DISCLAIMER

This report has been reviewed by the Chesapeake Bay Program, U.S. Environmental Protection Agency, and approved for publication. Approval does not signify that the contents necessarily reflect the views and policies of the U.S. Environmental Protection Agency, nor does mention of trade names or commercial products constitute endorsement or recommendation for use.

FORWARD

The submerged aquatic vegetation (SAV) of the Chesapeake Bay fill an important ecological role in the Bay system. Aquatic grasses function as food, shelter, and habitat and breeding areas for finfish and shellfish, waterfowl, and species of the lower trophic levels.

In recent years, a noticeable decline in the distribution and abundance of the SAV has been observed. The EPA Chesapeake Bay Program, in attempt to understand the role of the grasses, has developed an SAV research program which will examine the cause-and-effect relationships potentially responsible for the decline in bottom grasses. Research results will provide data for a management plan aimed at protecting and enhancing the growth and propagation of the Bay's submerged plants.

One of the tasks of the SAV program is the conduct of studies to delineate the distribution and abundance of the grasses in the Bay system. This report presents the results of that work in the Virginia waters of the Chesapeake Bay. Compatible studies are being conducted in the Maryland waters, and the results will soon be available.

This effort, in combination with the Maryland Study, establishes the first comprehensive inventory of the SAV in the entire Bay system. The products of the study, a series of maps (1:24,000 scale), will serve as a baseline to measure future changes in the abundance of the Bay grasses.

Follow-up studies are being conducted in 1979 and are projected for 1980. It is intended that the products of this research will not only be useful to Bay managers in making decisions concerning Bay resources and uses but also will assist in defining a cost-effective program for future monitoring of Bay grass populations.

ABSTRACT

The distribution and abundance of submerged aquatic vegetation (SAV) in the lower Chesapeake Bay and its tributaries were delineated with color aerial photography and surface information. Over 8500 hectares of SAV were identified on 31 topographic quadrangles. To enable computer retrieval of the aerial resource information, all information from the 1978 mapping effort was entered into a data base based on the Universal Transverse Mercator coordinate system.

The greatest concentrations of SAV were found at the mouths of the largest tidal rivers and creeks along the Chesapeake Bay shoreline, and to the east of Tangier and Great Fox Islands. Freshwater and low salinity portions of Virginia's tidal rivers were generally found lacking in large areas of SAV, although numerous small fringing beds and pocket areas associated with adjacent tidal marshes were identified.

Based on the co-occurrence of the 20 species found at 93 locations throughout Virginia's tidal waters three species associations of SAV were identified. Zostera marina and Ruppia maritima dominated the higher salinity regions, Zannichellia palustris and others the lower salinities regions and Ceratophyllum demersum and others in the freshwater regions. Of the total of 20 species of SAV that were identified, 18 of the species occur primarily within the tidal rivers. Species richness was inversely related to salinity with the low salinity areas having the greatest number of species.

Seventeen transects conducted across large SAV beds in six areas around the Chesapeake Bay shoreline revealed Ruppia to be dominating the shallow, more protected areas (+1 to -4 dm) with Zostera and Ruppia co-occurring at intermediate depths (-4 to -8 dm) and Zostera predominating at deeper depths (-8 to -12 dm). Bottom types varied from silts to coarse sands with variations in sediment not directly related to speciation of these two species.

Analysis of the historical distribution of SAV throughout the lower Bay was accomplished by use of aerial photography for six selected areas. Low levels of SAV in 1937 increased significantly until approximately 1971 when a precipitous decline in coverage occurred during the period of 1973-1974. This decline continued until 1978 when the lowest levels in SAV over the last 40 years were recorded.

LIST OF ABBREVIATIONS AND DEFINITIONS

ABBREVIATIONS

Submerged Aquatic Species

Cy -- Callitriche verna
Cd -- Ceratophyllum demersum
C -- Chara sp.
Ec -- Elodea canadensis
En -- Elodea nuttallii
Ms -- Myriophyllum spicatum
Nf -- Najas flexilis
Ng -- Najas guadalupensis
Nm -- Najas minor
N -- Nitella sp.
Ps -- Potamogeton crispis
Pi -- Potamogeton filiformis
Po -- Potamogeton foliosus
Pn -- Potamogeton nodusus
Pc -- Potamogeton pectinatus
Pr -- Potamogeton perfoliatus
Rm -- Ruppia maritima
Va -- Vallisneria americana
Zp -- Zannichellia palustris
Zm -- Zostera marina

Emergent and Other Species

B -- Bidens sp.
Bh -- Baccharis halimifolia
Jr -- Juncus roemerianus
L -- Lemna sp.
Nl -- Nuphar luteum
Pd -- Pontederia cordata
Pv -- Peltandra virginica
Sa -- Spartina alterniflora
Sc -- Spartina cynosuroides
Sp -- Spartina patens
Ta -- Typha angustifolia
Za -- Zizania aquatica

DEFINITIONS

Dominant -- The most abundant species characterizing the mapping unit.

Abundant -- Species found in quantity essentially throughout the mapping unit.

Frequent -- Scattered species or individuals occurring regularly throughout the mapping unit.

Occasional -- Individuals or colonies occurring infrequently. These may or may not be unusual.

Rare -- Individual occurring very infrequently. These may be considered unusual.

ACKNOWLEDGEMENT

We thank the following people for their indispensable help in the completion of the project and the preparation of this report: Charlie Alston who aided in the flight organization and preparation, aerial photography and data reduction, David Krantz who assisted in the field work as well as data reduction, and Sam White who piloted the VIMS aircraft and made it possible to obtain the excellent film coverage; personnel of the VIMS Wetlands Department who made observations and collections of plant species along several of Virginia's tidal rivers; Shirley Sterling, Nancy Hudgins and Carole Knox for typing the manuscript, Mary Jo Shackelford, Nancy Sturm and Joe Gilley of the VIMS art department and Ken Thornberry and Bill Jenkins of the VIMS photography department for drafting the numerous figures and providing photo-ready copies of the figures.

Mr. William Cook of the Environmental Protection Agency supported all our endeavors and had many helpful suggestions in the planning stages of this program. EPA's Environmental Photographic Interpretation Complex and especially Mr. William Rhodes were extremely helpful in their support of the aerial photography portion of our project. Our final thanks go to all the people involved in the Chesapeake Bay Program and especially those in the Submerged Aquatic Vegetation (SAV) section for their persistence in establishing SAVs as a high priority area of research in the Chesapeake Bay.

EXECUTIVE SUMMARY

The distribution and abundance of submerged aquatic vegetation (SAV) in the lower Chesapeake Bay and its tributaries were delineated with color aerial photography and surface information. Methods used in this study were reviewed and modified when necessary in response to comments from EPA's Chesapeake Bay Program, Quality Assurance Coordinator. SAV were mapped from aerial imagery onto topographic quadrangles (1:24,000) with a zoom transfer scope and areas of SAV beds computed with an electronic planimeter. All SAV beds were classified into four density categories based on a comparison with a crown density scale: <10% cover, 10-40% cover, 40-70% cover and 70-100% cover. Significant beds of SAV were identified on 31 quadrangles with 27 occurring in the mesohaline and polyhaline areas where *Zostera marina* and *Ruppia maritima* were found to cover over 8400 hectares (20,750 acres) of shallow bottom. The remaining four quadrangles depicted oligohaline and freshwater areas which were vegetated by a variety of species including: *Zannichellia palustris*, *Ceratophyllum demersum*, *Vallisneria americana*, as well as several species of *Potamogeton* and *Najas*. These totaled 137 hectares (340 acres).

Virginia's tidal rivers, which are largely oligohaline and freshwater, were generally found lacking in large areas of SAV, although numerous small fringing beds and pocket areas associated with adjacent tidal marshes were identified through field investigations. Several areas, including a region of the Potomac River in the vicinity of Dahlgren, and the Chickahominy River, a tributary of the James, contained large enough beds of SAV to be mapped. However, the greatest concentrations of SAV were found at the mouths of the largest rivers and creeks and along the Chesapeake Bay shoreline where mesohaline and polyhaline conditions predominate. The most significant areas of these were: 1. along the western shore of the Bay between Back River and the York River; 2. around the shoreline of Mobjack Bay; 3. throughout the shoal areas east of Tangier and Great Fox Island; 4. behind large protective sand bars near Hungar's Creek and Cherrystone Creek which are located along the Bay's eastern shoreline.

The distribution of SAV species in Virginia's tidal waters were classified into three associations based on their co-occurrence; one association consisting of eelgrass, *Zostera marina* and widgeon grass, *Ruppia maritima*, which dominated the mesohaline and polyhaline portions of the Bay; a second association found in the oligohaline regions including the pondweeds *Potamogeton* spp. and *Zannichellia palustris*; and a third association primarily restricted to freshwater including coontail *Ceratophyllum demersum*. Although *Ruppia* is much more tolerant of freshwater than *Zostera*, it was not found to any significant extent in Virginia's rivers upstream from those areas where it co-occurs with *Zostera*. Species diversity (numbers of species) increased in an upstream direction with the third group, those

restricted to freshwater, having the greatest species richness. *Myriophyllum spicatum*, water milfoil, occurred only in isolated areas and formed few significant beds, even in those areas where it previously had been very abundant in the 1960's.

Aerial overflights were made during the summer and winter of 1978. Comparisons of imagery obtained during these periods reflected, for the most part, the natural, late summer die-back of *Zostera* and *Ruppia*. Reductions in coverage on the imagery of between 40 to 83 percent were recorded. The densest areas of vegetation on the summer imagery were those most evident on the winter imagery. In addition, those areas which were observed to have the sparsest coverage (i.e. <40%) during the summer were not able to be observed during the winter flights. This does not mean that in these sparse areas there was no vegetation in the winter, but they were reduced to levels too low to provide an image on the aerial photography at the altitude flown.

The distribution of SAV (*Ruppia* and *Zostera*) in the last 40 years was delineated by changes in grass bed coverage in six selected areas. Mumfort Island and Jenkins Neck in the York, the East River in the Mobjack Bay, Parrott Island in the Rappahannock River, Fleets Bay and Vaucluse Shores at the mouth of Hungar's Creek on the Bayside of the Eastern Shore all showed a very reduced coverage in the late 1930's. This coincided with a period when *Zostera* had also declined along the entire East Coast of the U.S. The period between 1937 and 1953 showed a dramatic increase in areal coverage at all sites as well as increase in bed densities. The increase continued through the 1960's and in some areas until 1971 or 1972. Slight decreases were occasionally observed during this period at Mumfort Island, Jenkins Neck and Parrott Island. The largest loss of SAV occurred between 1971 and 1974, but especially in 1973. Both areal coverage and the density of the beds in all these areas, except the Eastern Shore site, showed a significant decrease. This decrease continued through 1978 when the distribution and abundance of SAV in each area was the smallest observed over the last 40 years.

In reviewing the past and present data, the distribution and abundance of SAV in the six selected areas in 1973 appeared very similar to the data collected for 1937-1938. This suggests that whatever factor or factors caused the major decline of the grass beds in the 1930's may also have been operating in the 1970's.

The dynamic nature found in certain grass beds was illustrated in the aerial photography by the dramatic changes in the distribution of the SAV at the Vaucluse Shores site. The grass bed alterations in this area were apparently due to the dynamics of the sandbars and sandpits found in this region. Both features had migrated and altered the contour of the shallows. Accompanying the changes in bar and spit formation were changes in grass bed distribution. As the bars and spits moved, certain habitats became unsuitable for SAV survival while other areas became more suitable with net migration of SAV into them. Evidence for this was confirmed by cores taken in the sand bar region adjacent to grass beds. Samples taken to depths of 1 meter contained remnants of eelgrass rhizomes at the core bottoms. These rhizome fragments were found closer to the surface as the existing grass bed was approached. In the northern section of the bed the area appeared to be shoaling. The habitat therefore had become more suitable for Ruppia than Zostera. General observations of sections of this northern part made between 1976 and 1978, indicated changes in species composition from Zostera to Ruppia. In addition, sediment cores taken in these predominantly Ruppia areas indicate dense Zostera rhizomes in close proximity to the sediment surface, confirming that Zostera was recently present. Thus, it appears that geological processes such as sediment transport are very important determinants in SAV distribution here.

Surface information was collected by field checking numerous sites along the lower Bay for species composition. More complete species composition distribution and percent cover data were analyzed in six vegetated areas (Mobjack Bay-Browns Bay, Ware Neck, and the mouth of the East River; Chesapeake Bay-Plum Tree Island and Horn Harbor; Bayside, Eastern Shore-Vaucluse Shores) of the lower Bay using a transect method. Seventeen transects conducted across these six areas revealed a co-dominance by two species, Zostera marina and Ruppia maritima. In general, Ruppia was found dominant in the shallow, more protected areas (+1 to -4 dm relative to MLW) with Zostera and Ruppia co-occurring at intermediate depths (-4 to -8 dm) and Zostera predominantly at deeper depths (-8 to -12 dm).

Bottom types found at the 17 transects varied from silts to coarse sands with the fine sand being the most common designation. Another bottom type not observed in the transects but found in a few SAV beds around the lower Bay was of relic oyster bars covered with a fine layer of silty-sand. Variations in bottom types did not appear to be directly related to speciation within the beds as both species were associated with each of the sediment types.

SECTION 1

INTRODUCTION

The shallow coastal regions of estuaries, bays, and rivers represent extremely important areas in coastal zone productivity. Their importance lies in the fact that these shallow zones are normally colonized by vast expanses of wetlands and submerged aquatic vegetation (SAV).

SAV systems serve multiple, functional roles in coastal ecosystems (Wood, et al., 1969; Thayer, et al., 1975; Stevenson and Confer, 1978). They superimpose a structural component on an otherwise bare sand or mud bottom. This structure serves as a habitat for many small sessile and slow moving invertebrate species such that the density and diversity of invertebrate species found in the sediments surrounding the leaves are significantly higher than adjacent, unvegetated areas (Marsh, 1973, 1976; Orth, 1977). There is also a much higher density of the more motile, macroinvertebrate species such as shrimp and crabs in vegetated areas compared with unvegetated areas (Heck and Orth, in press). In addition to the habitat function, SAV areas function as refuges for these same motile species by providing a source of protection from predators. The effectiveness of this refuge is apparently directly related to the density of vegetation (Heck and Orth, in press). The blades of SAV support a diverse and sometimes very dense epiphytic growth which is a source of food for herbivores and thus contributes to the overall high productivity of the system.

The combined primary productivity of the plant and associated algal components rivals that of many of the world's cultivated crops (Thayer, et al., 1975). There are also complex nutrient interactions occurring. For example, the individual plants have been shown to act as a "nutrient pump" moving nutrients from the sediment to the water column and vice versa (McRoy and Barsdate, 1970; McRoy and McMillan, 1977) with additional uptake of released nutrients by the attached epiphytes (McRoy and Goering, 1974). The leaves and roots of SAV are also capable of binding sediments and baffling currents, thereby stabilizing the bottom and preventing erosion and loss of sediment. Finally this overall importance of SAV does not end with the living plant. Detritus derived from SAV serves as a contributor to the detritus food chain, an attribute very important to the coastal areas.

Within the Chesapeake Bay, there are extensive shoal areas that are heavily vegetated with submerged aquatic vegetation. The Bay with its salinity regime spanning a range of 0 to 25°/oo is represented by a variety of different SAV community types (Stevenson and Confer, 1978). The polyhaline and mesohaline areas are dominated by eelgrass, Zostera marina and widgeon grass, Ruppia maritima, while in the oligohaline and fresh water regions, there are approximately 20 species of SAV which include redhead grass, Potamogenton perfoliatus; sago pondweed, Potamogenton pectinatus; wild celery, Vallisneria americania; horned pondweed, Zannichellia palustris. Historically, emphasis on Chesapeake Bay SAV has been directed to its importance as a food for waterfowl. However, with the decline of SAV throughout the Bay in the early 1970's (Stevenson and Confer, 1978), the importance of SAV for primary production, nutrient cycling, prey refuge, contribution to food webs and sediment dynamics is now becoming apparent. It may be that the SAV systems constitute one of the most scientifically as well as aesthetically interesting areas in the Bay.

Because of man's ever increasing use and abuse of the coastal zone, it is becoming apparent that those systems which are important to the ecological well-being of the Bay must be properly managed. Management of the SAV resource must not only recognize the importance of the resource as outlined above but also where the resource is located and its abundance, as well as the dynamics of the system in both space and time. Thus the overall objective of this study was to delineate the distribution of SAV communities and to assist in understanding the dynamics of these systems from an historical perspective.

The accurate delineation of communities of submerged aquatic vegetation for the purpose of mapping their distribution and abundance can be exceedingly difficult, if not impossible. These communities are not static but represent dynamic elements whose distribution and abundance can vary both in space and time. Distinct differences in SAV beds can be observed in time frames of less than six months. Remote sensing techniques offer distinct advantages for this type of analysis of SAV communities. The main advantage of aerial photography is its presentation of a synoptic view of an entire bed and the adjacent areas. Aerial photography offers a permanent record of the grass area which can aid in depicting historical changes in grass bed formation. This could also aid in identification of grass bed alterations due to land use changes. Aerial photography is a relatively inexpensive method of inventory as compared to intensive field survey work, and the final product can provide an accurate map of the entire distribution of SAV in an area. Grass bed anomalies are observable on aerial photographs, e.g. sand bar and sand spit formations, halos (Orth and Gordon, 1975; Davis and Brinson, 1976; Orth, 1979) which may not otherwise be visible from the water surface. This synoptic overview allows the researcher to minimize his time in the field spent searching for anomalous areas, etc. by pinpointing areas of interest on the photography.

Aerial photography has been used successfully around the world for mapping many different SAV community types and examining associated environmental problems (Edwards and Brown, 1960; Lukens, 1968; Kelly, 1969a, b; Kelly and Conrod, 1969; Wile, 1973; Harwood, et al., 1974; Orth and Gordon, 1975; Pooni, et al., 1975; Davis and Brinson, 1976; Orth 1976; Steffensen and McGregor, 1976; Good, et al., 1978). These efforts which have been conducted under a variety of environmental conditions suggests that remote sensing techniques are the most efficient and cost effective methods for understanding the dynamics of SAV.

OBJECTIVES

The primary objectives of this study are as follows:

1. To accurately map the distribution of eelgrass, Zostera marina (and widgeon grass, Ruppia maritima where it co-occurs with Zostera) in the saline portions of the lower Chesapeake Bay using remote sensing techniques and appropriate surface information.

2. To map the distribution and abundance of SAV in selected areas of the fresh and oligohaline waters of the lower Chesapeake Bay's tributaries.

3. To delineate the different SAV species and their distributional patterns in the lower Chesapeake Bay and its tributaries.

4. To determine the extent of SAV recovery or losses from selected mesohaline areas based on historical SAV data (e.g. historical aerial photographs and previous vegetation surveys).

SECTION 2

CONCLUSIONS

The mapping of SAV beds in Virginia was accomplished using a Fairchild CA-8 cartographic camera with a 152 mm (6½ inch) focal length lens. The camera was mounted in the belly of a single-engine, fixed high wing DeHavilland Beaver aircraft and flown at altitudes of 2740 m to 3660 m. Film type of Kodak 24 cm (9½ inch) square positive transparency Aerochrome MS, type 2448, provided excellent imagery for delineating most SAV beds which occurred at densities ranging from <1 plant per m^2 to over 1000 plants per m^2. Quality assurance guidelines addressing tidal stage, plant growth, sun elevation, water transparency, atmospheric transparency, turbidity, wind, sensor operation and plotting were found necessary to achieve maximum delineation of the SAV beds.

A total of over 84,000 hectares of SAV were located, mapped and outlined onto 27 topographic quadrangles located in the saline portions of Virginia's section of the Chesapeake Bay. Two species, Zostera marina and Ruppia maritima, were found to be the dominant vegetation in this region. However, speciation within the beds was not possible at the altitudes flown. The largest concentrations of these species were found at the mouths of the large rivers and creeks and along the Chesapeake Bay shoreline. The most significant areas were: 1. along the western shore of the Bay between Back River and the York River; 2. around the shoreline of Mobjack Bay; 3. throughout the shoal areas east of Tangier and Great Fox Islands; 4. behind large protective sand bars near Hunger's Creek and Cherrystone Creek along the Bay's eastern shoreline. Comparisons of imagery obtained during the summer and early winter periods reflected the natural, late summer die-back of Zostera and Ruppia. Only the densest areas of vegetation on the summer imagery were generally evident on the winter imagery with reductions in coverage for two areas ranging from 40 to 83%.

Mapping of SAV located within four selected topographic quadrangles along Virginia's freshwater and oligohaline regions, revealed 137 hectares of submerged vegetation. These areas contained a large number of species such as: Vallisneria, Zannichellia, Ceratophyllum, Najas, Potamogeton. In general, the SAV in these areas were primarily small, fringing grass beds whose imagery was difficult to observe from the air at the altitudes flown in this study.

A field survey made along the shorelines of the lower Chesapeake Bay and its tributaries revealed twenty SAV species comprising three associations. These species appeared to be distributed throughout the estuary based primarily upon the species' salinity tolerances. Ceratophyllum and other species were found along the freshwater areas of

Virginia's rivers. Areas of low salinities were vegetated with *Zannichellia*, *Potamogeton*, etc. while the areas of highest salinities, primarily along the Bay shoreline, were dominated by *Zostera* and *Ruppia*. Species richness was inversely related to the apparent salinities, with the low salinity areas having the greatest number of species and the high salinity areas the fewest.

Transects conducted across six vegetated areas found Virginia's Chesapeake Bay shoreline revealed a co-dominance by two species, *Zostera* and *Ruppia*. Distribution within these beds appeared to be a function of two factors, site exposure and water depth. *Ruppia* was dominant in the shallow, more protected areas while *Zostera* was more abundant in the deeper more exposed sites.

Analysis of the historical distribution of SAV throughout the lower Bay over the last 40 years revealed relatively low levels of SAV in 1937. This situation reflected the documented demise of *Zostera* in the early 1930's. From 1937 to 1950 the coverage by SAV increased significantly with continued increased coverage observed until the 1960's. High levels of SAV in 1971 were followed by a precipitous decline between 1973 and 1974. This decline continued until 1978 when, apparently, the lowest levels in SAV over the last 40 years were recorded. Areas of greatest recent decline were observed in the lower portions of the major rivers where in 1978 little significant SAV existed. The western portion of Virginia's Chesapeake Bay shoreline north of the York River also experienced a considerable reduction in coverage.

SECTION 3

RECOMMENDATIONS

1. Because SAV communities in the lower Bay are not static but dynamic systems that undergo both seasonal as well as annual changes in abundance, it is felt that imagery should be obtained over the next few years on an annual basis depicting maximum standing crop of all SAV areas. This would be of significant value because: 1. Interest in the status of Bay SAV communities by the general public as well as state and Federal agencies is currently very high; 2. SAV communities are at a very low coverage compared to past years, and up to date information is needed to document any continuing decline or rate of recovery; and 3. EPA's current funding of other SAV research programs will provide results that could be correlated with this distribution and abundance data. Obtaining imagery on an annual basis would provide those data necessary for deciding whether monitoring should be continued on an annual, biennial or less frequent basis. The costs to simply acquire the imagery for Virginia's portion of the Bay would be minimal, and the imagery thus obtained would be available for use by the many agencies concerned with managing this valuable resource.

2. It is important to stress that any imagery obtained for mapping SAV communities be acquired under the constraints of tidal height, sun angle, wind conditions, etc. that have been outlined by EPA for this current project. Attempts to coordinate the acquisition of SAV imagery with other programs requiring aerial photography, such as land use planning, that do not require similar constraints should consider these conditions or will most likely result in aerial photography unsuitable for accurate delineation of SAV communities.

3. It is recommended that altitudes of 3740 m be used for the acquisition of the imagery of SAV communities with a mapping camera. This results in a scale which allows a direct comparison to the standard topographic quadrangle (1:24,000). It also allows complete mapping of most SAV areas except for those minute areas in the freshwater and oligohaline systems where SAV beds are found fringing the marshes. Species determination at this altitude is difficult-if not impossible, and therefore not advised. Lower altitudes (1000 m) may yield the species information, and if necessary, studies could be directed along this avenue of research.

In addition, it is recommended that because of the extensive die-back of SAV throughout the lower Bay during winter months only one mapping flight be made per year. This preferably should be made during the early summer to record maximum standing crop of the vegetation.

4. The oligohaline and freshwater portions of selected areas along Virginia's tidal rivers have been shown in this study to contain scattered small beds of SAV that in many cases are not evident on high altitude aerial photography. It is recommended that future field study be conducted in these regions to provide understanding of their distribution, abundance, and resource values.

SECTION 4

MATERIALS AND METHODS

PRELIMINARY AERIAL SURVEYS

To facilitate the planned large scale mapping of submerged aquatic vegetation in Virginia's portion of the Chesapeake Bay and its tributaries, preliminary aerial surveys were made of these areas in early June, 1978. The flights provided an overview of where current beds of SAV exist and located specific areas for intensive surface measurements. Overflights were made using a single engine Dehavilland Beaver Aircraft at altitudes ranging from 300 to 200 m. They were conducted at times when weather and tide conditions allowed for maximum viewing of SAV beds: low tide, minimal cloud cover, and reduced wind conditions.

Prior to these preliminary overflights, available information on the distribution of SAV beds in Virginia was reviewed. Previously known bed outlines (Orth and Gordon, 1975) were drawn on 1:80,000 maps which were then carried inflight and additions or deletions were made as necessary to determine a preliminary qualitative identification of existing SAV coverage. This information was then used to prepare flight lines for the aerial mapping, to assist in delineating areas for transect analysis and for historical review of changes in SAV distribution.

MAPPING OF SUBMERGED AQUATIC VEGETATION

The method of mapping submerged aquatic vegetation is graphically depicted in Figure 1. The method consists of acquiring photography, transferring the SAV perimeter information from the photography to maps, measuring individual SAV bed areas, and compiling the data into a computer data base. Each component of the procedure is more fully described below.

