the literature nor can be explained biologically. However, the possible effect modification of mothers' age, profession, educational level and marital status in the ratio of male:female births by area of origin was assessed including an interaction term between these variables and mother's area of origin for the whole sample (sex selection might be more likely among mothers married, older, less educated or with less specialized occupations). The final models were used to report the effect of mothers' nationality in the total male:female ratio with the corresponding 95% confidence intervals (*Table 2*). A possible effect modification of birth order (*Table 3*) and sex of the previous males (*Table 4*) was explored including in the models an interaction term between these variables and mother's area of origin.

All the statistical analyses were performed with Stata 14 assuming a confidence level of 95%.

RESULTS:

Data selection

For the period of 2005-2015, 5,038,435 births were registered in the Spanish Vital Statistics Registry. Initially 17,727 births born dead or that survived less than 24 hours, 183 births occurred in or before the 23rd week of gestation, 103,260 multiple births and 16,098 registries in which the nationality/area of origin of the mother was missing were excluded. For the subsequent analysis different exclusion criteria were followed. The analyses of the total effect of mother's nationality in the male:female ratio and the analysis by birth other were carried out with the 3,989,985 remaining births after excluding 911,182 that occurred before 2007. For the analysis of the effect of mother's nationality in male:female ratio by sex of the previous birth the analyses were performed over 3,133,908 births after the exclusion of 1,237,681 mothers that had at least one previous live birth occurred before 2005 (and therefore not registered in our databases), 16,735 mothers that reported one or more multiple births and 512,842 births occurred before 2007 (*Figure 1*).

Bivariate results

The bivariate analyses showed a possible effect of mothers' nationality in the ratio of male:female births for the period under study. This might be related with the noticeable higher percentage of male births from Indian-born mothers (54.7%) in comparison with the rest of the areas of origin (percentage of male births between 51.2%-52.0%). As for the births characteristics, the proportion of males seemed to be smaller among low birth weight deliveries but bigger among preterm births. No important differences in these

188 percentages were observed by mother's profession, marital status, mother's age or
189 education (*Table 1*).

190 **Regression results**

191 Since no interaction effects were observed with mother's characteristics, the crude
192 male:female ratio and 95% confidence intervals were reported for all births (*Table 2*), by
193 birth order (*Table 3*) and by sex of the previous births (*Table 4*). Taking into account that
194 the common male:female ratio is between 1.03 and 1.07, our results showed an important
195 alteration of this ratio among Indian-born mothers with a male:female ratio (95%CI) of
196 1.21 (1.14;1.28) for all births (*Table 2*). The ratio increased exponentially for the second
197 1.29 (1.17;1.42) and 3rd or posterior deliveries 2.13 (1.68;2.72) (*Table 3*). The effect,
198 when taking into account the sex of the previous births (*Table 4*), was restricted to
199 deliveries from mothers whose all previous live born were females (male:female ratio
200 (95%CI) = 1.51(1.23;1.87)). Another noteworthy result is the increased male:female ratio
201 observed for Chinese-born women for 3rd or posterior births (male:female ratio (95%CI)
202 = 1.18(1.12;1.25) (*Table 3*) and only for mothers whose all previous live births were
203 females (male:female ratio (95%CI) = 1.10(1.03;1.18)) (*Table 4*). Despite of not being
204 considerably different from the common values, the ratio among North African women
205 was slightly increased, but did not show a particular increase for higher order births
206 independently of the sex of the previous deliveries **(***Tables 2-4***)**.

207

208 **DISCUSSION:**

209 Our results indicate that, in Spain, the ratio male:female is higher than expected
210 for Indian-born mothers, especially for deliveries from mothers with no previous male
211 births and, to a lesser extent, for Chinese-born women, specifically for third or higher
212 order births and slightly influenced by the sex of the previous births.

Our findings agree with those of previous studies carried out in India [22, 28] and China [6], and also in several European [27] and North American [1, 7-13] countries where, in women of Asian origin [8, 9] and more concretely among Indian [1, 5, 7, 10-13, 22, 27, 28] and Chinese [6, 7, 11-13], the sex ratio was higher than the ratio observed for other immigrant and native groups. Some of these studies also support our findings of a stronger sex-ratio modification among Indian than among Chinese women [10-13]. Few of them explored the effect of mothers' origin in the sex-ratio by birth order [5, 6, 10, 11, 13, 27] and even fewer took into account the sex of the previous births [8, 9, 12, 22]. The results previously published, in accordance with our results, provide evidence for a stronger sex-ratio modification for higher order births among Indians [5, 10, 11, 13] and, to a lesser extent, among Chinese [6, 9-11] that is especially noticeable for the second or higher order births with no previous females among Indian [9, 12, 22].