Aerial Photography

The first phase of the aerial photography effort was the planning of flight lines for complete coverage of all anticipated areas of SAV in the Virginia portion of the Chesapeake Bay. Preliminary aerial surveys for visual observations only were conducted as described above. Flight lines for photography were then planned for coverage of all areas where SAVs were seen during the aerial surveys or known from prior study. Flight lines were drawn on 1:250,000 scale USGS topographic sheets, 2^{o} by 1^{o} series, using a transparent frame-size overlay for coverage at a minimum altitude of 2740 m (9,000 feet). Flight lines were situated to ensure both complete

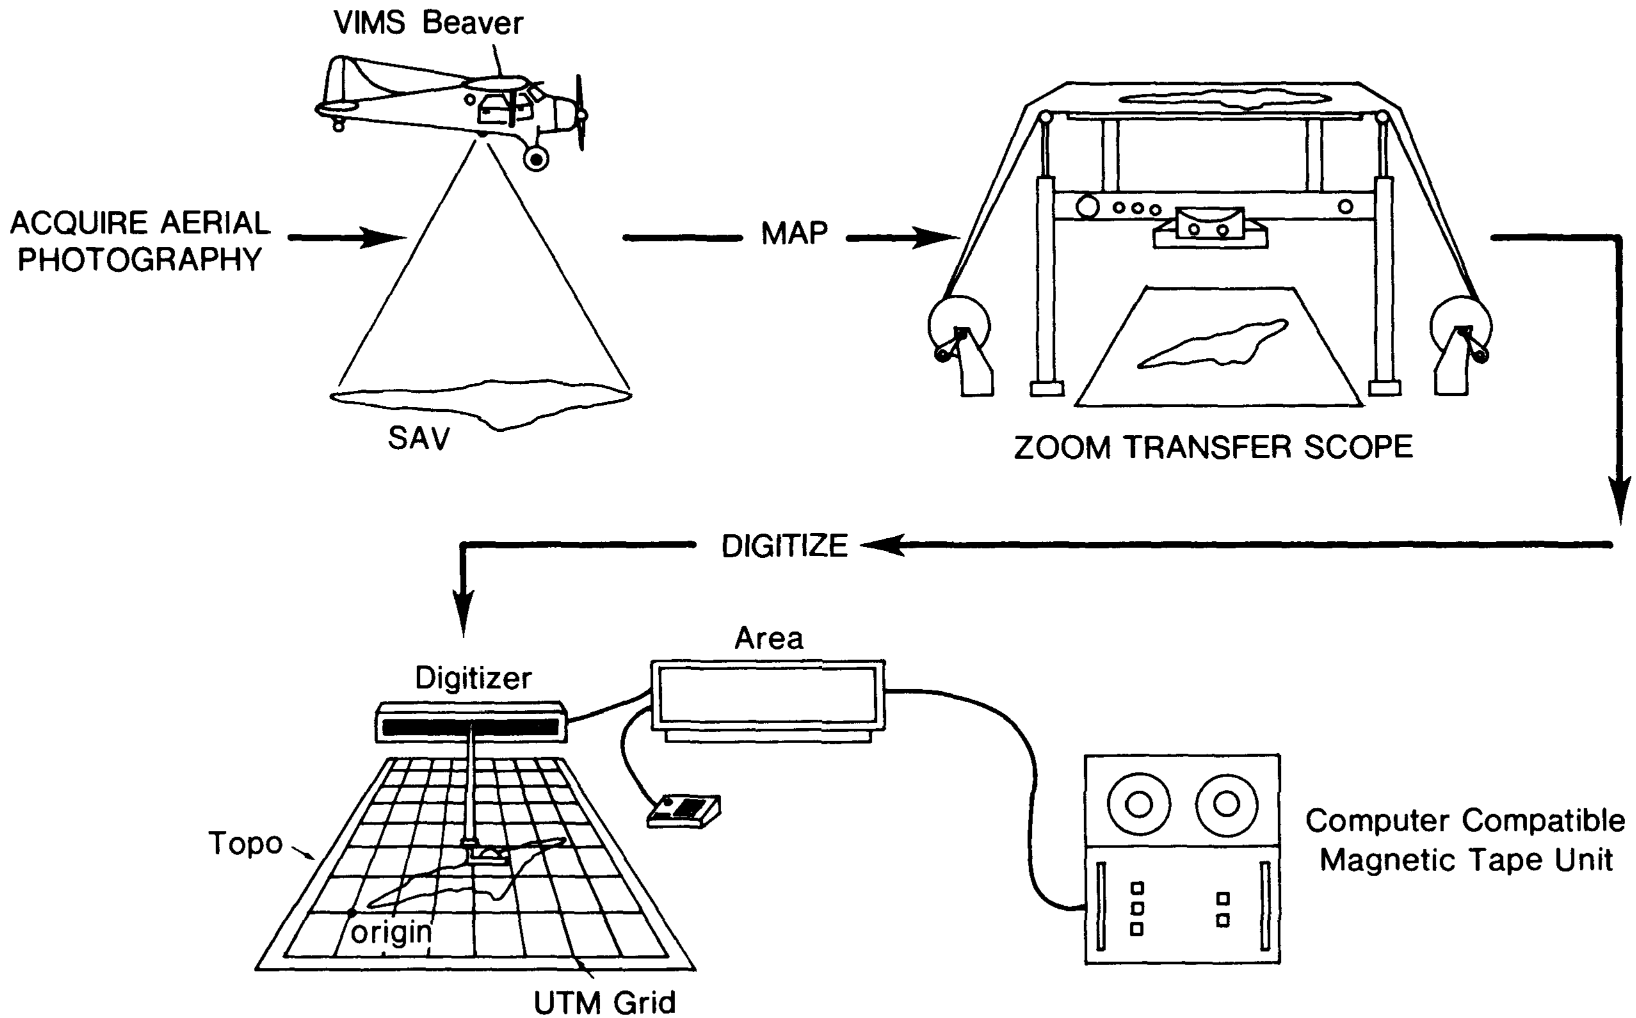

Figure 1. Transfer of SAV distribution information from photography to computer tape.

bed coverage and inclusion of land features as control points for mapping accuracy. Lines were also oriented to facilitate ease of flying where possible. Flight direction was oriented such that the overall mission would progress in the same direction as the tide propagation to ensure photography at the lowest possible tidal stage.

The general guidelines used for mission planning and execution were developed by EPA (Appendix A). These quality assurance guidelines address tidal stage, plant growth, sun elevation, water transparency and atmospheric transparency, turbidity, wind, sensor operation, and plotting. Although it was the overall intent to plan for optimum conditions in all items, some are necessarily more important than others and an order of priorities was established to guide mission planning.

The most critical of those items listed is plant growth stage. At the wrong time of year, it would be possible to fly an otherwise ideal mission and record no (or little) SAV. For the predominant species of grass in the southern Chesapeake Bay, early summer offers the best chance of recording maximum plant coverage. To ensure the most complete distribution information and to record seasonality, the entire area was photographed twice during 1978, once in the summer and once in the early winter.

The next most important condition is water transparency, which is itself a function of wind, tide, and turbidity (often related to weather during the previous 12 hours). Atmospheric transparency is important since a high sunlight-to-skylight ratio yields the best SAV-bottom contrast. Sun elevation is also a consideration since at high elevations (sun too high in the sky) sun glint will appear in a portion of the frame, masking the grass or other features used for mapping. This effect is minimized, however, by the proper choice of frame overlap and flight line sidelap. Sun elevations were kept between 25^{o} to 45^{o}.

The choice of flight altitude is generally a trade-off between areas covered by a frame and spatial resolution of the objects of interest. In previous SAV mapping reported in Orth and Gordon (1975) and in special film-filter-altitude experiments, it was found that a scale of 1:30,000 provided sufficient resolution to identify dense 1-meter patches of grass. The maximum operational altitude for the aircraft used in this operation is 3660 m (12,000 feet). This altitude and a standard mapping camera with a 152 mm (6-inch) focal length lens yields imagery with a scale of 1:24,000. Flights were made at altitudes as low as 2740 m (9,000 feet) to a scale of 1:18,000 when atmospheric conditions dictated.

Aircraft scheduling was done in advance around windows in the morning and afternoon (2 to 3 hours) near low tide for specific regions in Chesapeake Bay. NOAA tide tables were used for prediction of tidal stage throughout the Bay, and a table of suggested flight windows was made for a one to two-month period. For flights during the summer, the times from 1100 to 1300 EDT were generally avoided to minimize sun glint problems. The actual decision to fly on a particular day was made in the early morning, based on forecasts of regional weather systems, previous local weather (24 hours), and most important, current conditions. Because of weather variation, it was generally not possible to pick an "ideal" day for aerial photography in advance.

The camera used for all aerial photography of SAV was a Fairchile CA-8 cartographic camera with a 152 mm (6½-inch) focal length Bausch and Lomb Metrogon lens. Film was Kodak 24 cm (9½-inch) square positive transparency Aerochrome MS, type 2448, loaded into magazines in advance. The camera was mounted in a camera port in the belly of the VIMS single-engine, fixed high wind DeHavilland Beaver aircraft. The aircraft provides a stable platform for vertical aerial photography from 300 to 3700 m altitude (1,000 to 12,000 feet).

The camera was checked for vertical orientation before each exposure, using two-axis levelling. Exposures were timed to insure 60 to 65% forward lap (standard frame spacing), and times were adjusted according to flight line direction in relation to winds aloft. Where adjacent parallel lines were flown, 30% sidelap was planned to insure mapable quality contiguous coverage. A Wratten 1A haze filter was used inside the cone of the camera to reduce the degrading effect of atmospheric haze on image quality.

Personnel on the aircraft during a mission included a pilot, navigator, and a camera operator. While in the air, the navigator recorded notes as to atmospheric conditions, flight line number, altitude, heading, frame count, camera setting, and any unusual observations on cassette tape with a portable battery-operated recorder. The navigator signaled line start and line stop and watched for flight line drift (making suggested corrections to the pilot) during photography. The navigator was also experienced in the recognition of SAV areas and modified flight lines or added more lines during the mission to ensure better or more complete coverage.

Color film was chosen for this project since it offers adequate information for delineating SAV beds and a great amount of general information for use in other projects by EPA, VIMS and other agencies. When not used in the aircraft, film was kept refrigerated. Following exposure the 38 m rolls were flown to the EPA-EPIC facility for immediate processing in a continuous roll Kodak 1411 processor. Each roll contained some test exposures to permit selection of optimum transport speed and temperature during processing. A duplicate copy was made for data extraction while the original was retained (after screening) for archival purposes by EPIC. Film was generally returned to VIMS the same day as processed. At the VIMS Remote Sensing Center, the film was carefully reviewed for quality and adequacy of coverage and entered into the Center's photo-index system. Cassette photo-logs were transcribed to typed hard-copy and checked against the film. Based on this information, areas were selected for recoverage where sun glint or other problems dictated.

Mapping Process

Before mapping the film was reviewed by a photointerpretor and a biologist to select individual frames for best SAV coverage. The SAV beds were identified using all available information, including knowledge of aquatic grass signatures on the film, areas of grass coverage from previous flights, ground information, and aerial visual surveys. In areas where the SAV/bottom contrast was poor, the grass boundary was delineated using a fine point pencil on transparent tape placed on the film. This was done to aid in transferring the imagery on the film to the topographic quadrangles using the Zoom Transfer Scope. Extreme care was exercised to ensure the tape was put on the non-emulsion side of the film in a manner which will allow it to be easily removed at a later time. An estimate of percent cover within each seagrass bed was made visually in comparison with an enlarged Crown Density Scale similar to those developed for estimates of forest tree crown cover from aerial photography (Figure 2). Bed density was classified into one of four categories based on an objective comparison with the density scale. These were: 1. very sparce, (<10%); 2. sparce (10 to 40%); 3. moderate (40 to 70%); or 4. dense (70 to 100%). Either the entire bed, or sub-sections within the bed, were assigned a number (1 to 4) corresponding to the above density categories.

A Bausch and Lomb Zoom Transfer Scope, model ZT-4H, was used to trace the delineated SAV bed boundaries from the aerial photography to base maps of 1:24,000 scale USGS paper topographic (7½-minute series) quadrangles. The Zoom Transfer Scope enables the operator to view the photograph and the map simultaneously, adjust scale, rotate, and translate one in relation to the other optically, and draw the bed outlines and grass density information directly onto the base map. Non-changing features common to the imagery and the topographic quadrangle, such as road intersections, houses, creeks, ets., were used for alignment and scaling purposes. After transfer of the bed outlines onto the base maps the maps were reviewed with the aerial photography to insure accurate coverage. The original paper topographic quadrangles have been filed at VIMS for future reference. Translucent mylar stable-base topographic quadrangles were placed over the original base maps, and SAV bed outlines and density information were transferred with black ink. These maps were then photo-reduced and are included in Appendix B of this report. The full-size mylar quadrangles have been filed with EPA.

Area Measurement

Areas of SAV beds were derived from the 1:24,000 scale topographic quadrangles. Measurements were made on a Numonics Graphics Calculator, model 1224. The unit has a resolution in x and y of 0.25 mm and has registers for scaling and unit conversion so that areas can be read out in any units desired at map scale. Accuracy, determined by repetitive measurement of test areas, is better than 2%. Precision (standard deviation divided by the mean) ranges from approximately 2% at 16 mm^2 (10,000 m^2 at a scale = 1:24,000) to well under 1% at 160 mm^2 (100,000 m^2) with an overall average of 1.4%. Areas on each topographic quadrangle were summed and tabulated (Table 2).

Data Base

To enable computer retrieval of areal resource information and comparison of different aspects of one or more resources over time, a data base structure has been created. All the information from the 1978 SAV mapping effort has been entered into this data base. The geographical coordinate

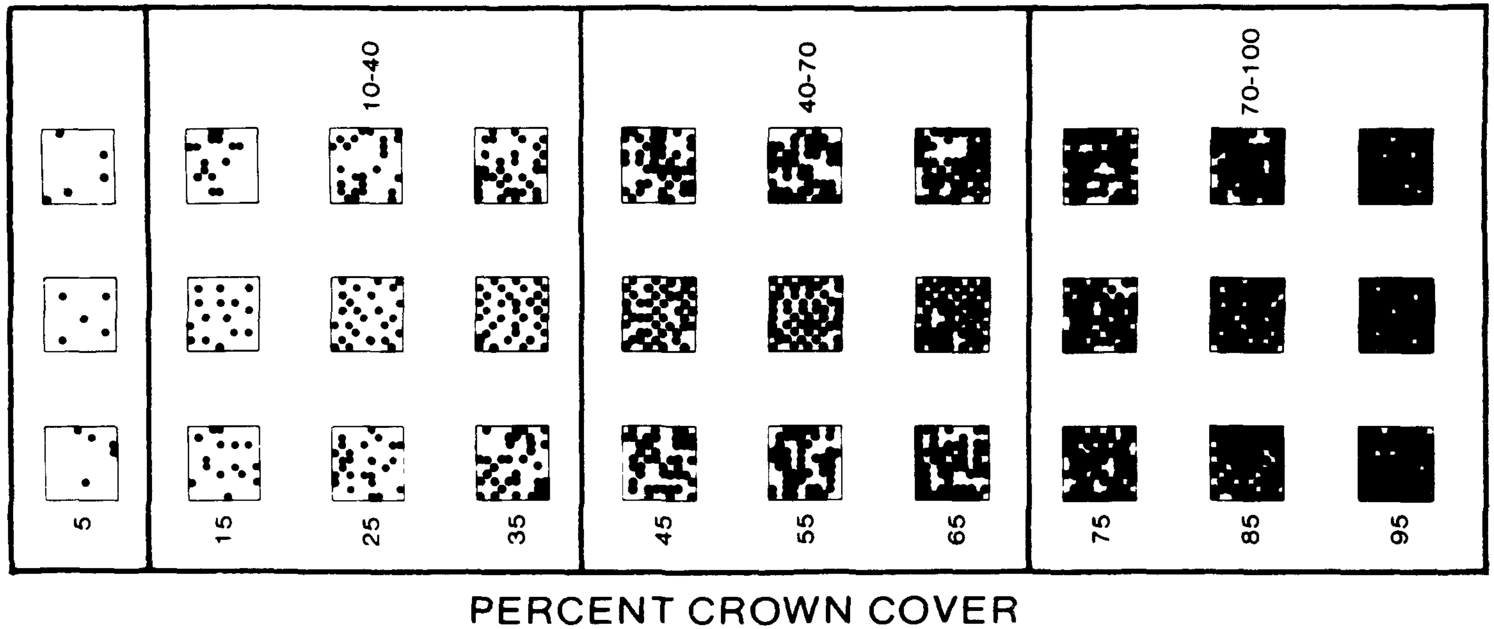

Figure 2. Crown density scale used to estimate SAV percent cover.

system for the data base is the Universal Transverse Mercator coordinate system (UTM). It is anticipated that other information summarizing areal resources, such as oyster bar areas and marsh distribution, could easily be entered into the data base.

The grid base for the areal data is the 1,000 m square defined by UTM easting and northing (x and y) coordinates found along the edge of each 7½-minute topographic sheet (the base map for this SAV study). In order to enter any areal data into the data base, the outline of the resource is drawn on a topographic map, as has already been done in this study for 1978 SAV beds. A clear grid containing 1,000 m lines drawn at a 1:24,000 scale is then placed over the base map and aligned with the 1,000 m UTM grid marks. The two are then taped to the Graphics Calculator table, and the areal data is transferred grid-square by grid-square to computer compatible magnetic tape (CCT using both the digitizing and area measurement functions of the Calculator. The lower section of Figure 1 illustrates this step.

The Graphics Calculator contains an integral microprocessor which controls the format of information sent to the CCT. For each topographic sheet a master header is used consisting of the topographic sheet quadrangle name, the Virginia alphanumeric index, date of the survey, and the UTM coordinates of the origin of the digitizer (Graphics Calculator) coordinate system. The digitizer x-axis is always electronically aligned with the UTM easting axis. For each 1,000 m grid square there is a 7-field data block sent to tape with the following information:

field 1 = UTM coordinates divided by 100,000 m (2 digits - x, 2 digits - y),

field 2 = UTM coordinates for the lower left corner of the 1,000-meter square (2 digits - x, 2 digits - y),

field 3 = topographic alphanumeric index,

field 4 = waterway code,

field 5 = resource code,

field 6 = resource area within 1,000 m square, and

field 7 = x, y coordinates in mm of the perimeter of the resource for replotting the boundary.

Field 1 generally remains the same throughout a topographic quadrangle (unless field 2 approaches 99 in x or y). Field 3 is the same alphanumeric topographic quadrangle index as entered in the master header. Field 4 is a 5-digit code for a particular bay, river, or creek within the Chesapeake Bay estuary as used by the United States Corps of Engineers, Norfolk District, and the State of Virginia. Field 5 is a 5-digit code to describe the resource being digitized. The first digit is the resource type. S for SAV is the only type considered thus far. The second digit is the season of data acquisition (a number from 1 to 4 for each 3-month quarter). The third digit is the salinity regime (1-saline, 2-brackish, 3-fresh, 4-euhaline >24°/oo, 5-polyhaline 18 to 24°/oo, 6-mesohaline 5 to 18°/oo, 7-oligohaline .5 to 5°/oo). The last two digits indicate the species, community type, or other classification to define the resource. Fields 2, 6, and 7 change for each 1,000 m grid square. Fields 3, 4, and 5 are changed when necessary.

An example of the data base for SAV beds is shown in Figure 3 and Table 1. Figure 3 illustrates the outline of a grass bed with the 1,000 m grid overlay in place. Several of the grid crossings have been numbered (e.g. 68,72 corresponds to 68,000 m E, 72,000 m N). Information from the shaded area would be put into the data base as shown in Table 1.

No computer programs to access the data base have been written at present. The information in the data base, however, has been structured for ease of information retrieval, and simple programs could be written in minimal time to access all of the information using fields 1 through 5 as search keys. In addition, the area perimeter has been digitized and the x - y coordinates stored so that partial or complete resource boundaries could be plotted either on a television type computer terminal or simple x - y plotter. The computer tape (CCT) containing the data from the 1978 SAV mapping effort is on file in the VIMS computer center and is available upon request.

It is anticipated that SAV information in this format will be of great utility to managers, decision makers, scientists and others, all of whom may need current and historical SAV resource information in a concise, quickly accessed form.

FIELD SURVEYS

The distribution of SAV in Virginia can be divided into at least two distinct zones: *Zostera* and *Ruppia* forming large beds in the polyhaline (18-24°/oo) and mesohaline areas (5-18°/oo), and *Vallisneria*, *Potamogetons*, *Zannichellia*, etc. comprising lesser but generally undetermined amounts in the oligohaline (0.5-5°/oo) and freshwater areas (<0.5°/o). Because of this, several approaches were used to gather surface information to assist the aerial photography in zone delineation.

At locations within the oligohaline and freshwater zones (in Virginia these fall wholly within the tidal rivers) where the preliminary overflights revealed observable beds of SAV, field checks were made by use of small boats to determine species present, relative abundance and habitat type (Figure 4). In addition, these areas were mapped using remote sensing techniques described in the preceeding section and the results displayed on USGS topographic quadrangles (7.5 minute series).

In the mesohaline and polyhaline zones (comprising Virginia's portion of the Bay proper and the lower sections of its major tributaries) a similar survey was undertaken (Figure 4). In this region the beds are generally large, well defined, and under appropriate conditions easily seen from the

DISTRIBUTION OF SUBMERGED AQUATIC VEGETATION IN VIRGINIA

air. It is this zone that has been the major focus of aerial mapping effort by this study.

Other selected areas where submerged vegetation was not evident from the air were also field checked to determine if SAV were indeed present (Figure 4). An attempt was made to investigate several areas along the salinity gradient in each of the major tributaries, since it is known that salinity is one of the main factors controlling species distribution throughout the Bay (Stevenson and Confer, 1978). Segments of shoreline along both the major rivers and creeks were surveyed by use of a small boat and samples obtained with a rake or collected by hand. The procedure involved slowly moving along the littoral zone and simply observing the water for signs of SAV presence or repeatedly raking the bottom in the most turbid areas for evidence of SAV. A 0.5 m periscope was used on occasion to view below the water surface. In those creek systems surveyed, an attempt was made to go upstream as far as possible into the head of the numerous marsh guts which are common throughout these areas. Personnel from the VIMS' Wetlands Department assisted in this survey while simultaneously conducting their state marsh inventory.

Locations of SAV were recorded on USGS topographic quadrangles (7.5 minute series; 1:24,000 scale). Areas of SAV were designated as mapping units. A mapping unit consisted of one of the following: a large bed; a narrow or intermittent fringe along a shoreline; a pocket area at the head of a marsh gut. For each mapping unit, species presence and relative abundance of each species were recorded. General observations on habitat were also made including the associated marsh vegetation. Representative samples were collected and returned to the laboratory for further species identification according to Gray's Manual of Botony, 8th Edition. Voucher specimens were pressed and mounted for herbarium storage.

To display species associations between mapping units, Dice's (Boesch, 1977) index of co-occurrence was calculated. Cluster analysis was performed using group average sorting (Lance and Williams, 1967) with the COMPAH Program (Boesch, 1977) on an IBM 370-15 computer. Dendograms were then constructed to distinguish significant groupings of SAV species.

TRANSECT ANALYSIS

In addition to the above field survey, the distribution of species within selected, large SAV beds in the mesohaline and polyhaline zone were investigated by an intensive, transect sampling program. Six areas along both the eastern and western shore of the lower Chesapeake Bay were selected for analysis after review of both current and historical aerial photography and surface information data. These areas (western shore: Plum Tree Island, Browns Bay in the Mobjack Bay, Ware Neck Point, Mouth of the East River and Horn Harbor; eastern shore: Vaucluse Shores at the mouth of Hungar's Creek) were representative of the dense areas of SAV presently found throughout the lower Bay. The site selected on the eastern shore was the same site selected for intensive study by the Functional Ecology, and Biology and Propagation Programs also funded by the EPA, Chesapeake Bay Program

The objective of the intensive transect analysis was to provide a more detailed examination of the species composition and plant community zones within these representative beds. In addition, other general relationships between species present, sediment type, depth, distance from shore, relative abundance, and relative importance of the species were investigated.

A line intercept method (Schmid, 1965; Lind and Cottam, 1969; Davis and Brinson, 1976) was chosen for conducting the vegetational analysis because of its ease in locating sampling points, accuracy in measuring distances, and sensitivity to measuring changes along a gradient such as depth. In this method, a 100 m line, marked at 2 m intervals, was run offshore from a permanent reference stake, along a fixed compass bearing to a second stake. Additional stakes and line in 100 m segments continued along this bearing to the offshore limits of vegetation.

A diver equipped with a 0.1 m^2 ring and depth pole graduated to mm, visually observed the SAV along the transect. A 0.1 m^2 sample size was chosen because the limited number of species expected, the high density of the vegetation (greater than 1000 shoots per m^2) and poor visibility due to high turbidity (Secchi disk <1 m). At 10 m intervals the sampling ring was placed on the bottom and the following data were recorded on polystyrene tablets: time, distance from shoreline, depth (cm), species presence and percent cover of each species, bottom type, and general observations noted over the last 10 m interval. Initially, two divers made independent observations of the percent cover to test the adequacy of the sampling and provide quality assurance for the data collected. These initial tests established that one diver could accurately describe the species present and species abundance.

A reference tidal staff graduated in mm was placed along the transect at a bottom where the depth was estimated to be greater than mean low water (MLW). Time and water depth (cm) were recorded at this reference stake at 15 minute intervals throughout the duration of the transect sampling. The tidal staff data served to relate data collected during the transect analysis with tidal data available from NOAA tidal charts. From this, the relationship between species presence and abundance could be related to true mean low water.

Salinity samples were taken and temperature measurements made at each transect. Temperature was recorded with a bulb thermometer and salinity samples analyzed with an induction salinometer located at the VIMS laboratory.

Percent cover was used as an indicator of abundance since it allowed a large number of observations to be made while processing of standing crop samples could be held to a minimum. Because of the few species present and the ability of percent cover estimates to delineate community zones (Wikum and Shanholtzer, 1978), it was felt that adequate information would be provided by this method. To determine correlation between percent cover and standing crop, a limited number of samples were taken at 50 m intervals along the Vaucluse Shores transects. After percent cover estimates were made of each of these 0.1 m^2 quadrats, the entire 0.1 m^2 quadrat including above ground and below ground portions of the SAV's were removed from the bottom and placed in a fine mesh bag. The bag was then washed to remove most of the sediment, and the contents transferred to a plastic bag for later analysis.

Harvested samples were divided into species and separated into above ground plant material, and roots and rhizomes. The plants were then counted, dried to a constant weight and weighed to the nearest 0.01 g. Product moment correlations (Sokal and Rohlf, 1969) were calculated between percent cover; number of shoots per 0.1 m^2 ; and above ground, below ground and total weights of each species. Comparisons were also made with the more complete seasonal standing crop data obtained at the Vaucluse Shores site for other projects.

Relative importance of the various plant species within each transect was illustrated by calculating importance values (Wikum and Shanholtzer, 1978) utilizing the percent cover data. Means, ranges and maximum depths of occurrence were also investigated.

Description of vegetation-environmental relationships along the transects was illustrated by the use of profile diagrams. Each profile diagram presents the bottom topography from shore to the offshore limits of plant growth in either a right-left or left-right direction depending upon the appropriate orientation of the SAV beds on a topographic sheet. Percent cover information for each 10 meter observation was presented by use of bargraph so that one can simultaneously visualize species cover, community composition and vegetation-topographic relationships.

Bottom elevations relative to mean low water (MLW) were calculated along each transect by a method of simultaneous comparisons similar to that method described by Boon and Lynch (1972) for the Elizabeth River, Virginia. Basically, the method is a leveling procedure in which the intervening water surface between two tidal stations during the same phase of the tide is assumed to act as a level plane for the transfer to tidal information. In this study, the VIMS tidal station located on the York River, served as a reference for each comparison. For each transect profile, MLW on the adjacent reference staff was calculated by the following based on Figure 5:

Given: h, h_2, h_3

If: $h_1 = h_3$

Then: $MLW = h_2 - h_1$

It is assumed that the sea's surface will not always act as a level plane and therefore increasing the number of comparisons made during periods of similar tidal phases (i.e. high water on low water) would increase the precision of the calculation of MLW for each transect reference staff. Boon and Lynch (1972) found, however, that as long as the compared tidal stations are subject to the same tidal influences, variations in the calculated MLW heights would be minor. They found that results corrected to within 0.1 foot could be obtained when a full month of data was used.

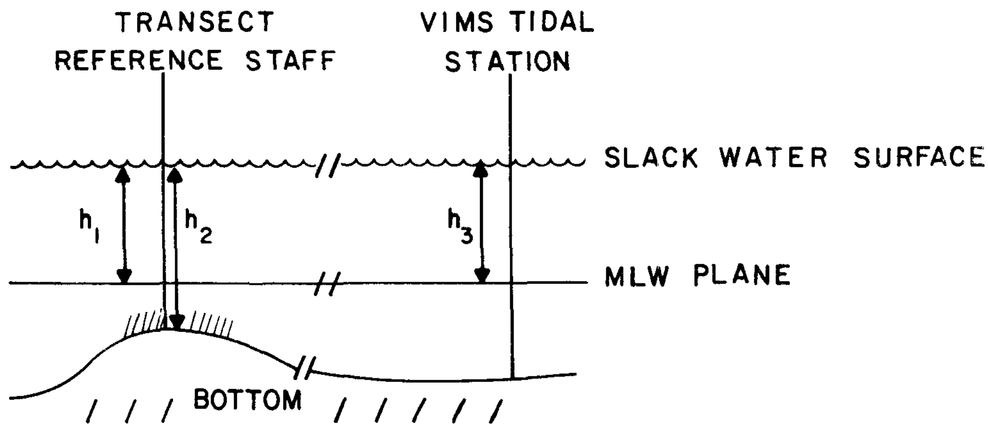

Figure 5. Relationship between transect reference staff and VIMS tidal station.

In this study, only one or two slack water periods were available for comparisons. Therefore, error in calculations of MLW could be greater than 0.1 ft. However, since the transect stations involved in this study are in close proximity to the VIMS station, have slack water periods within one hour of the VIMS station and have approximately the same tidal ranges (NOS Survey, 1978), it is likely, based on Boon and Lynch's work, that the MLW determinations are accurate to within 0.2 ft. or 0.6 diameter (dm). For comparisons between transects therefore, all elevations are rounded to whole dm.

Bottom elevations relative to calculated MLW were determined along each transect by comparisons with the adjacent reference staff as follows:

C	=	B	-	A
Transect point elevation relative to MLW		Transect point water depth at time t		Difference between tidal height on staff at time t and MLW on staff

Refer to Figure 6.

To determine "A" in the above equation the portion of the tidal curve covering time on site at each transect was plotted using the observed 15 minute reference staff tidal heights. An instantaneous tidal height for time (t) was then interpolated from this graph (Figure 7).

For example, if at time t the measured water depth at a sampling point 330 m from shore along a transect was 2.0 m and at the same time t the tidal height at the adjacent reference stake was calculated to be 1.0 m above MLW, then the bottom would lie,

$$-2.0\text{m} + 1.0\text{m} = -1.0\text{m}$$

or, 1.0 m below MLW at the 330 m sampling point.

ANALYSIS OF HISTORICAL SAV DISTRIBUTION

Six areas were examined for changes in the distribution of SAV over approximately the last 40 years (Figure 4): two locations, Guinea Neck and Mumfort Island, the York River; one in Mobjack Bay at the mouth of the East River; one in the Rappahannock River; one on the western shore in Fleets Bay; and one along the eastern shore of the Bay just north of Hungar's Creek. These areas were selected after review of many historical photographs covering Virginia's entire Bay shoreline as well as the lower portions of each of the major tributaries since 1937. They are thought to be representative areas demonstrating the changes in the *Zostera marina* and *Ruppia maritima* dominated SAV beds found throughout this region.

Aerial photographs available through the U.S. Geological Survey, U.S. Department of Agriculture-Soil Conservation Service, National Oceanic and Atmospheric Administration and the Virginia Department of Highways were

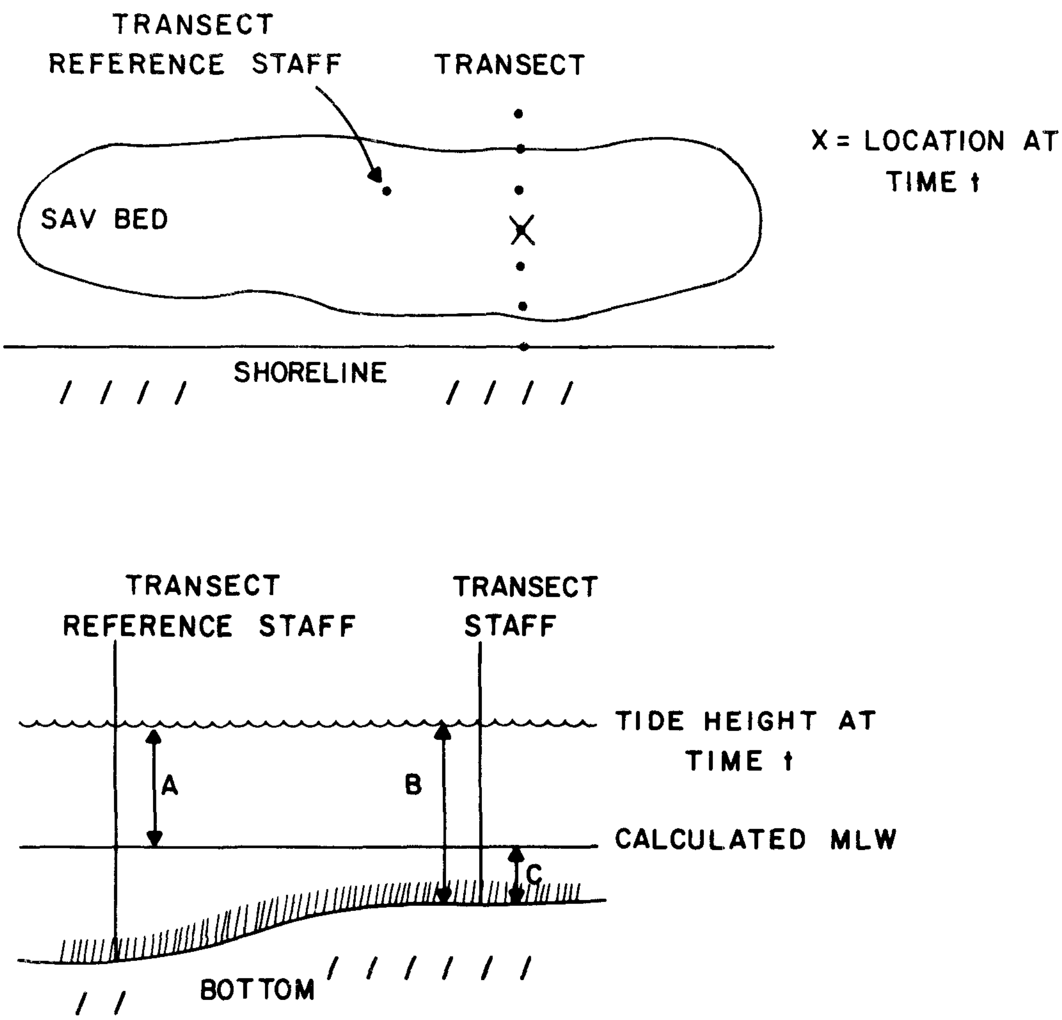

Figure 6. Relationship between transect reference staff and transect staff.

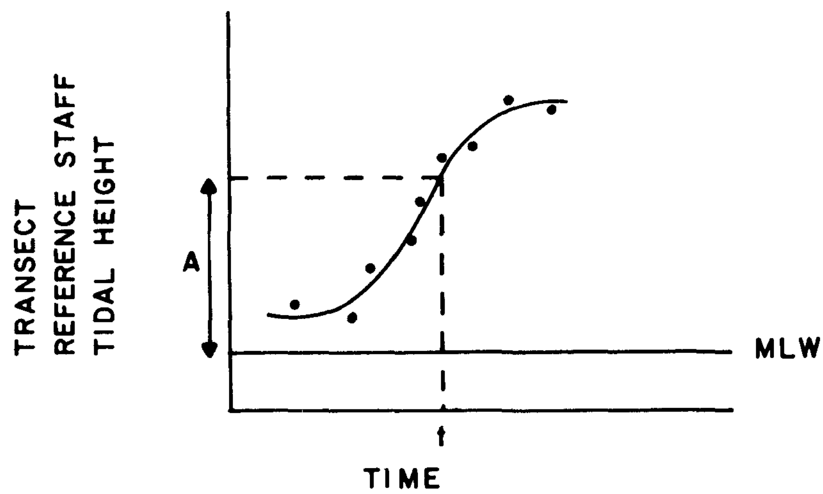

Figure 7. Determination of instantaneous tidal height from calculated tidal curve at time t.

reviewed for scale, completeness of coverage, time of year and apparent water clarity. Because the original photographic overflights were made for purposes other than the mapping of submerged aquatic vegetation, many of the conditions which provide for optimum coverage of SAV were not met. However, good coverage at approximately ten year intervals was obtained.

For the last decade more frequent intervals of coverage were available. Orth and Gordon (1975) had documented the demise of Zostera dominated SAV beds in several areas of Virginia since 1971. Utilizing the aerial photography obtained for that study, each of the selected areas, except for the Eastern shore site, were mapped for SAV coverage in 1974. In addition, the current 1978 coverage is used.

Information from historical photographs documenting the distribution of SAV within each of the six selected areas was transferred to base maps in a manner similar to that employed in mapping the current 22.9 x 22.9 cm (9 x 9 inch), 1978, coverage as previously described. Outlines of the SAV beds were rectified, scale adjusted, and transferred onto United States Geological Survey, 7.5 minute series paper topographic quadrangles using a Bausch and Lomb Zoom Transfer Scope (Model ZT-4H). Estimates of percent cover within each seagrass bed were made using the Crown Density Scale (Figure 2). Bed density was classed as very sparce (<10%), sparce (10-40%), moderate (40-70%) or dense (70-100%). If there were significant differences in density within a bed, these different zones of coverage were also outlined. Areas of SAV coverage within each historical site were measured using a Numonic Graphics Calculator. Areas of each of the four density classifications within each historical site were determined, as well as total area covered by all four categories.

SECTION 5

RESULTS AND DISCUSSION

AERIAL MAPPING

The aerial photography and the subsequent mapping process resulted in the delineation of the significant areas of submerged aquatic vegetation present in Virginia's tidal waters during 1978. These SAV areas are outlined on 31 mylar USGS topographic quadrangles (7.5 minute series) supplied to the U.S. Environmental Protection Agency in partial fulfillment of this grant. Of these 31 topographic maps 27 depict mesohaline and polyhaline areas along both the eastern and western shores of the Bay and, as such, are dominated almost exclusively by a species mixture of Zostera marina and Ruppia maritima (Figure 8). The remaining four topographic sheets (Mathias Point, Dahlgren, Colonial Beach, Norge) display significant areas of oligohaline and freshwater species found along several sections of the tidal rivers (Figure 8). These 31 sheets do not represent all of Virginia's shoreline but only those where SAV was observed. Reproductions of all these quadrangles are included in Appendix B of this report.

To assist in the visual interpretation of the areas of SAV, zones of similar percent cover within the beds are outlined on each quadrangle with the appropriate numbers indicative of one of the four density classes (1=<10%, 2=10-40%, 3=40-79%, 4=70=100%). Although it is evident to the authors that this technique is subjective, it is believed that this does contribute significantly to the results of the study. Many of the Zostera and Ruppia dominated beds found throughout the lower Bay are characterized by large areas of sparse coverage (e.g. Parksley, Fleets Bay quadrangles). If these areas were presented as simple outlines, there would be a gross overestimation of the amount of SAV present. In addition, without a density classification scheme those areas which contain very dense stands of submerged grasses (e.g. Franktown, Achilles quadrangles) could not be identified as being of high environmental value.

DISTRIBUTION OF SAV IN MESOHALINE AND POLYHALINE AREAS

Discussion of the distribution and abundance of SAV in the mesohaline and polyhaline regions of the lower Bay where SAV were found is presented below based on major sections of the Bay rather than individual topographic quadrangles (e.g. the York River rather than Clay Bank, Achilles, Yorktown, Poquoson West quadrangles). The total areas of SAV as displayed on each quadrangle are presented in Table 2. In addition, because of the availability of other data from previous surveys (Orth and Gordon, 1975),

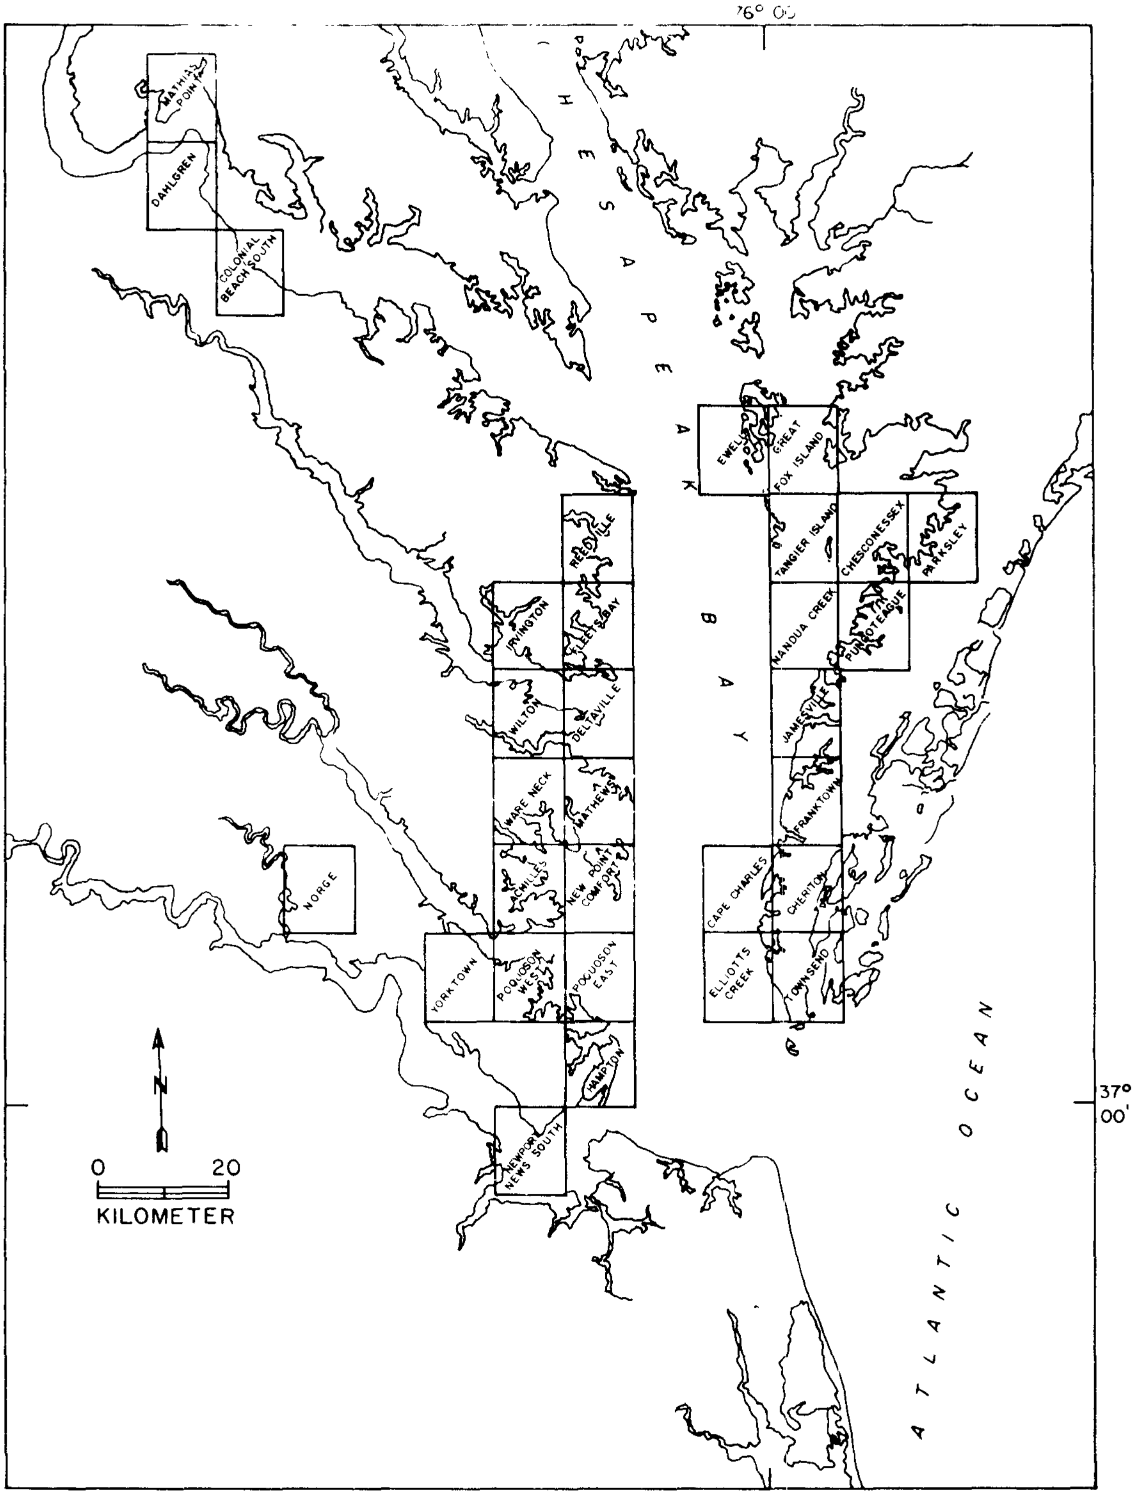

Figure 8. Locations of topographic quadrangles in Virginia where SAV was observed and mapped in 1978.

TABLE 2. TOTAL AREAS OF SAV BY TOPOGRAPHIC QUADRANGLES FOR 1971, 1974, 1978

Quadrangle	Area (m^2) by Year		
	1971	1974	1978
Hampton	2,958,100	3,064,600	2,182,500
Poquoson East	9,456,000	4,355,900	5,166,300
Poquoson West	4,892,900*	3,681,700*	2,104,400

Colonial Beach South	- -	- -	619,500
Norge	- -	- -	464,766

Note: -- indicates the area within Quadrangle was not mapped.

similar to the 1978 mapping, the distribution of SAV in 1971 and 1974 are presented for comparison.

Imagery was obtained from a series of mapping overflights that were made along the vegetated portions of Virginia's shoreline during mid-summer (July or August) and early winter (November or December). All outlines and densities of SAV noted on the topographic quadrangles reflect maximum plant coverage which occurred normally on the summer imagery. Comparisons between the summer and winter imagery are discussed later.

Lower James River (Newport News South, Hampton quadrangles)

The Lower James River contained only a small area of SAV, primarily along the north shore of Hampton Roads. These areas were dominated by *Zostera* and are similar in coverage to those observed in 1971 and 1974. However, the density was much less than that found in the previous two surveys. The remainder of the lower James River was virtually devoid of any SAV. Presumably, this is due to the high turbidity levels found in that region.

James River to the York River (Hampton, Poquoson East and Poquoson West quadrangles)

This region contained significant concentrations of *Zostera* and *Ruppia* in both the Back and Poquoson Rivers and adjacent to Plum Tree Island. Back River had moderate to dense beds behind Northend Point. There were also moderately dense beds adjacent to Plum Tree Island at the mouth of the river. The reduction of SAV in the Northwest Branch of Back River accounted for most of the areal decrease reflected in Table 2. The upstream portions of the River were virtually devoid of SAV. Most probably a combination of high turbidity and a very shoal, silty littoral zone prevents their establishment.

The area adjacent to Plum Tree Island on the Poquoson East quadrangle contained moderate to dense beds of *Zostera* and *Ruppia*. Combined with the SAV beds found on the Poquoson Flats, this region has some of the largest grass areas in the lower Bay. Based on the areal computation for 1978, 1974 and 1971, there was however less grass in 1978 than observed in 1971 and 1974 (Table 2).

The Poquoson River and Crab Neck Areas contained sparse to moderately dense beds of *Zostera* and *Ruppia*, but compared with SAV areas denoted in 1971 and 1974 there had been a reduction in some areas off both Fish Neck and Crab Neck, adjacent to the Goodwin Islands and in the Thorofare. As with Back River, the upstream portions of the Poquoson River were devoid of SAV.

York River (Poquoson West, Achilles, Clay Bank and Yorktown quadrangles)

The distribution of SAV in the York River, an area where SAV has been intensively studied in previous years (March, 1970, 1973, 1976; Orth, 1971 1973, 1975, a,b, 1977 a,b; Orth and Gordon, 1975), was significantly different from that observed in 1971 and 1974. In 1971 extensive beds of Zostera and Ruppia were present on the south shore of the river from the Goodwin Islands to Yorktown. On the north shore, SAV beds were found from the Guinea Marshes as far upriver as Clay Bank, 30 km from the mouth of the York River. By 1974, only small scattered beds were evident on the south shore, while on the north shore, significant reductions in SAV density were observed from the Guinea Marshes to Gloucester Point with almost complete loss from Gloucester Point to Clay Bank. At that time, only a few scattered beds were observed around the Mumfort Islands and Blundering Point. In 1978, no significant vegetation was observed from Gloucester Point to Clay Bank and vegetation was still sparse from Gloucester Point to the Guinea Marshes when compared with 1971 distributions. Vegetation along Goodwin Neck and Goodwin Islands also showed reductions from 1974 to 1978.

Mobjack Bay (Achilles, Ware Neck, Mathews and New Point Comfort quadrangles)

The Mobjack Bay contained significant stands of SAV along most of its shoreline and the lower portions of its four tributaries: the Severn, Ware, North and East Rivers. The heads of these rivers were generally devoid of any SAV. Three areas along this region were investigated with intensive transects: the mouth of Browns Bay, Ware Neck Point and the mouth of East River. They contained dense beds of Ruppia and Zostera at all locations. In addition, the surface information obtained from many other locations indicated that the beds of SAV mapped throughout this region are predominately a mixture of Zostera and Ruppia. Interestingly, the Mobjack Bay area reflects the least alterations with respect to the distribution of SAV, of any other area observed in the lower Bay. Beds of SAV have maintained somewhat similar distributional limits since 1971.

Horn Harbor Area (New Point Comfort and Mathews quadrangles)

This area, extending from New Point Comfort north to the Milford Haven area, had moderate to dense beds adjacent to Horn Harbor and Potato Neck. Intensive transects conducted off Potato Neck revealed significant concentrations of Ruppia and Zostera. As in the Mobjack Bay, the distribution of SAV in this area has remained relatively stable since 1971.

Piankatank River Area (Mathews, Deltaville and Wilton quadrangles)

Very little SAV was observed in 1978 in the lower Piankatank River and Milford Haven area. Patchy SAV was observed adjacent to Gwynn Island, Stone Point Neck and at the mouths of Healy and Cobbs Creek. These areas had abundant grass in 1971 but had declined to very low levels by 1974. Much of the SAV observed in 1974 around Milford Haven and Stingray Point was gone in 1978. Zostera and Ruppia dominate the grass beds observed in this region. The head of the Piankatank contained small amounts of several oligohaline species (Nitella, Ceratophyllum, etc.) which could not be adequately observed from the air and therefore were not mapped onto the topographic quadrangles.

Rappahannock River (Deltaville, Wilton, Irvington, Urbanna quadrangles)

There were virtually no significant SAV beds in the lower Rappahannock River in 1978. Only very sparse beds were found on the north shore from Windmill Point to Towles Point. In 1971 there were extensive beds of Zostera and Ruppia on both shores of this river which had declined to very low levels by 1974.

Fleets Bay to Potomac River (Fleets Bay and Reedville quadrangles)

Sparse to moderately dense beds of SAV were found along this entire area. Most beds were small and very sparse and confined to the lower portions of the creeks and the Bay proper. The Fleets Bay area contained much more grass in 1974, but it was the only area in this region that was surveyed at that time. Many of the beds observed then declined in area or decreased in density by 1978. No SAV were observed within the lower portion of the Potomac River.

Northampton County (Townsend, Elliotts Creek, Cape Charles, Cheriton, Franktown and Jamesville quadrangles)

SAV were observed along most of the Bayside shoreline of this eastern shore county from Old Plantation Creek north to Occohannock Creek. The presence of SAV was generally associated with offshore bar formations, such that the areas with the most well defined and protective bars had the densest beds of SAV.

For much of this region the SAV consisted of large areas of quite sparse coverage. Vegetation in these sparse areas consisted primarily of Zostera. However, in two sections, dense beds of SAV were observed. The first area was adjacent to Cape Charles where moderate to dense beds were found adjacent to Savage Neck and the town of Cape Charles. These beds consisted of a mixture of Zostera and Ruppia. The second area was at the mouth of Hungar's and Mattawoman Creeks. Here exists a large bed along the south end of Church Neck off Vaucluse Shores that has been intensively studied by this and other projects. It has formed to the east of a large offshore bar and represented one of the heaviest concentrations of SAV along Virginia's eastern Bay shore. The vegetation is primarily Zostera and Ruppia.

The large tidal creeks which are found in this region contain vegetation only in their most downstream sections. Here Ruppia predominates with lesser amounts of Zostera scattered throughout. As with Hungars Creek, many of these beds have formed on old oyster bars which have not been maintained since the infestation of oyster pathogens in the 1950's.

Accomack County (Jamesville, Nandua Creek, Pungoteague, Chesconessex, Parksley, Great Fox Island, Ewell, Tangier Island quadrangles)

Large areas of relatively sparse SAV were observed along much of the Bayside shoreline of this county from Occohannock Creek north to Beasley Bay just south of Saxis. Most of these beds of SAV were vegetated with

Zostera and Ruppia. They were adjacent to the large brackish marshes found between the numerous tidal creeks. All SAV were observed within the lower portions of these creeks.