As stated in the introduction, the magnitude of the ratio can hardly be attributed to biological reasons. The hypothesis of a differential occurrence of stillbirths by area of origin in favour of males (more stillbirths among female foetuses from Indian or Chinese mothers which would translate into more male live births) is also unlikely. According to our data (not shown), for the period 2007-2015, Indian mothers had 31 stillbirths (39% females and 61% males) out of 4821 total births and Chinese women had 73 stillbirths (53% females and 47% males) out of 36063. The low proportion of stillbirths is unlikely to have an effect on our final estimates of sex ratio and, even if it would do, the data indicates that the difference in the occurrence of stillbirths is the opposite to the expected to explain our results (higher proportion of stillbirths among males from Indian mothers which would reflect in more female births, altering the sex ratio in the opposite direction to our results). Thus, the most likely explanation is sex selection. The reasons for such selection may stem from strong cultural gender biases that remain with immigrants who

238 come to Spain. In China, sex-selection is mainly attributed to political reasons, with some
239 areas limiting to one the number of children that families can have, inclining sex selection
240 in favour of males. Some residual effects of such policies together with some cultural
241 background might accompany Chinese families abroad, which could be responsible for
242 the slightly altered sex ratio observed for this group of immigrants. However, in India,
243 sex-selection is fully attributed to rooted cultural reasons that remain across borders.
244 Parents from Indian females should provide a dowry that male families receive when
245 couples get married. The obvious economic reasons together with cultural consideration
246 of women as a weaker and less valuable part of society, whose social value resides in her
247 capability to procreate, might be behind the more pronounced alteration of sex ratio
248 observed for this group of immigrants in their own countries and also in Spain.

249 The most likely mechanism for sex-selection is sex-selective abortions. Most of
250 the literature on altered sex-ratio among Asian women consider sex-selective abortions
251 as the main reason to explain the altered sex ratio in favour of males [1, 5-13, 22, 27, 28].
252 Jha et al.[28] estimated, in a relatively recent publication that the number of selective
253 abortions have increased in India from 2 million in 1980 to 6 million in the 2000s. In
254 Spain, most pregnant women find out their baby's sex during their mid-pregnancy
255 ultrasound, usually between 16 and 20 weeks (or around week 14-18 by amniocentesis).
256 Despite that legal regulation in Spain only allows abortions during the first 14 weeks of
257 pregnancy, the percentage of abortions carried out in Spain after 14 weeks (when women
258 may already know the sex) was 6.17 in the last year of our study[32]. It would be of
259 interest to have direct evidence on the incidence of abortions among Indian and Chinese
260 women in Spain. Regrettably, available data on abortions do not report the specific
261 country of birth of the parents. Nevertheless, indirect evidence by region of origin, based
262 on our elaboration of data from voluntary termination of pregnancy (*Supplementary Table*

1) supplied by the Ministry of Health [32-39] and available data on births shows that the ratio of abortions per live single births is considerably higher for Asian (47% of voluntary abortions per 100 single live births in 2015) than for Spanish women (18% of voluntary abortions per 100 single live births in 2015).

The possible limitations and concerns about the data used for this study have been carefully considered and addressed. On the one hand, the estimation of the sex ratio by birth order for the whole sample and by sex of the previous births, assumes that the newborns from previous births are still alive, which might not always be true. In order to reduce this source of error, all births that occurred at or before the 23rd gestational week were excluded due to their low viability [40]. As for the remaining error, in Spain, the estimated infant mortality (0-1 year) rate has decreased gradually from 4.02 deaths/1000 births in 1990 to 3.07/1000 births in 2015. Therefore, in the worst case scenario only 7431 infants of 1,857,808 reported previous births will be dead before one year. Even adding up to these figures, the 31,297 deaths occurred in infants of ages 1 to 15 from 1990 to 2014, the total percentage of deaths in previous live births represents a very conservative estimation of 0.021% deaths of the total prior deliveries [41], which is unlikely to have an important impact in the final estimations.

Additionally, some concerns might arise from the suspicion of lower registration rate of births from non-Spanish mothers. However, some previous studies exploring the quality of data used to calculate reproductive and perinatal health indicators in native and migrant populations in some areas of Spain have demonstrated the rigor of these registries. The estimated under registration of births from immigrant mothers is very low (2-3%) and comes mainly from Latin-American, East-European and sub-Saharan women [42].

Furthermore, as explained in the methods section, for the calculation of the sex of previous live births, only deliveries from mothers that had all their children in the period 2005-2015 were included, ensuring that no information on previous live births was missing, especially for mothers from foreign countries that might had previous deliveries in their country of origin.

Finally, some sensitivity analyses were carried out. The potential effect modification of some mother's characteristics in the ratio of male:female births by area of origin was explored and no interaction was found. The same analyses presented here were also performed using father's area of origin and couple area of origin classified as no Indian/Chinese parents; both Indian; both Chinese; only mother Indian; only father Indian; only mother Chinese and only father Chinese. Similar results were obtained for Indian and Chinese-born fathers and for both Indian and both Chinese couples to the reported here for Indian and Chinese-born mothers (data not shown). This is greatly explained by the fact that, for the different analyses carried out, 85-93% of births from Indian-born mothers have Indian-born fathers and 94-97% of births from Chinese-born mothers have Chinese-born fathers.

This is the first study exploring a possible sex-ratio alteration for some immigrant groups in a country of Southern Europe. Our results show a similar pattern in sex ratio among Indian and Chinese immigrant women to that observed in their own countries or in countries from North Europe or North America. This reinforces the notion that the culture and values of the country of origin is more influential than the country of residence.