One of the densest concentrations of Zostera and Ruppia in the lower Chesapeake Bay occurred in the area to the east of Tangier Island and Smith Island. The very large, shoal area found here provides a very suitable habitat for SAV growth. The other Bay islands, especially the Fox Islands were also observed to have significant beds of SAV.

In summary, the distribution of SAV in the mesohaline and polyhaline regions of the lower Chesapeake Bay in 1978 was limited to the mouths of the major rivers and the east and west shorelines of the Bay. This is in contrast to 1971 when both the York and Rappahannock Rivers had extensive beds of SAV extending 20-40 km upstream of their mouths. Although the James River has not in recent history had extensive beds of SAV, those that did occur in 1971 had declined significantly by 1978. In addition the Potomac River, which was not formally studied in 1971 or 1974, is shown through historical photographs to have had significant beds of SAV in 1971 as far upstream as the mouth of the Coan River.

By comparing historical information, historical photography and anecdotal information, it has become apparent that since 1971 there has been a significant decline in total area vegetated with SAV. From 1971 to 1974, it appears that the submerged grasses (dominated by Zostera and Ruppia) had moved out of the rivers and decreased in abundance along the northern portions of Virginia's Chesapeake Bay shoreline (Figure 9). This dramatic decline from 1971 to 1974 has continued between 1974 and 1978. In addition, Dr. Richard Anderson (personal communications) of the American University reports finding little Zostera in Maryland waters in 1978.

This decline in distribution and abundance of SAV leaves Virginia with only a few areas of large, dense beds of submerged vegetation. These include: 1. along the western shore of the Bay between Back River and the York River, 2. the shoreline of Mobjack Bay, 3. shoal areas east of Tangier Island and other Bay islands, and 4. large beds formed behind protective sandbars along the Bay's eastern shore.

DISTRIBUTION OF SAV IN SELECTED OLIGOHALINE AND FRESHWATER AREAS

Observations made during the June, 1978, preliminary overflights of Virginia's tidal shoreline indicated an apparent lack of submerged vegetation within the oligohaline and freshwater portions of the major river systems. These include the Potomac, Rappahannock, Piankatank, York (including the Mattaponi and Pamunkey), and James Rivers as well as their major tributaries. The only areas where aerial reconnaissance revealed any SAV beds were: from Mattox Creek to Mathias Neck Point along the Potomac River, and along the Chickahominy River, a tributary of the James.

These two areas were thus selected for aerial mapping. The observed SAV beds along with the species information are included in Appendix B on the

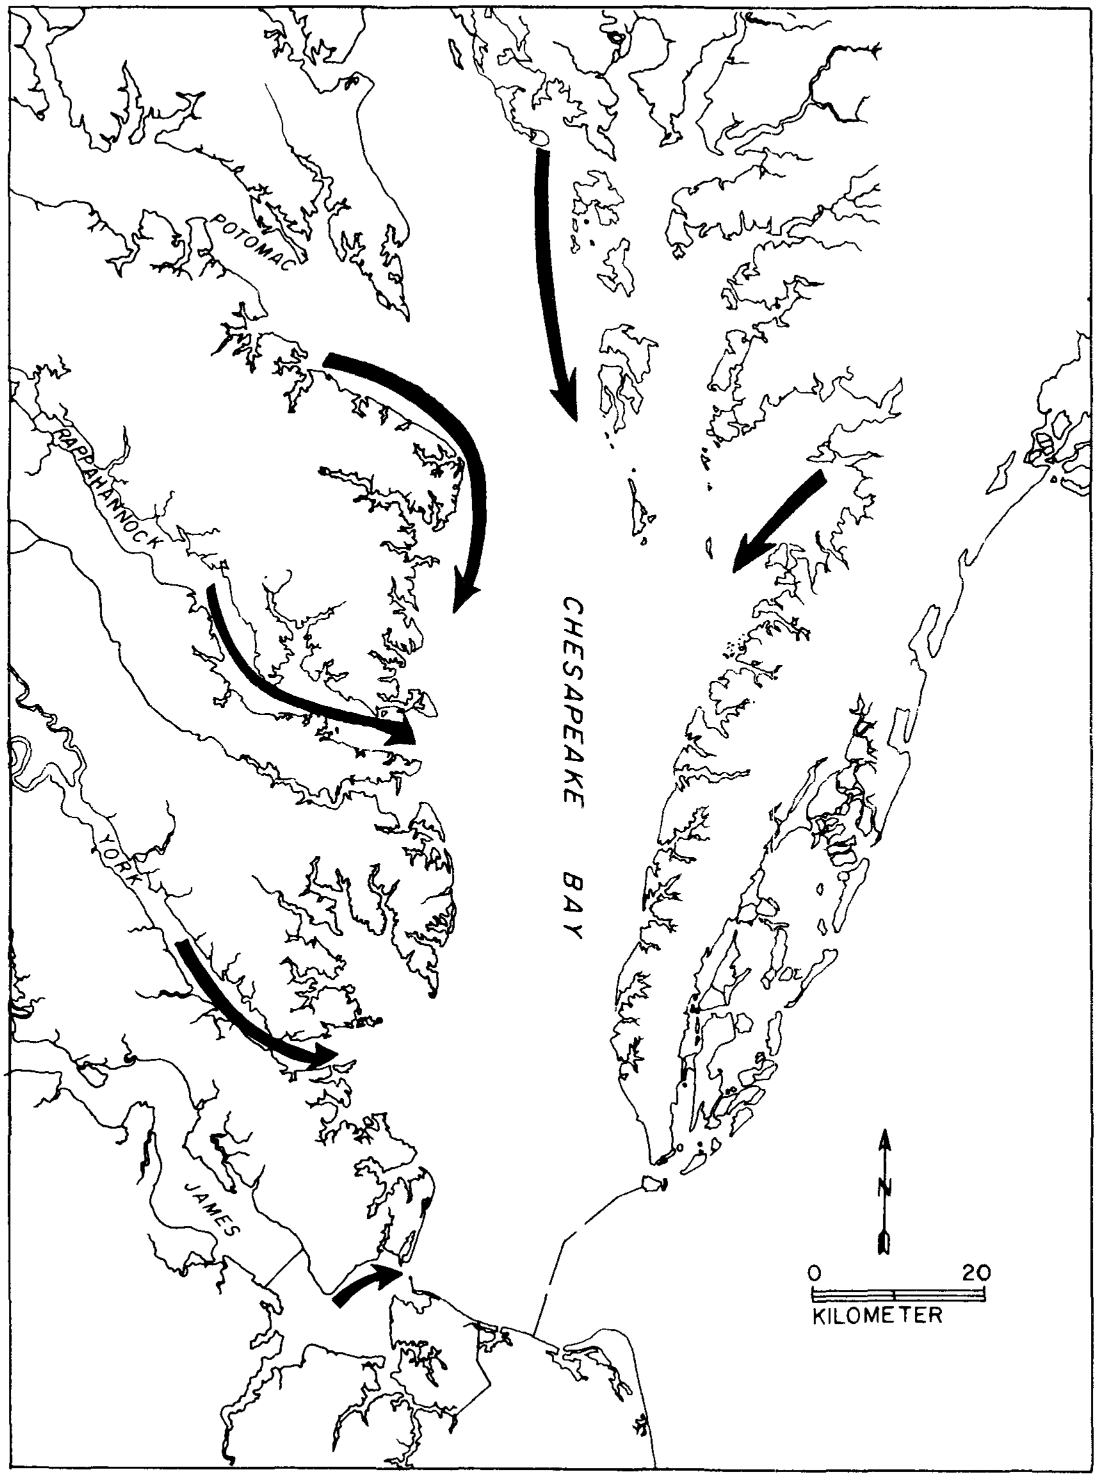

Figure 9. Direction of recent changes in the distribution of Zostera dominated SAV beds.

Norge, Mathias Point, Dahlgren and Colonial Beach North Topographic sheets. More complete surface information obtained for these two areas is provided in Appendix C including species present, relative abundance and general observations. Sampling locations are illustrated in Figure 4.

Potomac River (Mathias Point, Dahlgren, Colonial Beach quadrangles)

The submerged aquatic vegetation found in the region between Mattox Creek and Mathias Neck Point consists primarily of intermittent beds fringing along the shorelines of the major creeks (<2 m depth at MLW). The most common species appears to be *Zannichellia palustris* which is found in numerous small (<5 m wide) patches along the creek shoreline. Other species including *Potomogeton crispus*, *Potomogeton perfoliatus*, *Vallisneria americana* dominate in much larger beds (5-20 m wide); *Zannichellia* is also present but only as an occasional species. It is these larger beds that are evident from the air. Salinities in this region vary considerably but are usually in the range of 5-10 ppt (Lear, unpublished data; Lippson et al., 1979).

Myriophyllum spicatum is a pest species which was common throughout this region from 1959 to the early 1970's (Beaven, 1960; Haven, 1961; Steenis, 1970). Moore (personal observation) reported dense stands of milfoil completely across the portions of Mattox Creek in the summer of 1975. During the summer of 1978, however, *Myriophyllum* was virtually absent from the major tidal creeks between the Yeocomico River and Upper Machodoc Creek, along the Virginia side of the Potomac. Scattered plants were observed at the head of Lower Machodoc Creek. Dense stands were observed only across the most upstream marsh channels of Rosier Creek. In both cases the *Myriophyllum* was mixed with *Zannichellia* in locations where it did not form extremely dense mats. There was no *Myriophyllum* found at all in Mattox Creek, while the Yeocomico River, which was reported to have had dense stands of milfoil in 1974 (Mercer, personal observation), was found to be devoid of all submerged aquatic vegetation. Also, no submerged aquatics were found in Bonum, Jackson, and Gardner Creeks located immediately north of the Yeocomico River.

Chickahominy River (Norge quadrangle)

The Chickahominy River, a major tributary of the James River, is the second low salinity area where submerged aquatics were observed from the air. For this study only the submerged aquatics occurring on the Norge topographic sheet have been mapped although they do occur throughout the river system. More complete surface information is provided in Appendix C and sampling locations are illustrated in Figure 4. The Chickahominy River is primarily an oligohaline to freshwater, tidal river (mean tidal range of 0.7 m, NOS Tide Table) in which salinities rarely exceed 0.5°/oo (VIMS, Data Base). Water samples taken from Shipyard, Yarmouth and Gordon's Creeks on August 24, 1978, during high tide, revealed salinities of between 0.15 and 0.45°/oo. Like many of the rivers and creeks in the vicinity, the Chickahominy is a drowned, Pleistocene river valley that has been filled to about present sea level with layers of sands, clays, and muck (organic matter). It is a relatively undisturbed, natural area characterized by over

2,500 hectares of tidal marsh. Over thirty species of emergent vegetation have been recorded for this area (Moore, 1979) with the most dominant being Peltandra virginica, Pontederia cordata, Zizania aquatica, Nuphar luteum and Bidens sp. Extensive areas of swamp forest dominated by Taxodium distichum are also found in bands between the open marsh and the surrounding hardwood-pine forest.

The Chickahominy region is a confirmed nursery and spawning area for many species of anadromous fishes, particularly those of the genus Alosa (Van Engle and Joseph, 1968). It also supports many resident species such as Micropterus salmoides (large mouth black bass) (Raney, 1950). In addition, it is a valuable habitat for many species of waterfowl; particularly during the winter months when the area is inhabited by many species of migrating ducks and geese.

The submerged aquatics found here occur primarily as narrow (<2 meters) fringing beds located along the edge of the marsh channels at water depths of less than 1 meter. Dominant species include Ceratophyllum demersum and Najas minor but commonly associated species are Nitella sp., Elodea canadensis, Najas guadalupensis, with Najas flexilis recorded at one location. In many cases, because of the presence of the emergent Peltandra, Pontederia and especially Nuphar species, the submerged aquatics are not readily seen from the air. Ceratophyllum was commonly observed from the surface growing under areas of Nuphar. This combined with heavy encrustation by epiphytes and silts and the likewise dark background of the bottom makes it difficult to distinguish the Ceratophyllum from an airplane even at low tide.

In addition to the fringing and embayed SAV beds found along the Chickahominy River, numerous small pockets of submerged vegetation were discovered at the most upstream portions of the marsh guts. Not every gut contained vegetation, however, those that did generally contained both Najas minor and Ceratophyllum demersum and in the deepest sections Vallisneria americana. In most cases these small pockets of submerged grasses were not evident from the air.

It appears then, that from our experience in these two oligohaline and freshwater portion of Virginia's tidal rivers, aerial reconnaissance combined with aerial photography is useful in mapping the larger beds of SAV. However from altitudes (1500-3700 meters) suitable for mapping large areas of shoreline SAV, those located in the many smaller fringing beds, as well as small pocket areas, are not readily detectable.

COMPARISON OF IMAGERY OBTAINED ON SUMMER AND WINTER OVERFLIGHTS

Significant reductions in the amount of SAV were evident on the winter imagery when compared to the summer imagery and confirmed with surface ground truth information. This reduction was due to the normal die-back of the submerged vegetation and, although not uniform, reductions were observed in nearly every SAV bed. For comparison, two areas (Back River and Tangier Island) were selected as representative of seasonal changes observed in the imagery throughout the lower Bay. These areas reflect the range of reduction that might be expected at any one site for 1978. From year to year, however, this change in coverage will vary for each individual bed. During some winters virtually no SAV can be observed from the air (Orth, 1976).

Figure 10 presents the SAV bed outlines and the appropriate percent cover estimates for the areas surrounding Tangier Island during July and December 1978 (Tangier Island quadrangle). Tangier Island is one of the areas that experienced an exceptional reduction in SAV as evidenced by the aerial imagery. This amounted to nearly an 83% decrease in coverage (Table 3).

TABLE 3. SUMMER-WINTER COMPARISONS OF AREAL COVERAGE BY SAV AT TANGIER ISLAND AND BACK RIVER

		Area ($meter^2$)				
Date	Location	<10%	10-40%	40-70%	70-100%	Total
7-7-78	Tangier Island	124,500	374,820	1,763,538	18,612	2,281,470
12-6-78	Tangier Island	33,522	139,908	225,22	0	398,652
6-29-78	Back River	212,388	159,180	262,194	1,456,410	2,090,172
12-7-78	Back River	0	0	841,362	420,480	1,261,842

Back River (see Hampton quadrangle) experienced somewhat less of a dieback from summer to winter. Figure 11 presents the SAV bed outlines and percent cover zones for an area at the mouth of Back River. This seasonal change amounted to a 40% reduction in observable SAV coverage (Table 3).

In both of the areas described above (Tangier Island and Back River), the beds of SAV are dominated by a mixture of both Zostera and Ruppia. Evidence from these as well as many other areas around the lower Bay indicate that both species decline in a similar fashion during the fall and winter. Figure 12 illustrates seasonal changes in both standing crop (biomass) and number of shoots of Zostera at Vaucluse Shores on the Bayside of Virginia's eastern shore. As evidenced from Figure 12, maximum standing crop occurs in the June-July period, with minimum coverage in the September-October period. Zostera has two growth phases, the strongest one occurring in the spring and a second, less intense one, in the fall after die-back in late summer. Though similar data are not available at present for Ruppia, personal observations at several sites in the lower Bay indicate that this species has a peak standing crop in August with minimum standing crop during the winter months. Therefore, attributing declines in coverage to one or the other of the species are probably not valid.

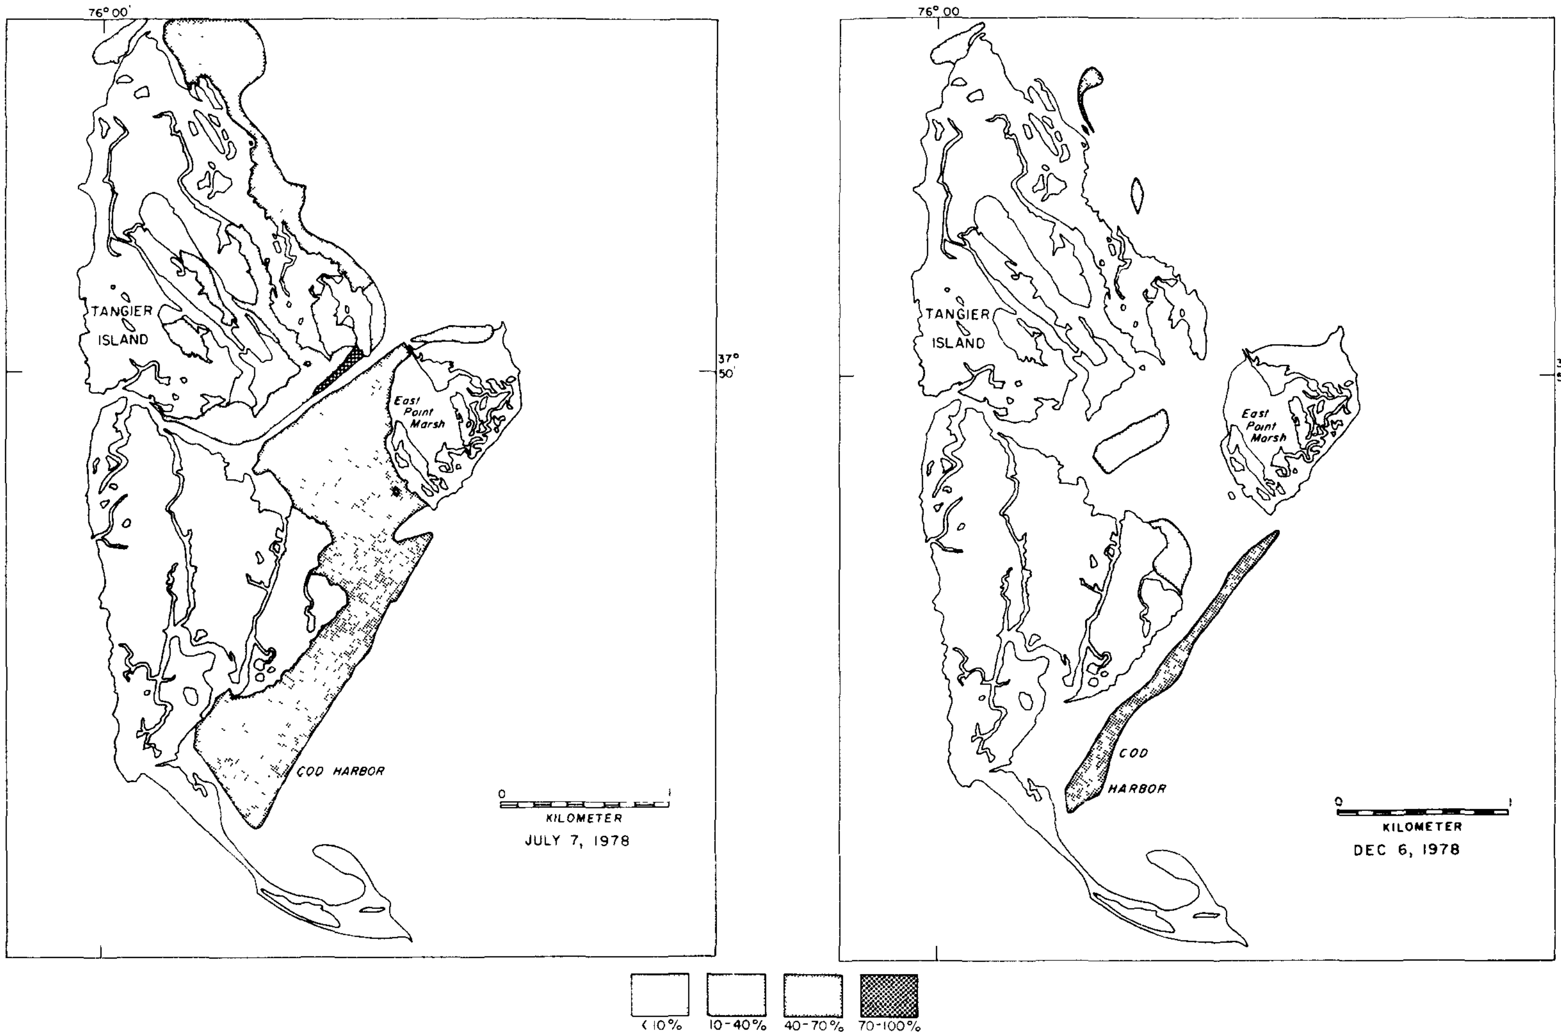

Figure 10. Distribution and abundance of SAV delineated from summer and winter photography at Tangier Island.

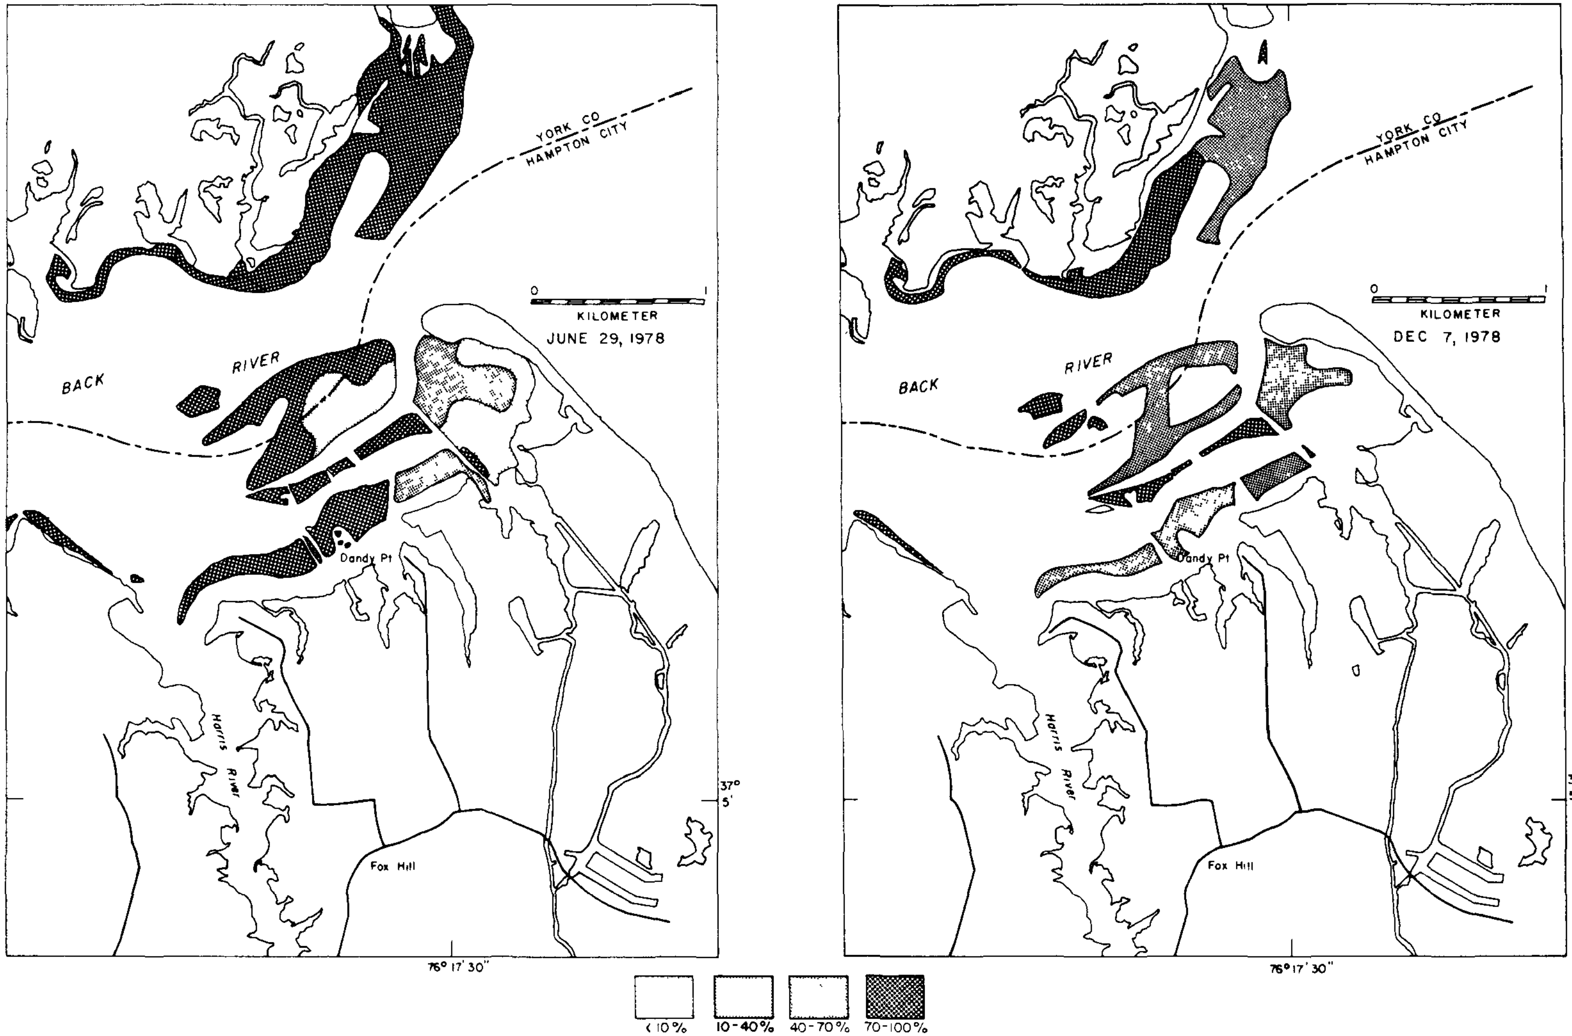

Figure 11. Distribution and abundance of SAV delineated from summer and winter aerial photography at Back River.

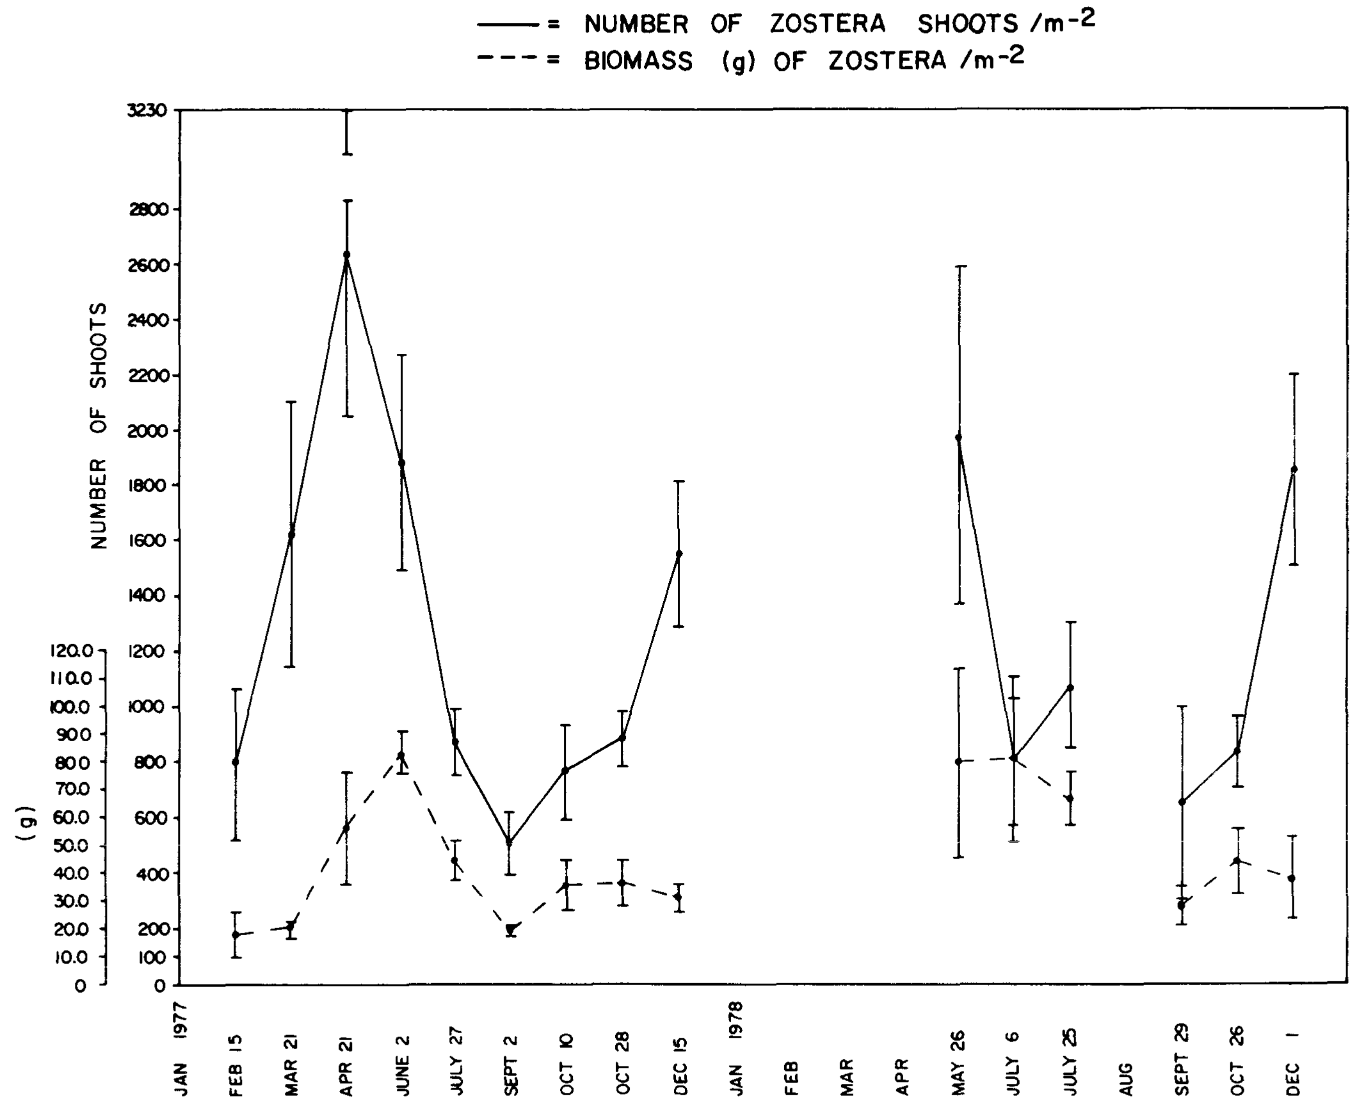

Figure 12. Seasonal changes in the number of shoots and biomass of Zostera at Vaucluse Shores, 1977-1978.

It was evident that the areas throughout the Bay which were observed to have the sparcest coverage during the summer (i.e. <40%) were not able to be observed during the winter. The reduction in standing copy of those sparce areas during the late summer - early fall period resulted in virtually no SAV on the imagery even though there may have been a minimal standing stock present. It is possible, though, that had the photography been flown at a much lower altitude some SAV would have been detected.

Those areas with the highest concentrations of SAV during the early summer had the best chance of being observed during the winter. For example, Tangier Island which contained a large proportion of very sparce (<10%) and sparce (10-40%) SAV areas, showed very little SAV during the winter. Back River, in contrast, contained a large proportion of very dense (70-100%) areas. These areas were still observed during the December overflight, although in generally a less dense status.

HISTORICAL DISTRIBUTION OF SAV

A review of the past photography for five of the six historical areas revealed significant alterations in the distribution and abundance of SAV. Only the eastern shore site did not show significant alterations. The earliest photographs obtained for each area are 1937 or 1938 and, thus presented is a 40 year period on which to base changes in SAV in the lower Bay. We attempted to secure photographs taken during the early summer period when the SAV would be at their maximum abundance. However in most cases, available photographs were for the late spring and fall periods and, therefore, may not reflect the maximum occurrence of SAV for that year. Photographs for years not presented here were carefully reviewed for SAV distribution, so as to present the most accurate picture of the changes of SAV beds.

All areas used in the historical analysis currently contain *Zostera*. It was noted that in the 1937 photographs there was less grass than in the 1950's and 1960's. This period of the 1930's coincided with the well-documented massive decline of *Zostera* on the East Coast of the U.S. and the west coast of Europe (Rasmussen 1973, 1977). During the early 1930's, eelgrass in many bays and rivers in coastal areas declined drastically. At first, this decline was thought to be caused by a parasite, *Labyrinthula* spp. (Renn, 1934, 1935). Later hypothesis suggested that environmental factors such as temperature may have been involved (Rasmussen, 1973). Whatever factor(s) caused this major decline, *Zostera* beds in the Chesapeake Bay were similarly impacted.

Parrott Islands (Table 4; Fig. 13)

In 1937, there were 1.89×10^6 m^2 of SAV adjacent to the Parrott Islands with the grass being sparce to moderate in all areas. By 1951, the SAV occupied area increased to 3.55×10^6 m^2 with 67% of that area having moderate to dense grass. SAV had expanded outward from land and less dense areas became more dense. In 1960, 3.53×10^6 m^2 were occupied by SAV with 70% being moderate to dense vegetation. However, by 1968,

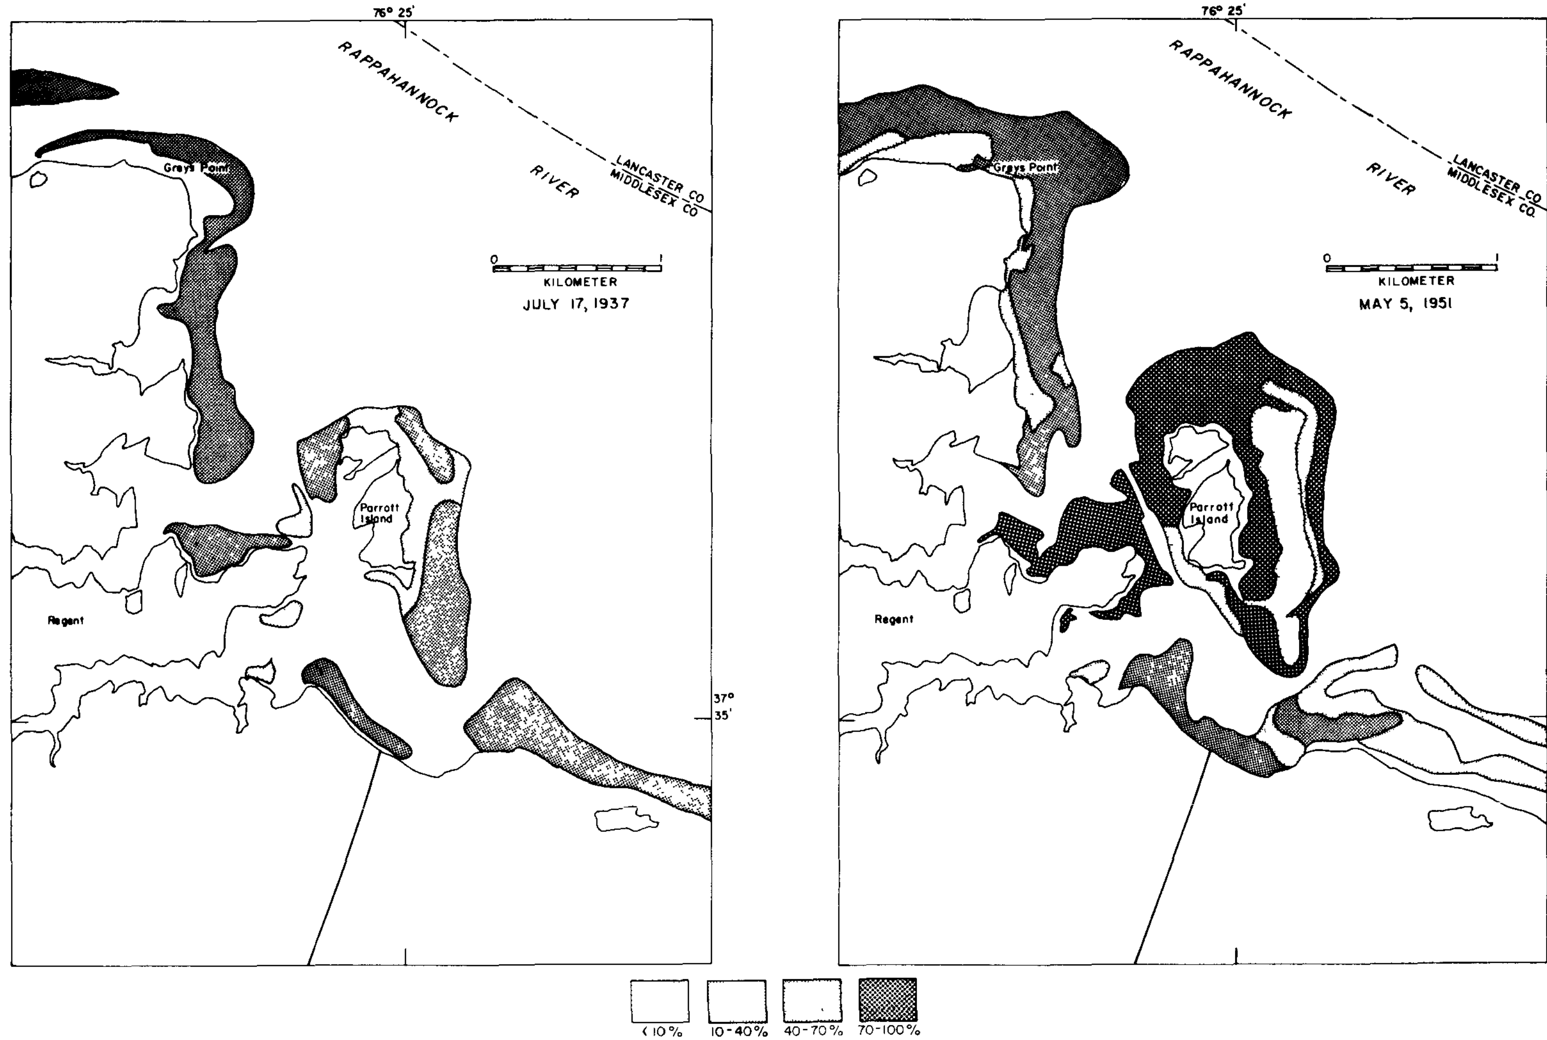

Figure 13. Changes in the distribution and abundance of SAV at Parrott Island, 1937-1978.

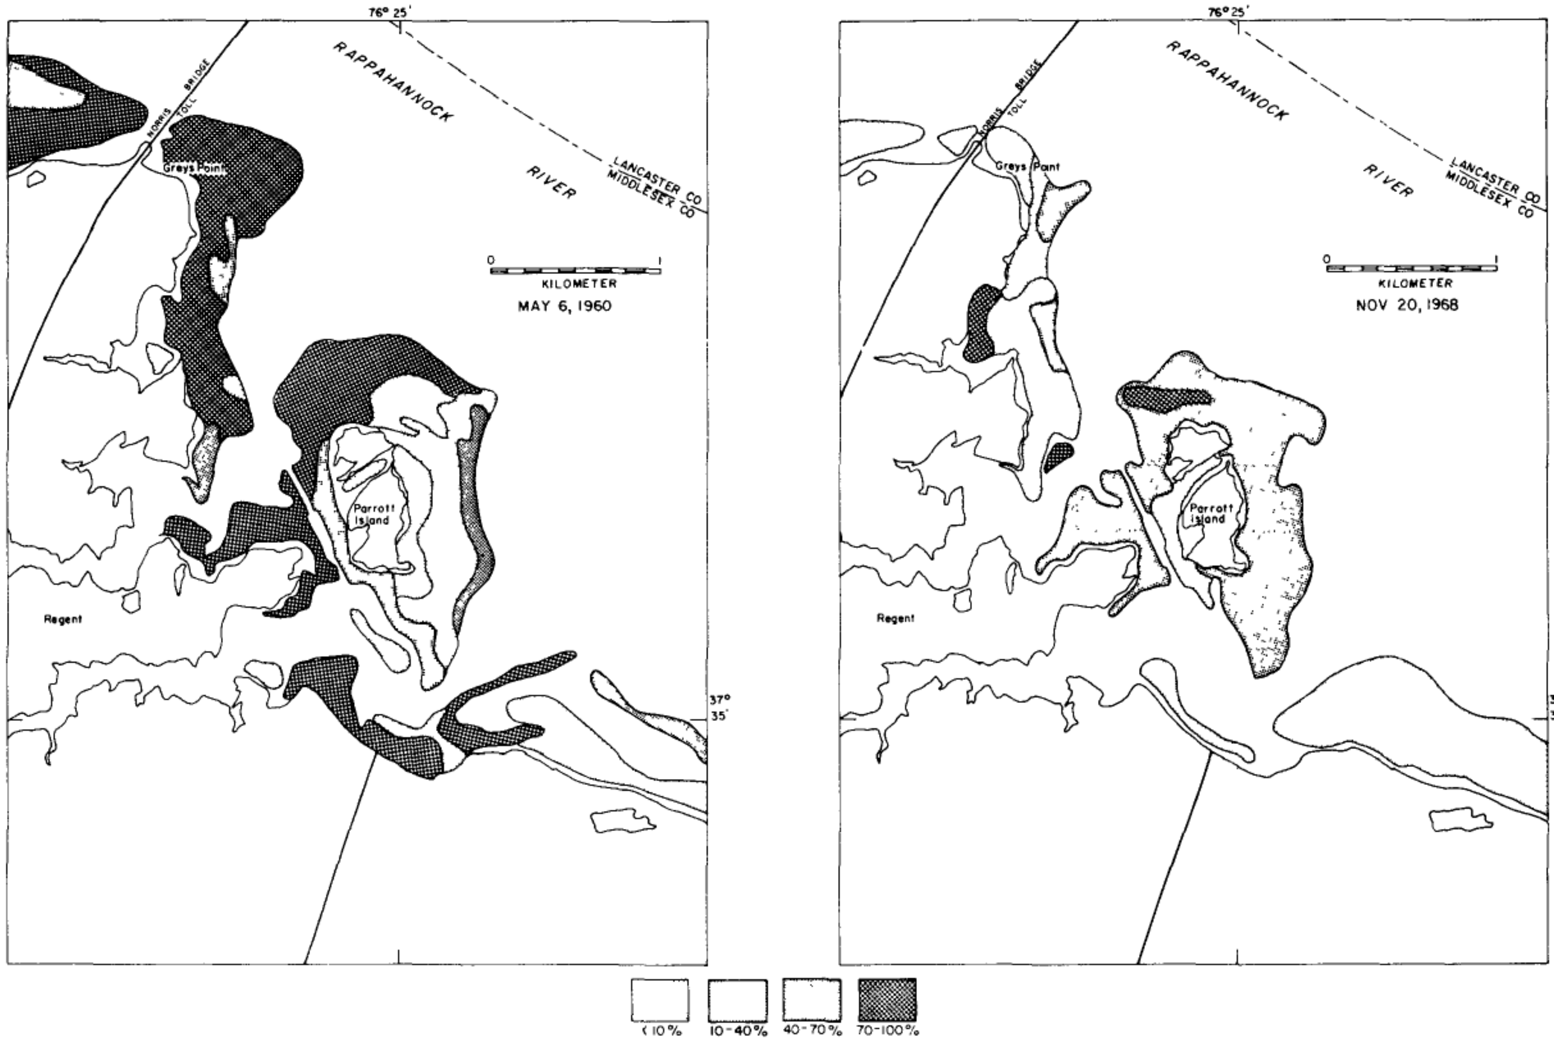

Figure 13. (Continued)

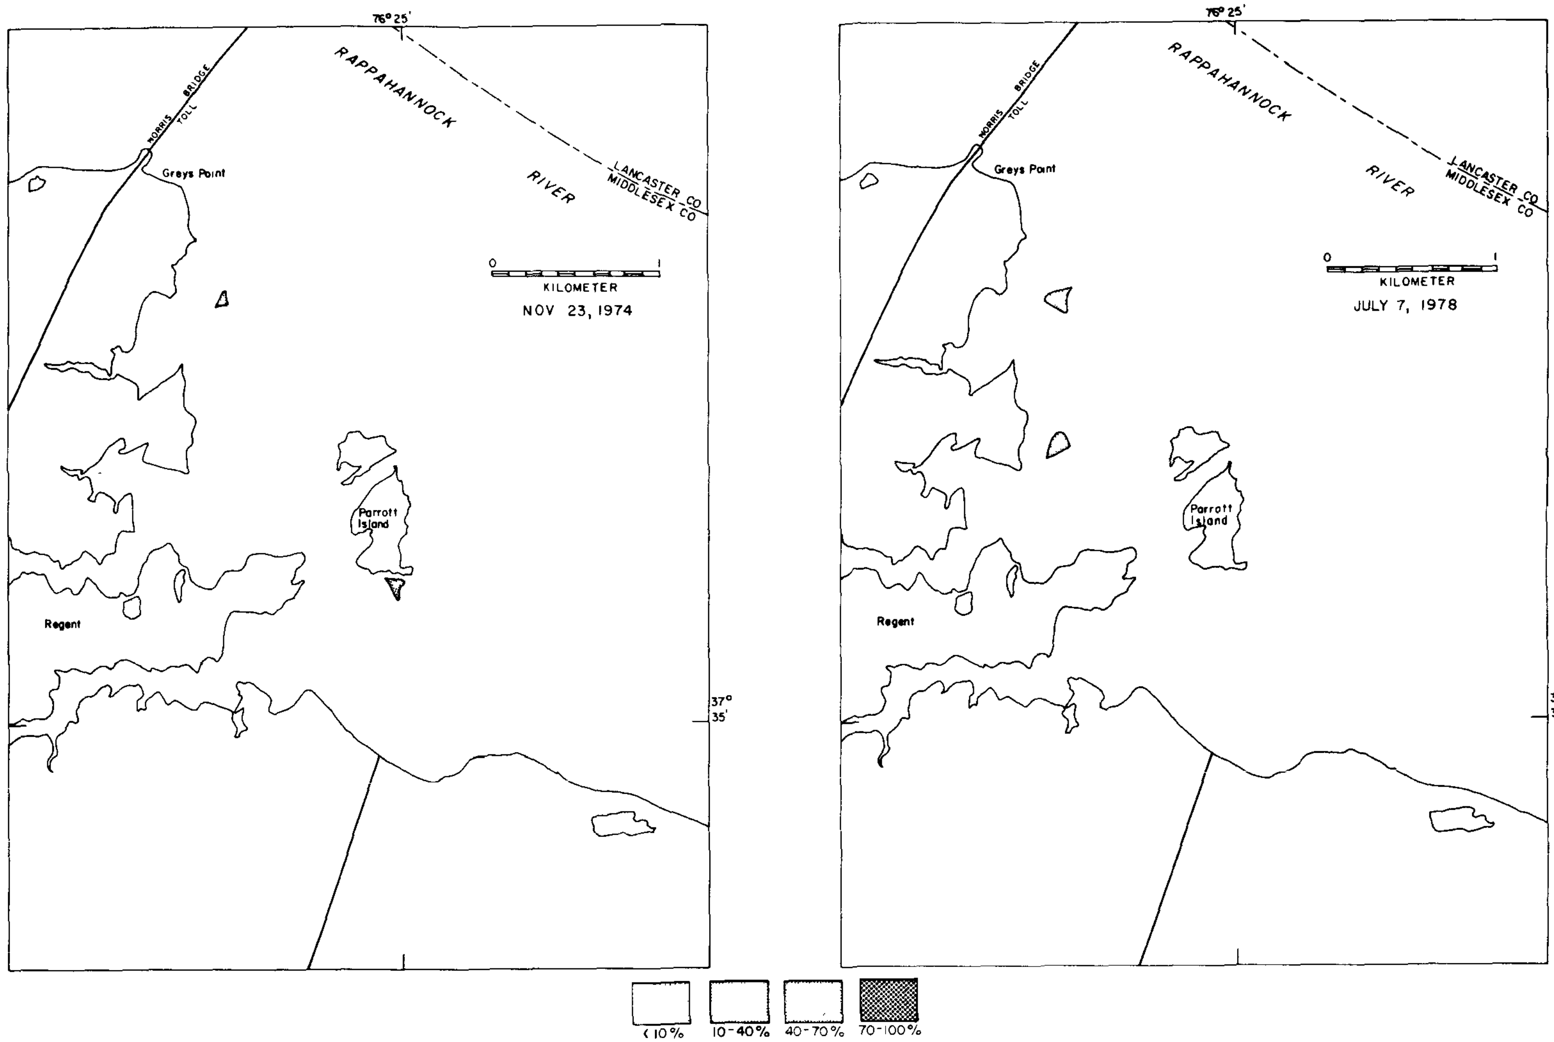

Figure 13. (Continued)

SAV area was reduced to 2.77 x 10^6 m^2 with 92% of that area in sparce to moderate densities. The SAV density data for 1968 was acquired in November and may not indicate an actual decline of SAV but rather a winter density minimum. It is assumed then that the difference in area described here between 1960 and 1968 may not be real but actually an artifact of the time the imagery was taken. In 1974 the changes were drastic; only 10,000 m^2 of SAV remained, a 99% reduction. Even though these data were derived from November photographs, an aerial reconnaissance of this river, and this area in particular in 1974 revealed no SAV even during the early summer months. The abundance of SAV has remained low in this area through 1978. Presently, SAV around Parrott Island is at the lowest density observed in the last 40 years.

Fleets Bay (Table 4; Fig. 14)

In 1937, there were 2.67 x 10^6 m^2 of SAV in the Fleets Bay area with 50% of this area having only sparce coverage. No significant changes occurred by 1953 when 2.96 x 10^6 m^2 were recorded. This data was from a fall period and densities for both years may be low because of low SAV standing crop at that time of year. By 1961, there were 5.43 x 10^6 m^2 of SAV with 46% in the moderate to dense category. It can be seen from Figure 14 that SAV was increasing Bayward from land. Total area in 1969 was 5.23 x 10^6 m^2. However, the fall data for 1974 indicated only 3.05 x 10^6 m^2, a decrease of 40%. The largest decrease has occurred during the last four years with only 0.73 x 10^6 m^2 of SAV being left, most in the very sparce to sparce category.

Mumfort Islands (Table 4; Fig. 15)

The SAV's in the shallow area around the Mumfort Islands have been studied more intensively than other SAV areas in the lower Bay. Most of these studies, however, have been concerned with the animal community associated with the SAV's (see references by Marsh and Orth). In 1937 this area had less than 0.91 x 10^6 m^2 of SAV with 70% of this area being sparce to moderate in density. By 1953, this increased to 2.41 x 10^6 m^2 with 60% of the area being dense beds. In 1960, 2.13 x 10^6 m^2 was estimated but by 1971, this had been reduced to 1.77 x 10^6 m^2. The greatest reduction of SAV occurred between 1971 and 1974. By 1974, the total area occupied by SAV was only 1.51 x 10^6 m^2. There was a further decline after this year so that by 1978, there was no SAV in this area.

Jenkins Neck (Table 4; Fig. 16)

The area adjacent to Jenkins Neck in 1937 contained 2.03 x 10^6 m^2 of SAV in 1937. Despite this large area, however, 98% was classified as sparce or moderate in density. By 1953, as in the other areas discussed above, the grass beds increased in size by expanding out and increasing in density. During this period, 3.60 x 10^6 m^2 contained SAV with 50% classified as dense beds. In 1960, 3.64 x 10^6 m^2 of SAV was estimated with 57% classified as dense. This area diminished to 2.66 x 10^6 m^2 by 1971 and declined to 2.19 x 10^6 m^2 by 1974 with further reductions in succeeding years. By 1978, there were only 1.26 x 10^6 m^2 of SAV remaining.

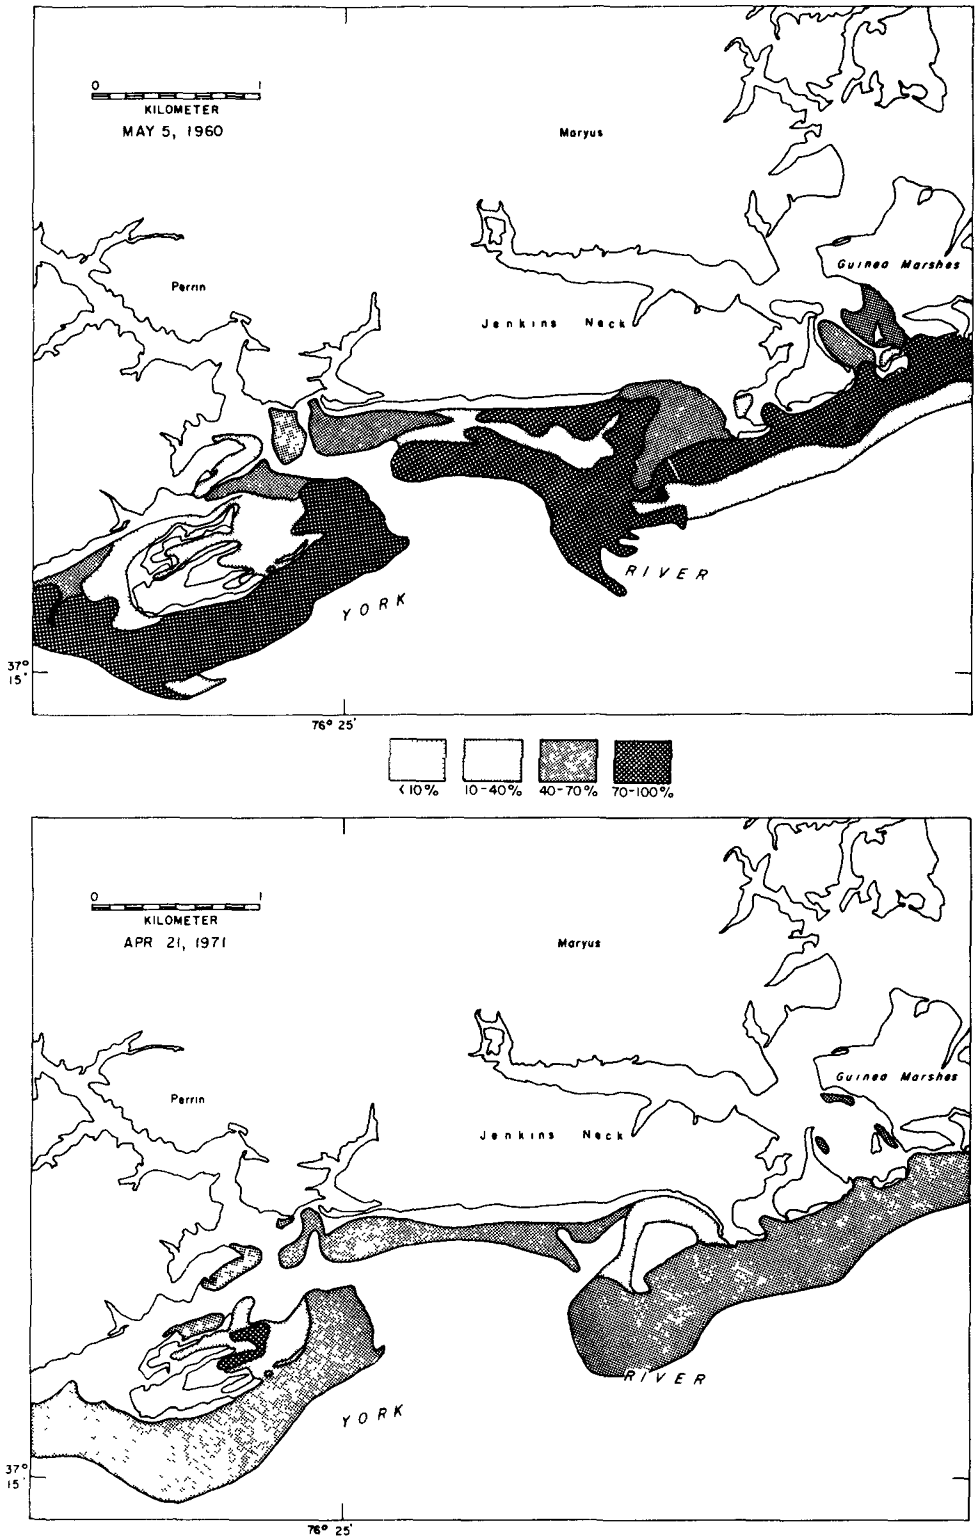

Figure 16. (Continued)

East River (Table 4; Fig. 17)

The area at the mouth of the East River encompasses a broad, shoal area. In 1937, 3.27 x 10^6 m^2 of this area contained SAV (most likely Ruppia and Zostera) with 55% of this area in very sparce to sparce vegetation. By 1953, this area had increased to 4.88 x 10^6 m^2 of SAV with 65% in moderate to dense stands of grass. The total area of SAV was similar in 1963, but there were no dense areas. The fact that the photograph was taken during the fall period probably accounted for most of the area being classified as sparce to moderate. In 1971, the total area was 4.30 x 10^6 m^2, similar to the data for 1953 and 1963. 35% reduction of SAV occurred between 1971 and 1974, with the greatest decrease occurring along the outer limits of the beds where Zostera normally dominates.

There was a 13% reduction between 1974 and 1978, when only 2.42 x 10^6 m^2 were covered with SAV. The outer edges of this area which previously had sparce coverage of SAV in 1978 were devoid of any grass although the habitat was suitable for SAV growth, as indicated by previous data for 1953 to 1971.

Vaucluse Shores (Table 4; Fig. 18)

This area represents the only anomalous pattern to the SAV distribution. Despite the supposedly large scale reductions in Zostera around the Bay region in the early 1930's, there apparently were still extensive grass beds in this region (assumed to be Zostera and Ruppia). In 1938, it is estimated that a total of 4.05 x 10^6 m^2 of SAV existed. This total area of coverage remained approximately the same in 1955, 1966 and 1972 despite some changes in the distribution pattern. The 1978 data showed the total area declined to 2.81 x 10^6 m^2. Thus over the last 40 years, this area has fluctuated the least in total grass bed area of all studied. It is significant to note that the grass bed alterations in this area are apparently due to the dynamics of the sandbars and sandpits found in this region. Both features have migrated and altered the contour of the shallows. Accompanying the changes in bar and spit formation were changes in grass bed distribution. As the bars and spits moved and caused certain habitats to become unsuitable for SAV survival, other areas become suitable with migration of SAV into them. Evidence for this can be found in cores taken in the sand bar region adjacent to grass beds. Cores taken to depths of 1 meter contained remnants of eelgrass rhizomes at the core bottom. These rhizome fragments were found closer to the surface as the existing grass bed was approached. In the north section of the bed the area was found to be shoaling. The habitat therefore has become more suitable for Ruppia than Zostera. General observations of sections of this northern part made between 1976 and 1978 indicated changes in species composition from Zostera to Ruppia. In addition sediment cores taken in these predominately Ruppia areas indicate dense Zostera rhizomes in close proximity to the sediment surface, confirming that Zostera was recently present. Thus, it appears, that geological processes such as sediment transport are very important determinants in SAV distribution here.

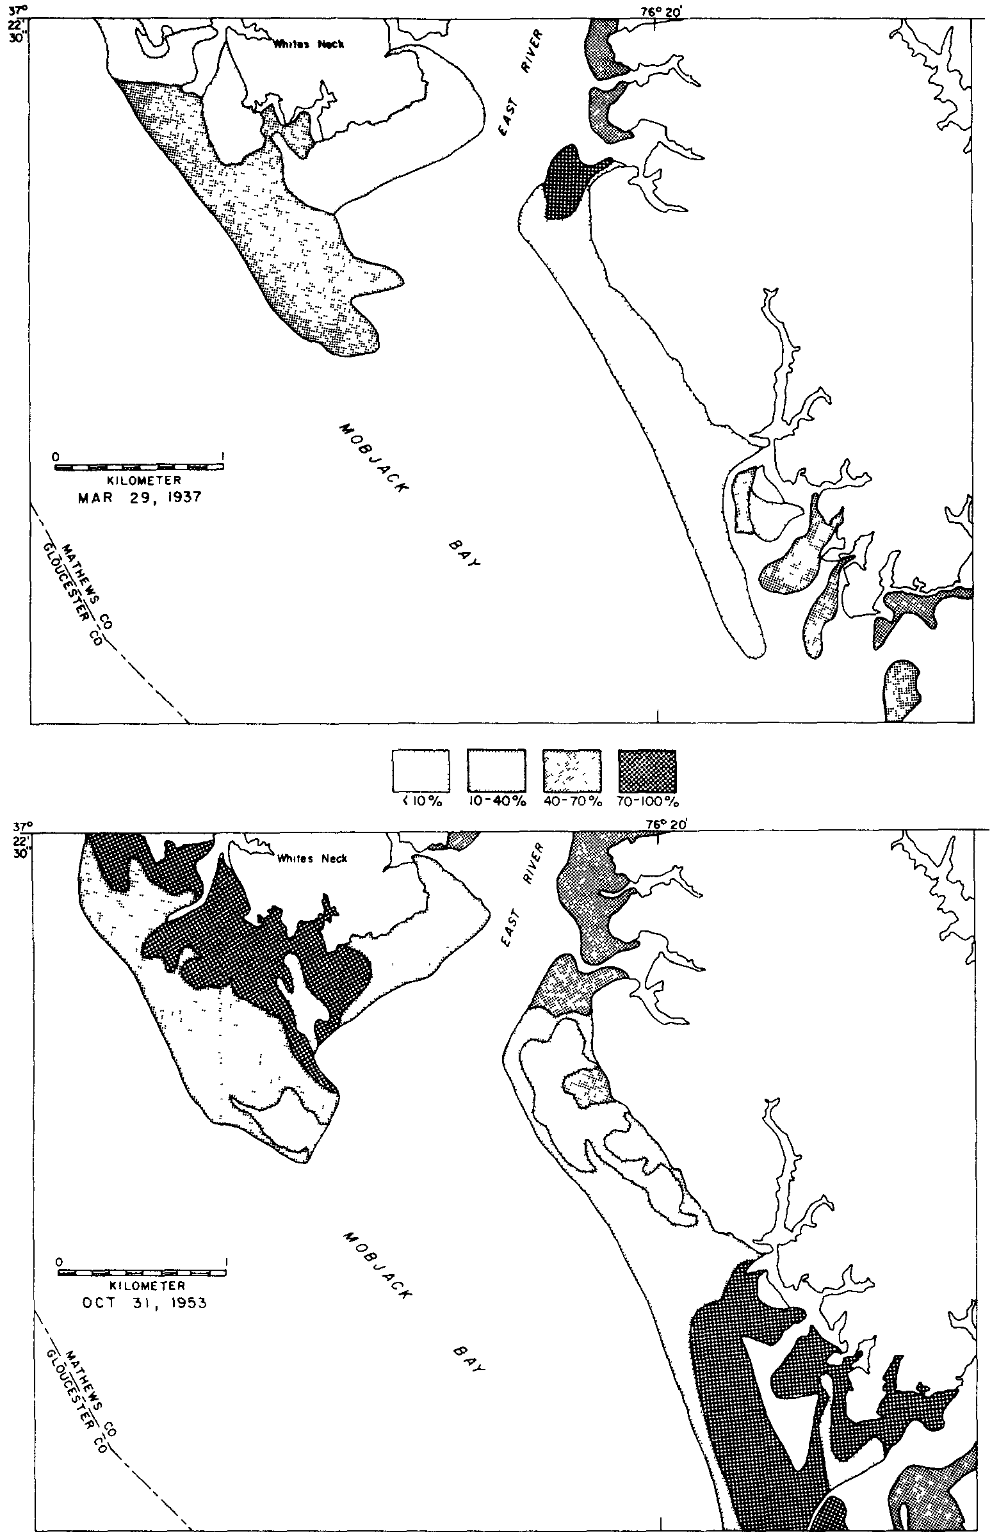

Figure 17. Changes in the distribution and abundance of SAV at the East River, Mobjack Bay, 1937-1978.

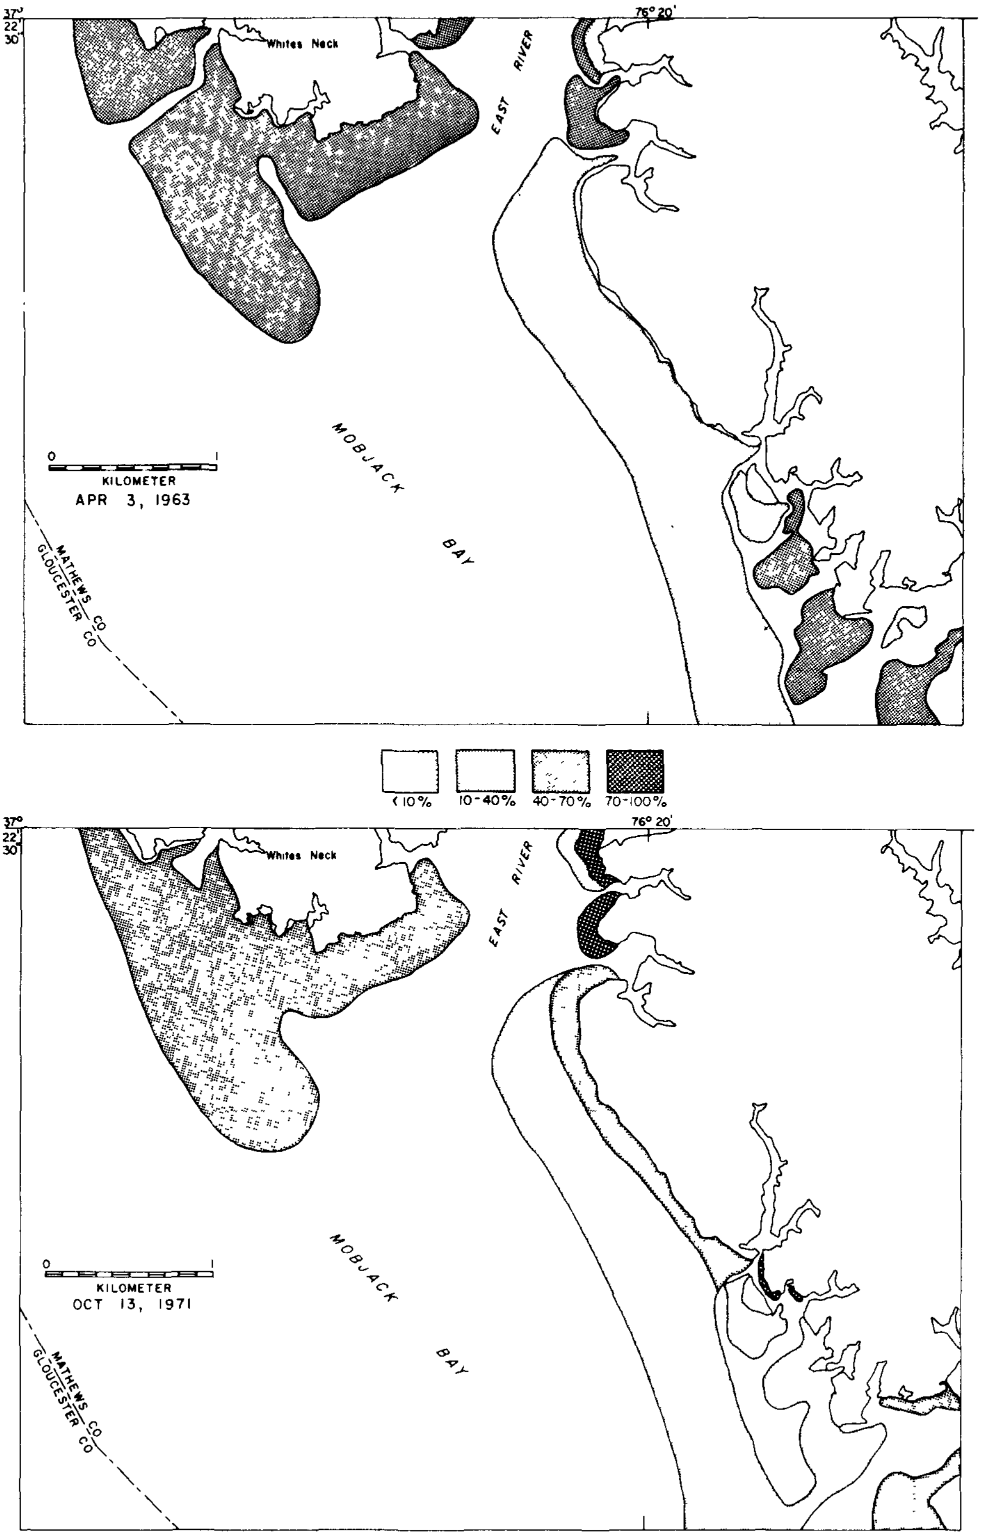

Figure 17. (Continued)

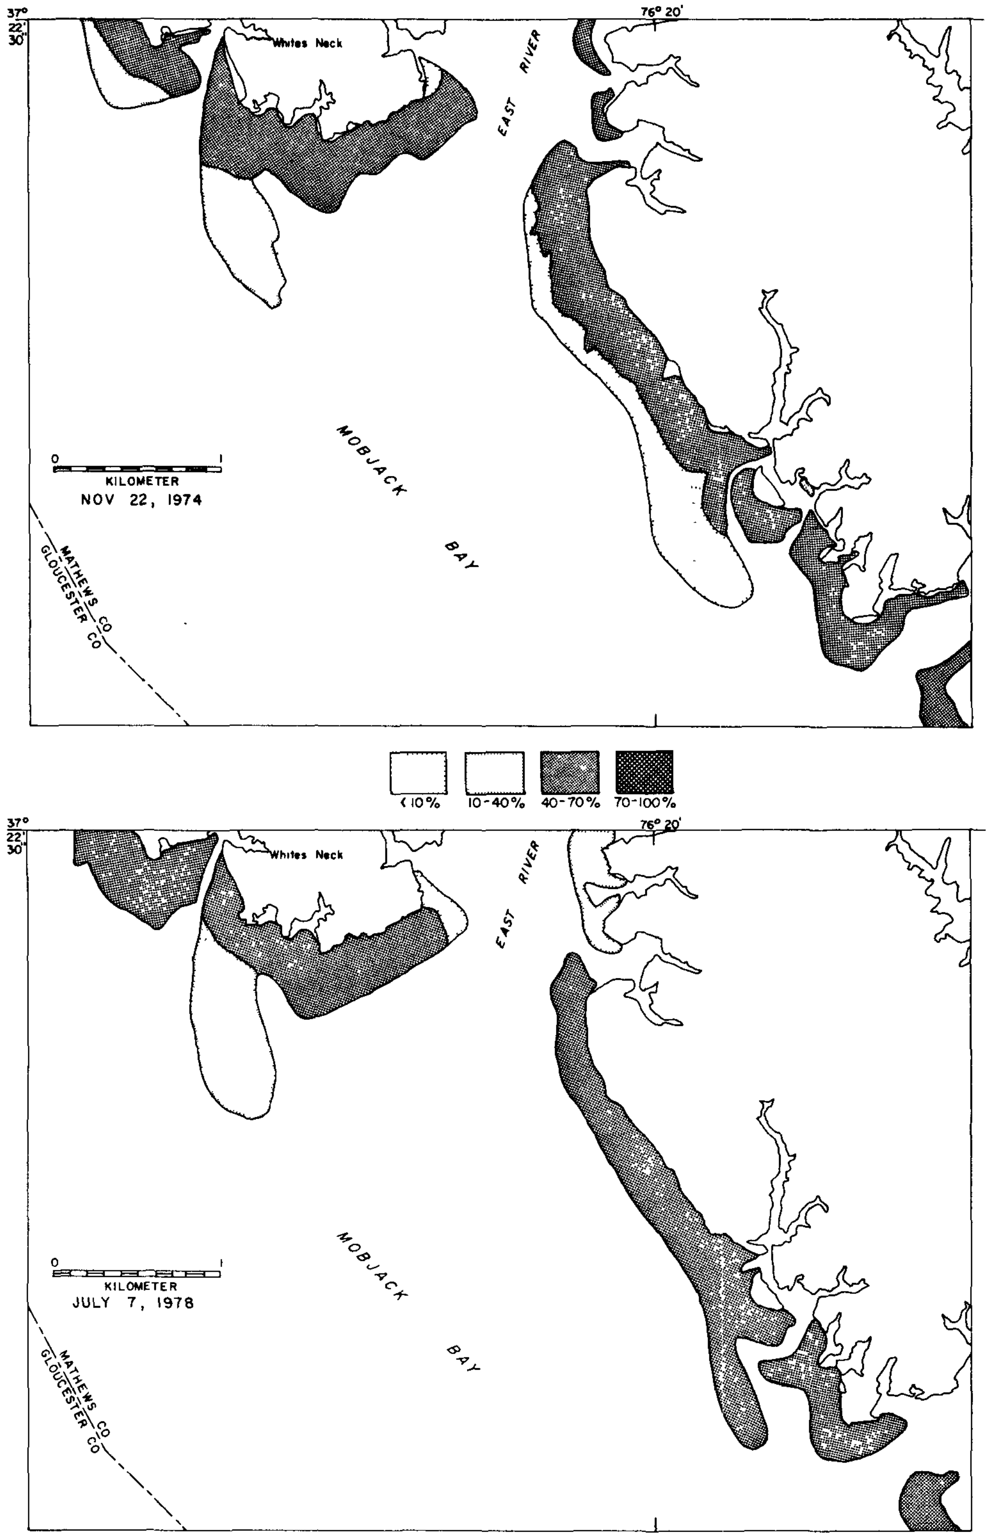

Figure 17. (Continued)

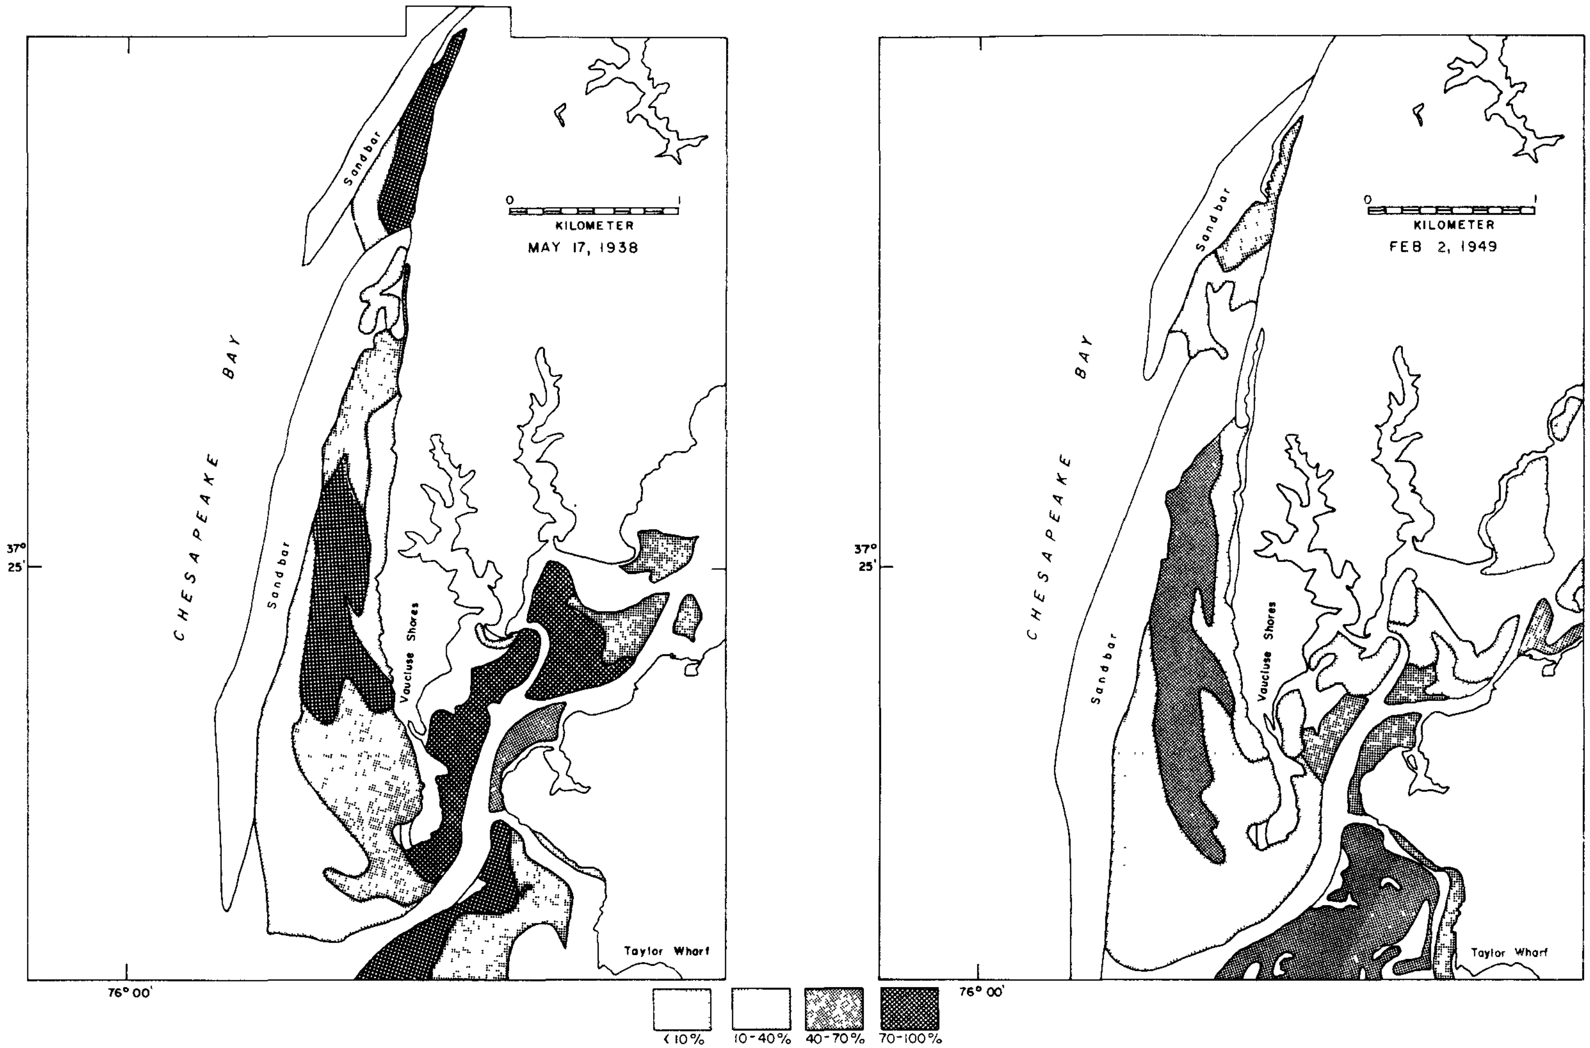

Figure 18. Changes in the distribution and abundance of SAV at Vaucluse Shores on the Eastern Shore, 1938-1978.

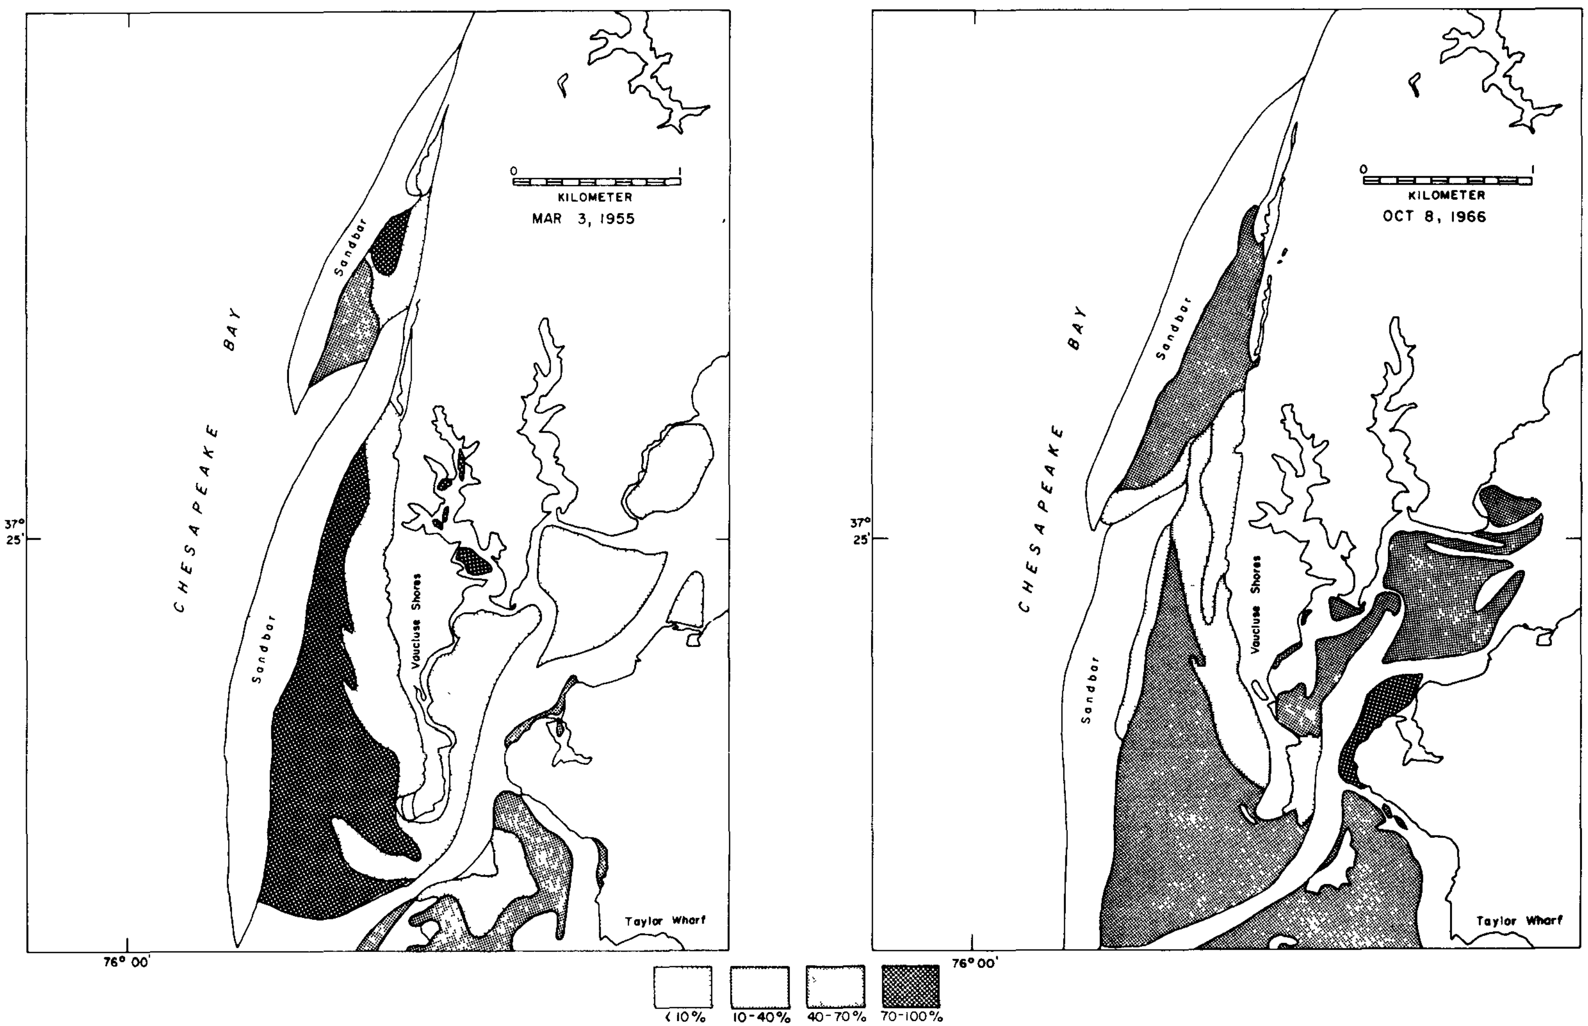

Figure 18. (Continued)

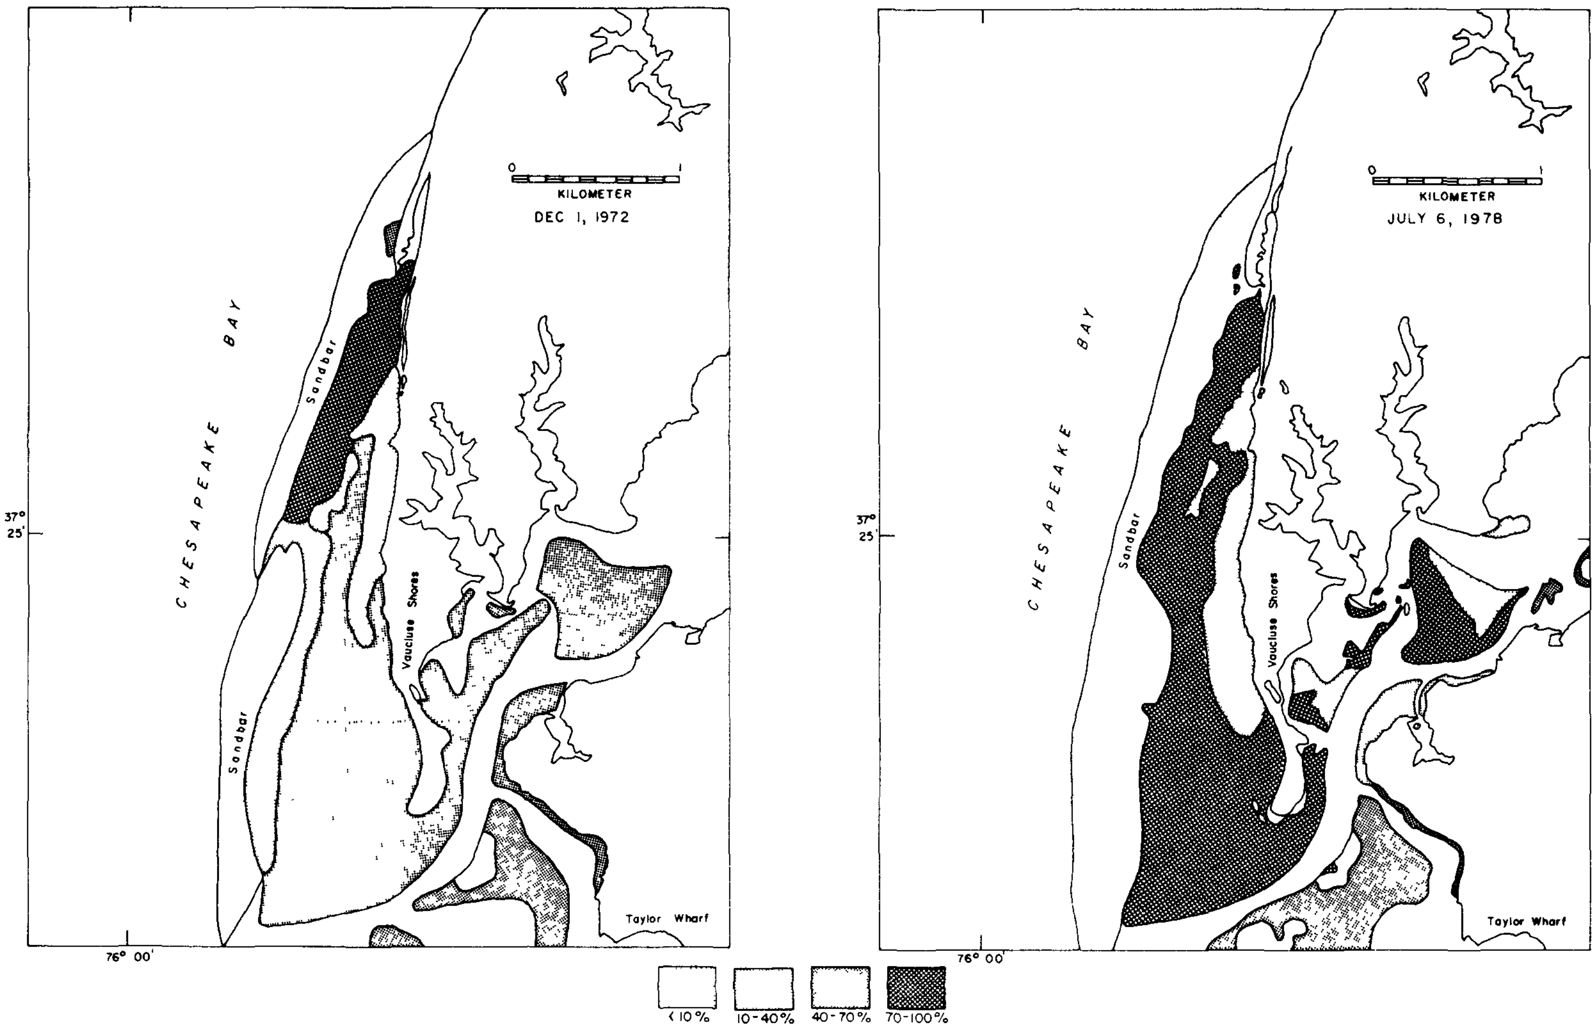

Figure 18. (Continued)

The distribution of SAV (Ruppia and Zostera) in the last 40 years, as delineated by changes in grass bed coverage in the six specific areas, showed a very reduced coverage in the late 1930's. This coincided with the period when Zostera had also declined along the entire East Coast of the U.S. The only anomalous area was the eastern shore site which showed a more extensive grass area than the other sites. The period between 1937 and 1953 showed a dramatic increase in area coverage as well as increase in density of the beds. The increase continued through the 1960's and in some areas until 1971-1972. Slight decreases were observed during this period at Mumfort Island, Jenkins Neck and Parrott Island. The largest decrease of SAV in all areas occurred between 1971 and 1974 and more specifically in 1973 (Orth and Gordon, 1975; Orth, 1976). Both area coverage and the density of the beds showed a significant decrease. This decrease continued through 1978 when the distribution and abundance of SAV in each area was the smallest observed in the last 40 years.

In reviewing the past and present data, the distribution and abundance of SAV in these selected areas in 1978 is very similar to the data collected of 1937-1938. This suggests that, perhaps, whatever factor or factors caused the major decline of the grass beds in the 1930's may also have been operating in the 1970's. The possible cause(s) for the recent decline of SAV in the Chesapeake Bay are numerous and have been thoroughly discussed by Stevenson and Confer (1978).

TRANSECT ANALYSIS OF MESOHALINE AND POLYHALINE SAV BEDS

Data obtained from the seventeen transects located at six areas around the lower Bay are found in Appendix D. Location of each transect is displayed on the appropriate topographic quadrangle in Appendix B. The sampling areas, number of transects and topographic quadrangles are as follows:

Area	No. Transects	Quadrangles
Plum Tree Island	2	Poquoson East
Brown's Bay	2	Achilles
Ware Neck	2	Achilles
East River	2	New Point Comfort
Horn Harbor	2	New Point Comfort
Vaucluse Shores	7	Franktown

The large, mesohaline SAV beds sampled by the seventeen transects were found to be composed almost exclusively of a mixture of Zostera marina and Ruppia maritima. At only one location, Vaucluse Shores, transect F, was another species, Zannichellia palustris, recorded. Comparisons of individual transects showed a consistent pattern of distinct zonation. Ruppia occupied the near shore, shallow areas and graded to mixed zones of Ruppia and Zostera. At greater depths, Ruppia ended and Zostera was the only species found. The size of each of these three zones varied greatly and in some areas was not present at all. The primary controlling factor for the configuration of this zonation appeared to be depth and, therefore, bottom topography, although site exposure also seemed important. Salinity did not appear to be much of a factor within each bed but could be important in comparing different sites. Temperature and turbidity were probably also important but were controlled to a great extent by water depth. At different sites however, variations in turbidity probably controlled the depths to which the two species will occur. In the least turbid areas both species grew to the greatest depths.

Comparisons of the percent cover data with the biomass measurements made at the Vaucluse Shores site indicated significant positive correlations. Table 5 presents the data obtained at approximately 50 m intervals along the Vaucluse Shores transects. Because of difficulties associated with determining numbers of shoots of Ruppia as well as separating the above ground and below ground portions of the plants, only total biomass is presented for that species. Product-moment correlations calculated between the percent cover estimates and the number of shoots of Zostera, total weight of Zostera, above ground and below ground weights of Zostera, and total weights of Ruppia per 0.1 m^2 are presented in Table 6. All are significant at the 1% level, indicating that percent cover provided a good estimation of the amount of vegetation present.

Means of 741 shoots per m^2 and 78.2 g per m^2 were obtained for those samples containing Zostera during this August, 1978, transect sampling. These numbers compared favorably with the more complete seasonal data obtained at the Vaucluse Shores site for another project (Figure 12). No data were available for comparison with the Ruppia which had a mean total weight of 43.2 g per m^2. It appears that the data collected at Vaucluse Shores during the transects reflects the maximum seasonal standing stock of Zostera. Although the observations made at the other transect sites around the lower Bay followed the Vaucluse Shores work by several weeks to a month, there seemed to be no great deterioration of the beds during that time. It is therefore assumed that the data obtained during all the transects reflect near maximum standing stock conditions.

Percent cover data for the seven Vaucluse Shores transects were summed and the means and standard deviation of the means determined for each 1 dm depth interval. This provided a composite picture of how the two submerged species varied with depth throughout the entire bed (Figure 19). The standard deviations were quite large since all observations at each depth were averaged, including those with no SAV present. The distinct zonation with depth was evident for the two species, with Ruppia dominating the shallow depths and Zostera most abundant at the greater depths. Ruppia was found to exhibit a significant percent cover (>5%) from +1 to -9 dm mean low water (MLW). Maximum percent cover for Ruppia occurred at -3 dm depths. Zostera on the other hand occurred at -10 dm MLW. Both exhibited a greater range of depths with Ruppia recorded from +2 to -10 dm MLW and Zostera from +1 to -13 dm MLW. In general Ruppia was found dominant in the shallow more protected area of +1 to -4 dm MLW with Ruppia and Zostera co-occurring at intermediate depths of -4 to -8 dm MLW. Zostera dominated at the greater depths of -8 to -12 dm and in the most exposed sites. These ranges of depths were characteristic of the other transected areas around the lower Bay, although the specific depth ranges varied from site to site.

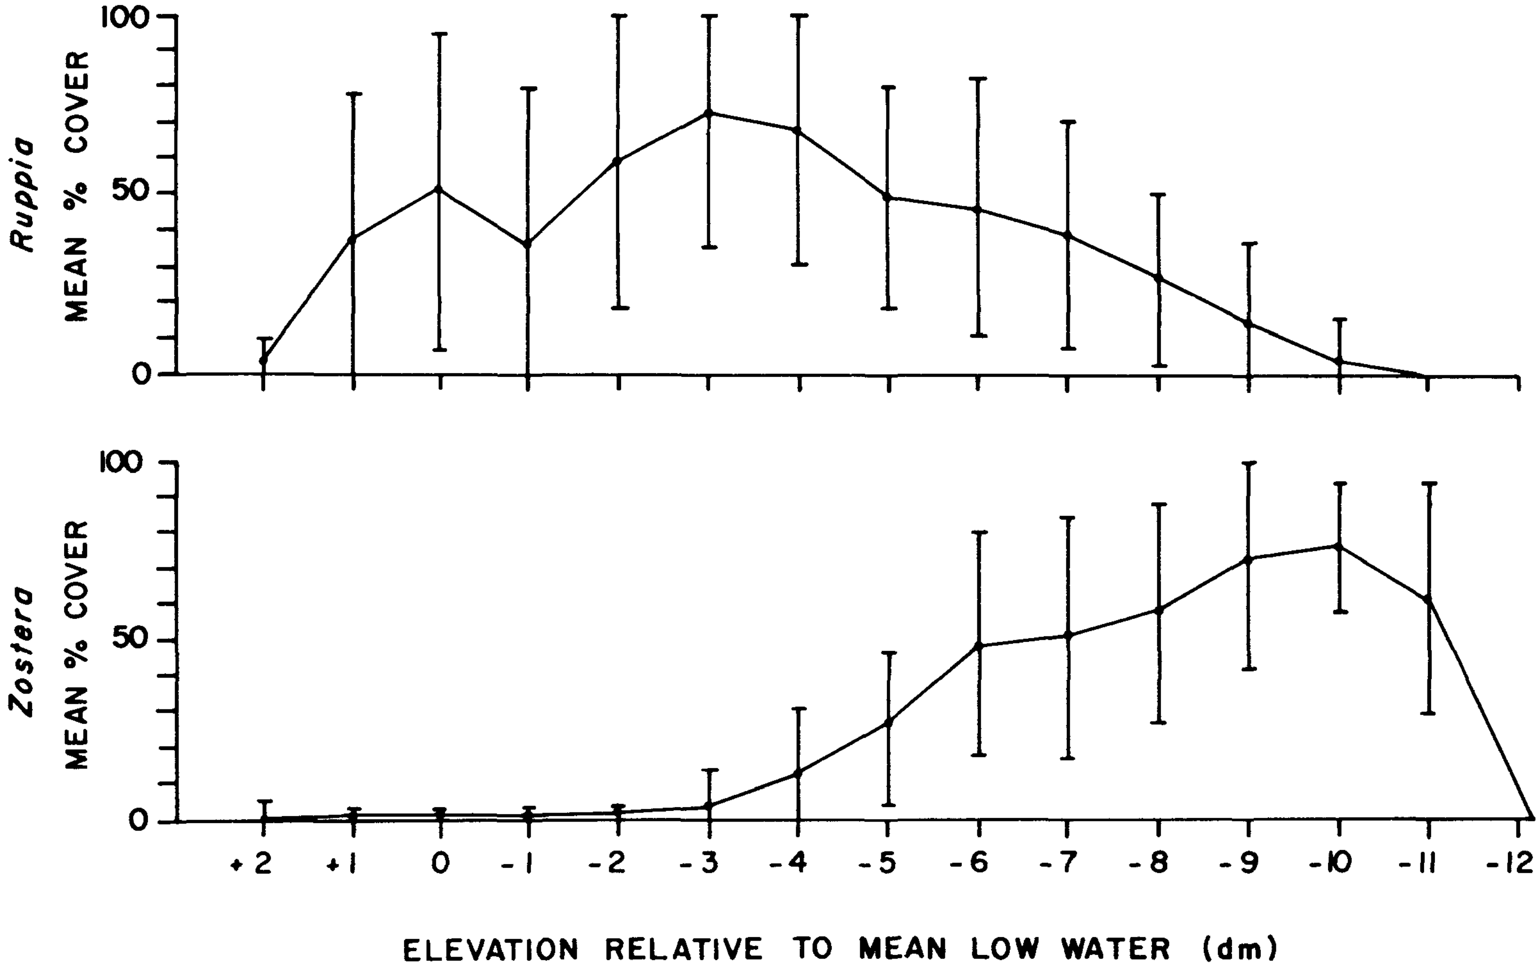

Figure 19. Relationship between percent cover and depth for Zostera and Ruppia at Vaucluse Shores. Brackets indicate standard deviation.

Bottom types found at the 17 transects varied from silts to coarse sands with fine sand being the most common designation. Another bottom type observed in a few SAV beds around the lower Bay was of relic oyster bars covered with a fine layer of silty sand. Variations in bottom types did not appear to be directly related to speciation within the beds as both species were associated with each of the sediment types.

Table 7 presents the relative importance values calculated for each species at each of the transects. At the Vaucluse Shores area *Ruppia* appears to be the most important species across 6 of the 7 transects. As illustrated in Figure 19 this seemed to be depth related. At the other transects located along the western shore of the Bay both *Zostera* and *Ruppia* varied in importance, with *Zostera* most important in some areas and *Ruppia* in others. These data indicated that although *Zostera* has long been recognized as the dominant species in Virginia's mesohaline and polyhaline SAV beds, the importance of *Ruppia* should not be underestimated.

Plum Tree Island (Poquoson East quadrangle)

Figure 20 presents profile diagrams of the two transects conducted at the Plum Tree Island area. The SAV in this region was characterized by a nearly continuous fringing bed beginning just below MLW and extending offshore for varying widths, depending upon bottom topography. The adjacent shoreline was one of extensive brackish marshes composed largely of *Spartina alterniflora*, *Spartina patens* and *Juncus roemerianus*. Salinities recorded here were between 20 to 21 ppt and water temperatures approximately 24^{o}C.

The width of the SAV bed at transect A was quite narrow (<150 m) with the bottom rapidly increasing in depth from the marsh shoreline outward. Apparently as a result of both this relatively steep shore and the high wave energy at this site only *Zostera* was present. This seems reasonable considering the extensive root and rhizomes system of *Zostera* and less extensive below ground system of *Ruppia*.

In contrast to the narrowness and steep slope of transect A, transect B located several kilometers to the north was characterized by an extremely broad zone of submerged vegetation. From the adjacent marsh shoreline, the bottom dropped to a wide trough vegetated by a sparse coverage of *Ruppia*. Although this portion of the transect had water depths suitable for the growth of *Zostera*, none was found. *Zostera* did occur in a narrow zone as the bottom gradually began to rise to a broad offshore bar. At the shallowest portions of the bar (<1 dm MLW) dense stands of *Ruppia* were mixed with intermittent areas of open sand. Continuing offshore, the depths again increased, and on this slope *Ruppia* was gradually replaced by *Zostera*. At approximately -8 dm MLW the vegetation ceased, although the bottom continued to increase in depth.

The effect of site exposure was evident along the offshore slope of transect B. At 800 m to 1000 m from shore, with elevations of -2 dm to -5 dm, large patches of exposed roots and rhizomes of *Zostera* were observed. The weather preceeding the sampling of this transect had consisted of

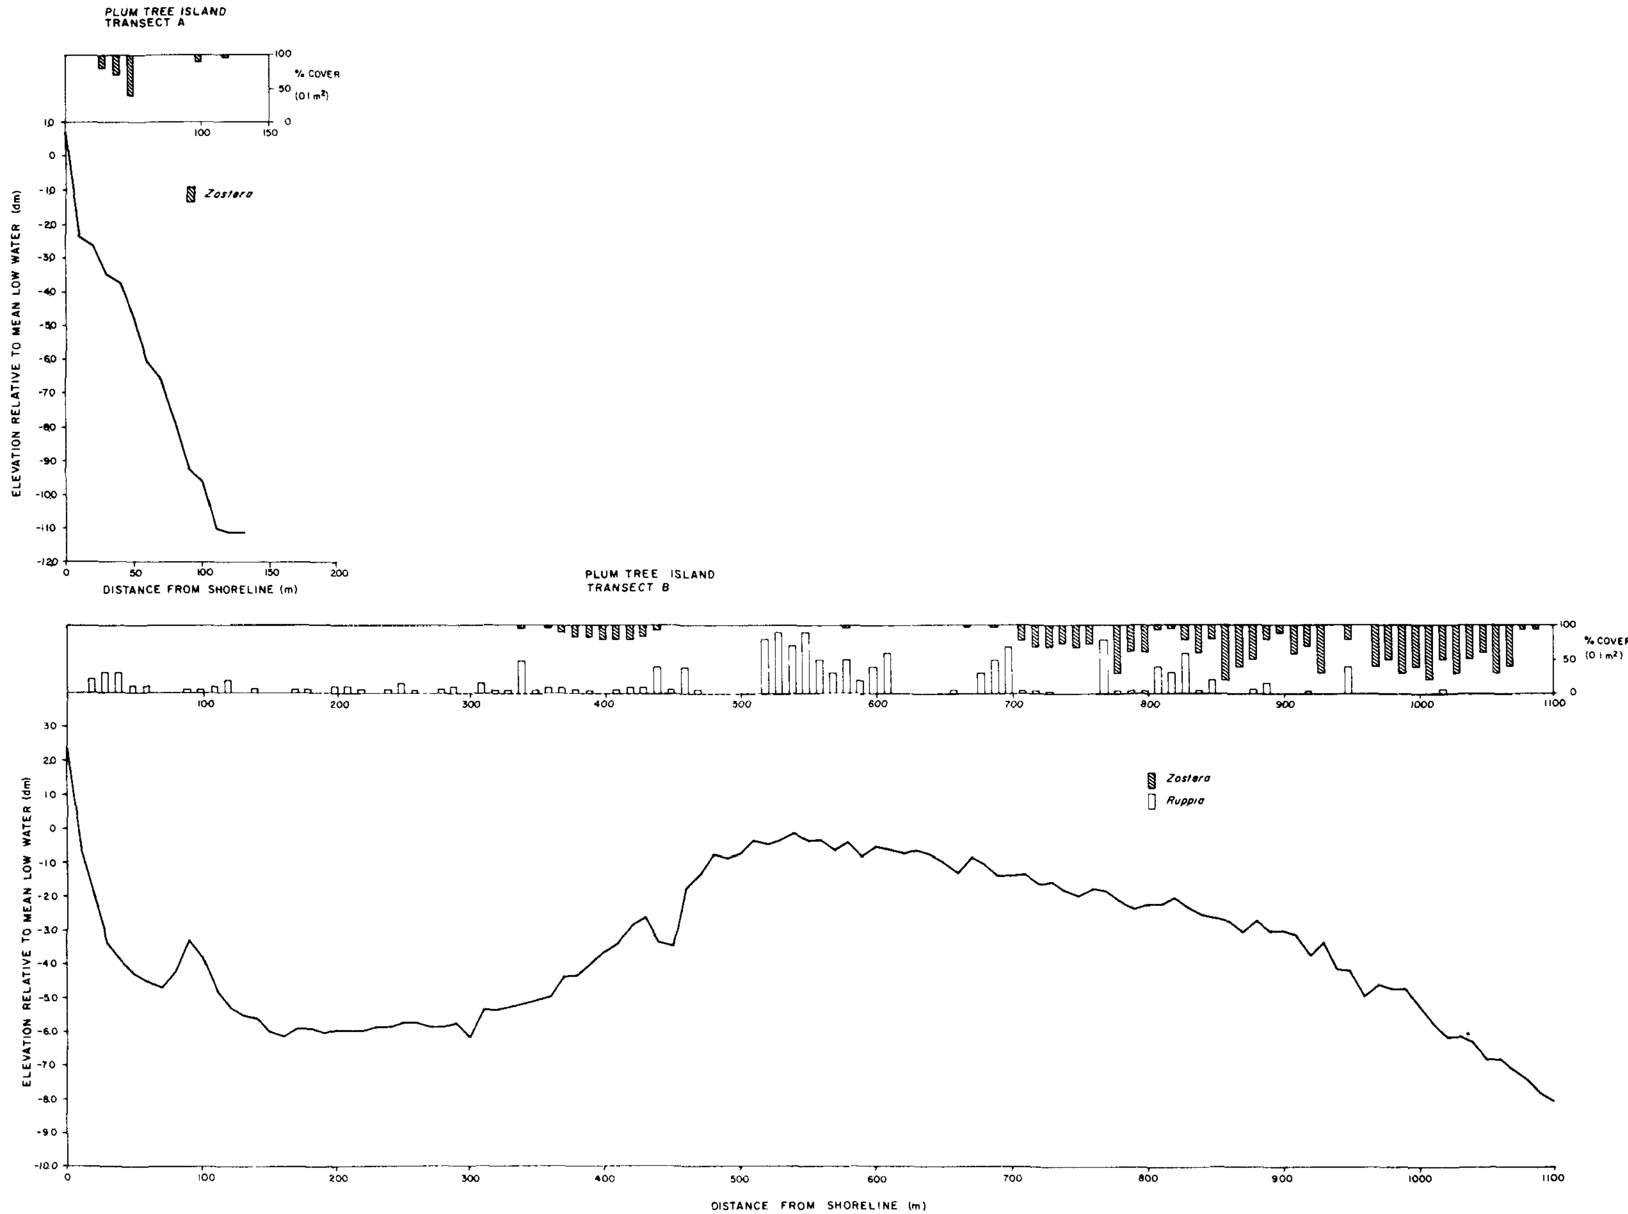

Figure 20. Depth profiles and percent cover estimates for Plum Tree Island transects.

several days of strong northeast winds. It appeared that nearly 10 cm of sand had been removed from portions of the bed. The *Zostera* looked quite healthy, however, and was being held in place by the remaining uncovered root system. The only *Ruppia* observed were those plants whose roots were entangled in the *Zostera* rhizome network. Apparently *Ruppia* may have difficulty remaining established at exposed locations. A return several weeks later to the same location indicated that fine sands were gradually filling in these exposed areas.

The importance values calculated for both species (Table 1) indicated *Ruppia* slightly more important than *Zostera* across transect B. This was primarily due to the greater relative frequency of occurrence of the *Ruppia* since both species had nearly equal relative cover.

Brown's Bay (Achilles quadrangle)

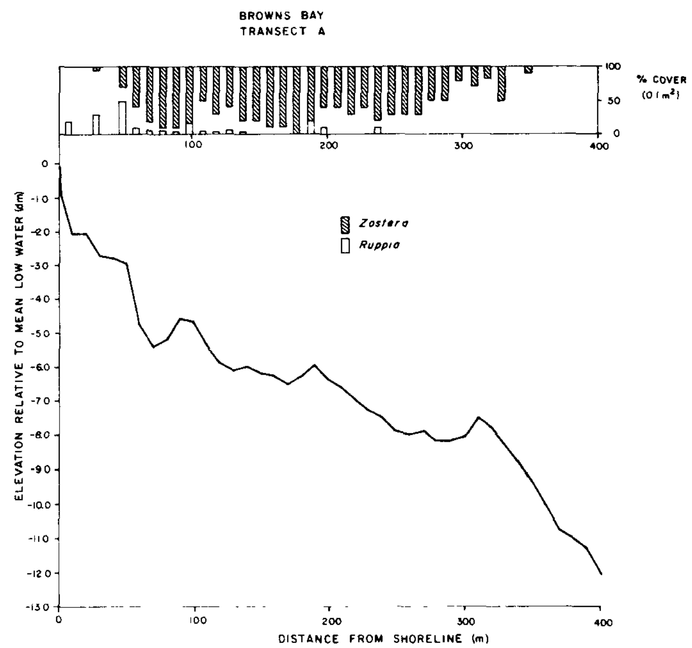
The Brown's Bay area is a large embayment located along a section of Mobjack Bay. It was characterized by very dense beds of *Zostera* and *Ruppia* nearly 400 m in width which were adjacent to extensive marshes dominated by Spartina alterniflora. Salinity values for samples taken while onsite averaged 18 ppt and water temperatures, 29°C. At low slack water one sunny afternoon, however, a temperature of 36°C was recorded in a nearshore *Ruppia* dominated zone.

Figure 21 presents two profile diagrams illustrating the transects conducted across this area. Transect A, the more northern of the two, was found to be composed predominately of *Zostera*. The importance value of this species was calculated to be 160.4 while that of *Ruppia* was 39.6 (Table 7). Of the two transects, transect A appeared to be the more exposed. It was adjacent to a creek channel and subject to strong winds from the north and northeast. *Ruppia* was never very abundant here and was not observed below -7.5 dm depth. *Zostera* on the other hand, continued offshore to a depth of -11.0 dm where the bottom continued to increase in depth but no further vegetation was observed. Throughout this transect the bottom was composed of fine sands with some eroded peat adjacent to the marsh shoreline.

Transect B was somewhat the more sheltered of the two in this area with a slope less than that of transect A. *Ruppia* was observed to be much more abundant here with an importance value of 90.0 versus 109.1 for *Zostera* (Table 7). For the most part this transect was characterized by dense mixed stands of the two grasses. *Ruppia* was observed last at a depth of -7.0 dm while *Zostera* continued to a depth of nearly -10.0 dm along a bottom composed of fine sand.

Ware Neck (Achilles quadrangle)

Two transects were conducted on either side of Ware Neck Point (Figure 22), a narrow peninsula located at the confluence of the Ware and North Rivers. Dense beds of *Zostera* and *Ruppia* are found along the lower shorelines of both of these rivers where they connect at Ware Neck Point.



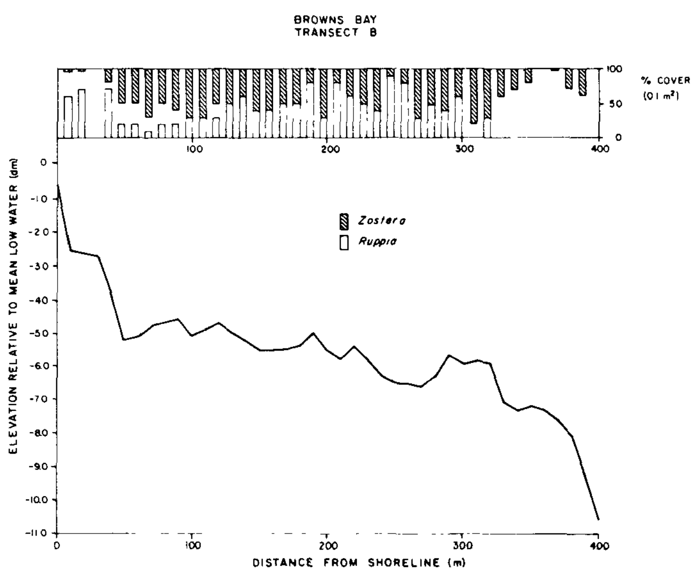


Figure 21. Depth profiles and percent cover estimates for Zostera and Ruppia at Brown's Bay transects.

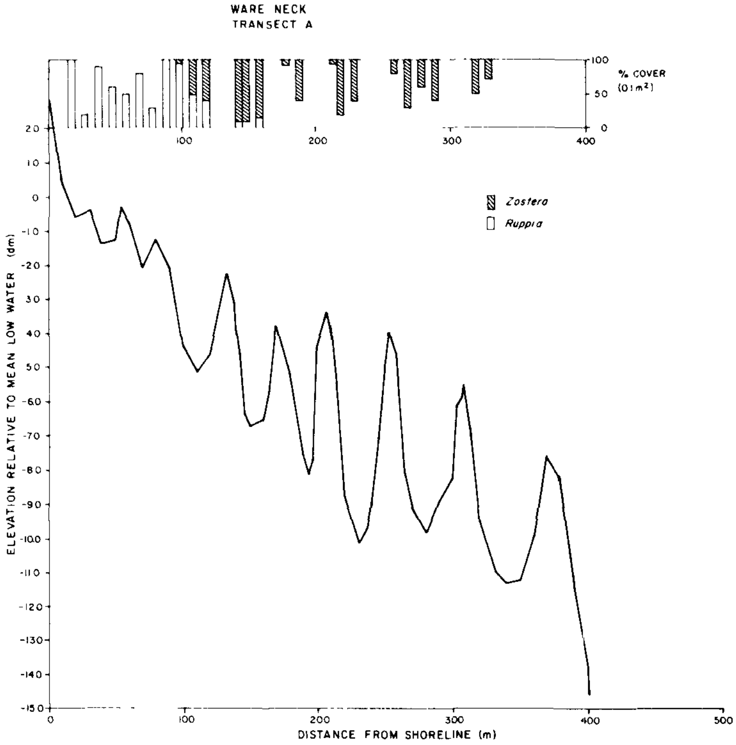

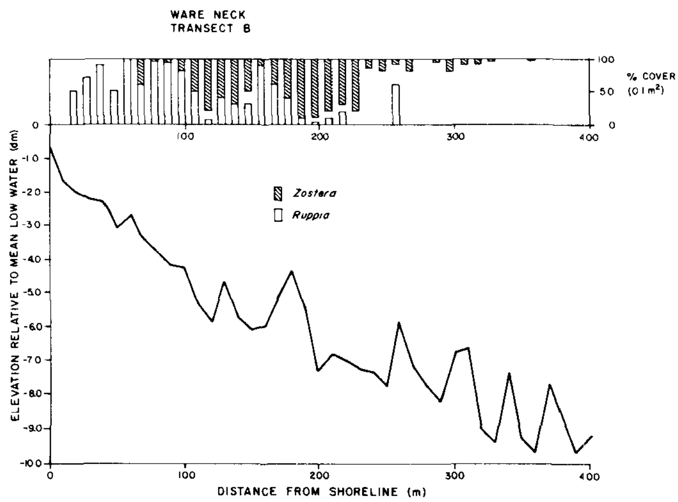

Figure 22. Depth profiles and percent cover estimates for Zostera and Ruppia at Ware Neck transects.

Salinities were found to average 17.5 ppt and water temperatures 30.0°C. The point itself was characterized by a series of radiating, parallel bars separating patches of SAV. Review of historical photographs for this site indicates that these bars have remained relatively stable over the last 20 years.

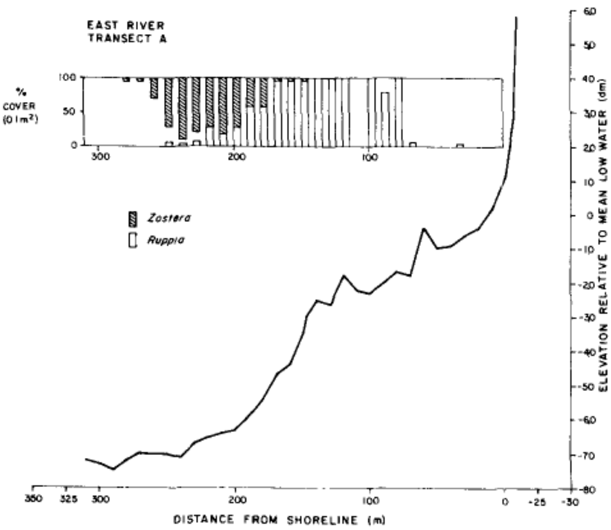
Transect A was run from a shoreline of sandy beach on the North River side of the point in a direction approximately perpendicular to the radiating bars. The nearshore zone of this transect was characterized by dense stands of Ruppia which began at a depth of near MLW. The first significant bar was observed at a distance of 54 m from shore and was unvegetated at its highest elevation (-0.3 dm). Ruppia continued again on the offshore side of this bar but was absent again at the shallowest portion of the next bar located at a distance of 75 m from shore and an elevation of -1.0 dm. Zostera was first observed in a swale between two bars at a distance of approximately 100 m from shore. Each succeeding bar was unvegetated along its crest although the depths varied only from -2.0 dm to -5.0 dm, elevations suitable for the growth of both Zostera and Ruppia. Interestingly, from 150 m outward, only the offshore slopes of the bars were vegetated until at a distance of 290 m and depth of -9.0 dm, the vegetation ended. Ruppia was last observed at 160 m from shore at a depth of -6.5 dm. From then on the pattern of bar - vegetation - bar consisted solely of Zostera. Integrating the whole transect, Ruppia was found to have an importance value of 111.6 compared to Zostera's 88.4 (Table 7). The greater relative cover by Ruppia, especially in the nearshore zone, was primarily responsible for this dominance.

Transect B was run offshore in similar manner to transect A but on the Ware River side of the point. It was characterized by a series of less distinct bars as well as a broader zone vegetated with Ruppia mixed with Zostera. For the most part both the ridges and swales of the parallel bars were vegetated with grasses, however, the slopes of the bars were much less than that observed along transect A. Ruppia was found to occur offshore to a distance of 260 m and a maximum depth of -7.3 dm. Zostera was observed to be growing at a maximum depth of -9.7 dm nearly 360 m from shore. Importance values for both species were nearly identical, 102.0 for Zostera versus 98.0 for Ruppia (Table 7). Zostera had the greater relative frequency but Ruppia the greater relative cover.

East River (New Point Comfort quadrangle)

The East River is located along the eastern shoreline of Mobjack Bay and was characterized by broad fringing beds of SAV located near its mouth. Few submerged aquatics were recorded within the river system. The shoreline of Mobjack Bay both north and south of the river also consisted of broad areas of submerged aquatics. As with the other areas of SAV around the Bay, Zostera and Ruppia were the only two species found.

Figure 23 presents profile diagrams of the two transects conducted along this region. Transect A was located immediately south of the East River along the Mobjack Bay shoreline and transect B immediately north of



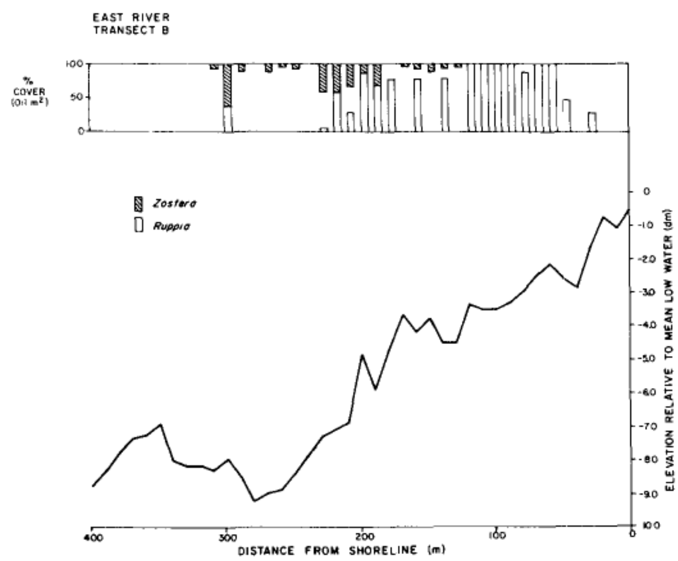


Figure 23. Depth profiles and percent cover estimates for Zostera and Ruppia at East River transects.

the river's mouth. Salinities at both sites averaged 18 ppt and water temperatures varied between 29°C and 32°C.

Transect A was characterized by a nearshore zone of Ruppia grading to an offshore zone of largely Zostera. The shoreline was one of rapidly eroding upland with a fringing marsh of Spartina alterniflora located nearly 10 m offshore. Ruppia was not observed until nearly 30 m from this marsh fringe at a depth of -.07 dm, the intervening bottom was composed largely of coarse sand. Between the 70 m and 170 m distance, Ruppia predominated with dense stands of flowering shoots. At a depth of -0.5 dm and a distance of 175 m, Zostera rapidly increases in abundance and continued its dominance until the end of the grass bed at approximately 300 m. Comparison of the importance values for both species, 122.8 to 77.2 (Table 7), indicates Ruppia to be clearly the most dominant species. It was found to occur at both greater density and relative cover.

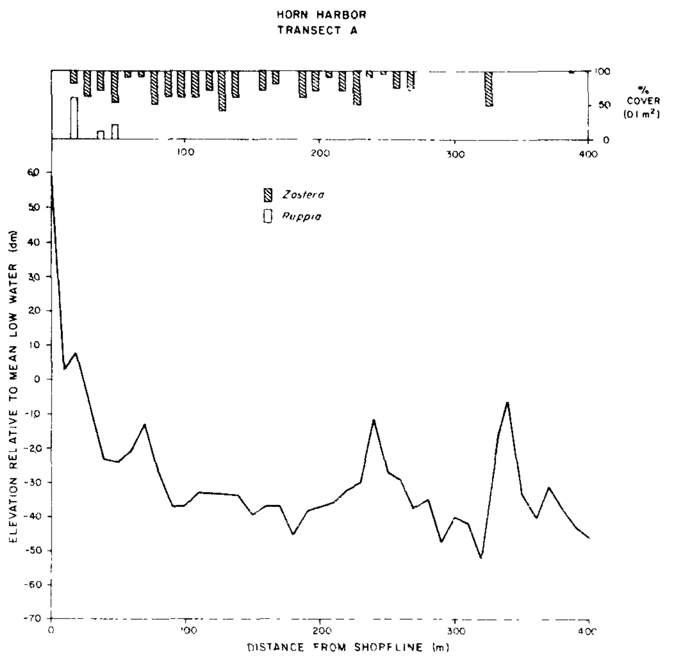
The outer edge of the bed consisted of sparse coverage by Zostera along a relatively flat bottom of fine sand. The depth, approximately -7.2 dm, continued without much increase for a considerable distance offshore. Despite the fact that this depth is suitable for growth of Zostera, none was present. A review of the historical aerial photography (see Historical Areas-East River) indicated that as recently as 1974 this area was indeed vegetated with SAV. Reasons for the retreat of the edge bed are as yet undetermined.

Transect B was run offshore from a relatively stable shoreline of Spartina alterniflora dominated marsh. The SAV bed was characterized by a broad, shallow (<-0.5 dm) Ruppia zone grading to a narrow, deeper (>0.5 dm) zone with sparce coverage by Zostera. Again Ruppia had the greater importance value, 134.8 to 65.2 for Zostera (Table 7). Although the relative frequency of both species were similar, Ruppia with its greater relative cover, primarily in the dense nearshore zone, was determined to be the most dominant. A small submerged bar was evident along the outer edge of the bed; however, it was unvegetated and no vegetation was observed beyond the bar.

Horn Harbor (New Point Comfort quadrangle)

Figure 24 presents profile diagrams of the two transects conducted at the Horn Harbor area off Potato Neck. The region is characterized by a shoreline of Spartina alterniflora dominated marsh with an adjacent broad zone of SAV. It lies along the Chesapeake Bay and, as such, is exposed to strong winds and long fetch from the northeast, east, and southeast. Considering this exposure, it was not unusual to find that both transects were dominated by Zostera. At transect A Zostera was found to have an importance value of 181.3 compared to Ruppia's 18.7 (Table 7). Transect B was similar with values of 177.7 and 22.3 for Zostera and Ruppia respectively (Table 7). Salinities were found to average near 18 ppt and water temperatures of 24.5°C were recorded at both sites.

Transect A was characterized by a narrow zone of mixed grasses along the shoreline, rapidly changing to a Zostera dominated community only 50 m



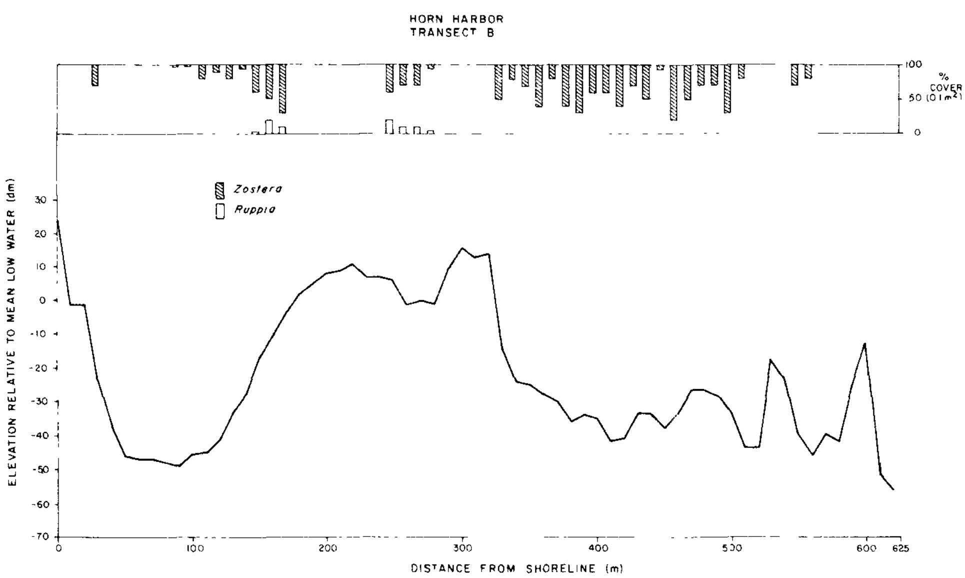


Figure 24. Depth profiles and percent cover estimates for Zostera and Ruppia at Horn Harbor transects.

from shore. Zostera was also found to be growing at quite shallow depths here. This transect and transect B to the south were the only two areas where Zostera was found above calculated MLW. Since these elevations were only +0.7 dm and +0.6 dm, they are within the error measurements of the technique and may in fact not be above MLW. Zostera also appeared to end at much shallower depths here than at any of the other transected areas. It was generally not found below -4.5 dm at either transect, as compared, for example, with -11.0 dm at the Ware Neck site.

On several occasions winds from the south were observed to have re-suspended sediments in the area to such an extent that visibility in the water was virtually zero and transect operations had to be halted. Since southerly winds are common during the growing season here, perhaps, the Zostera has been relegated to the shallow depths by severe light limitations due to turbidity conditions.

Transect B, located several kilometers south of Transect A, crossed an offshore sandbar vegetated with Spartina alterniflora and continued to the outer edge of SAV growth. On the landward side of this bar the area was quite protected and the sediments consisted of thick deposits of silt. Almost no SAV was found growing here but large amounts of detached Zostera and Ruppia was observed, apparently washed in from adjacent areas. Scattered Ruppia was observed growing on the offshore bar at depths near MLW. On the Bay side of the bar however, only Zostera occurred. The bottom here consisted of fine sands and, as with transect A to the north, the Zostera ended at a relatively shallow depth of -4.6 dm.

Vaucluse Shores (Franktown quadrangle)

The Vaucluse Shores area consisted of a large, triangular-shaped bed of SAV which was 700 m across at its widest point and over 3500 m in length. The system is protected from strong west and northwest winds and long fetch of the Chesapeake Bay by a series of broad, well defined offshore bars. Review of historical photographs (see Historical Analysis-Vaucluse Shore) indicated that these intertidal bars were moving in a north-south direction along the shoreline in conjunction with the movement of large sand spits. The northern half of the bed was actually a fairly recent phenomenon (<20 years) and was formed as one of the more northern bars migrated south. The bars protecting the southern half of the beds, possibly controlled by tidal movements through the Hungar's Creek inlet, have remained relatively stable over the last 40 years.

The distribution of SAV within the Vaucluse Shores site has been sampled with seven transects (A1,A,B,C,D,E,F). Figure 25 illustrates the locations of these transects across the SAV bed. Zones of similar vegetational composition as determined from the transects are also outlined. The profiles of these transects are presented in three figures 26a, b and c.

As with the other areas of SAV previously described around the lower Bay, Zostera and Ruppia dominated this site. A zone of Ruppia and Zannichellia palustris was, however, noted at transect F. As described

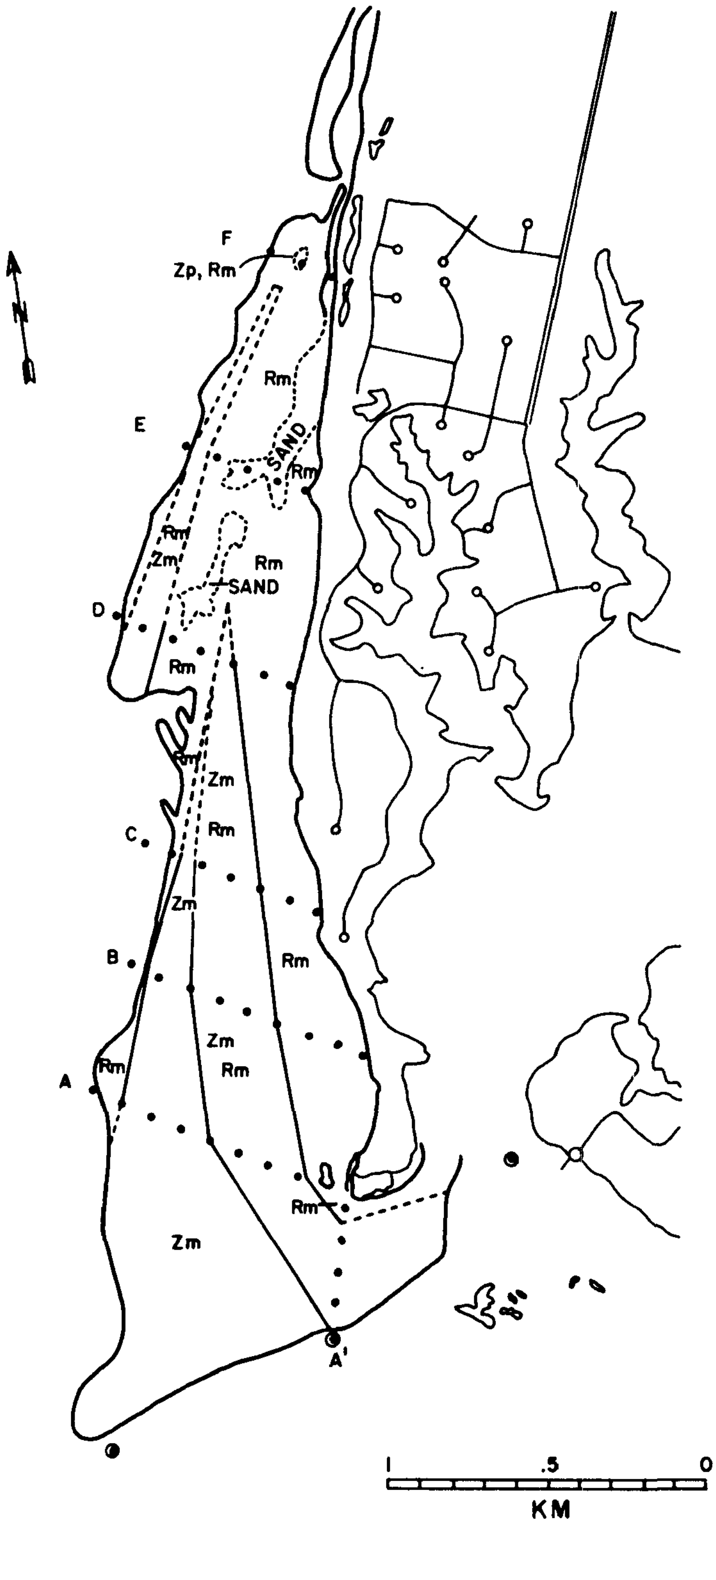

Figure 25. Delineation of SAV bed, zones of similar vegetation and position of transects at Vaucluse Shores area.

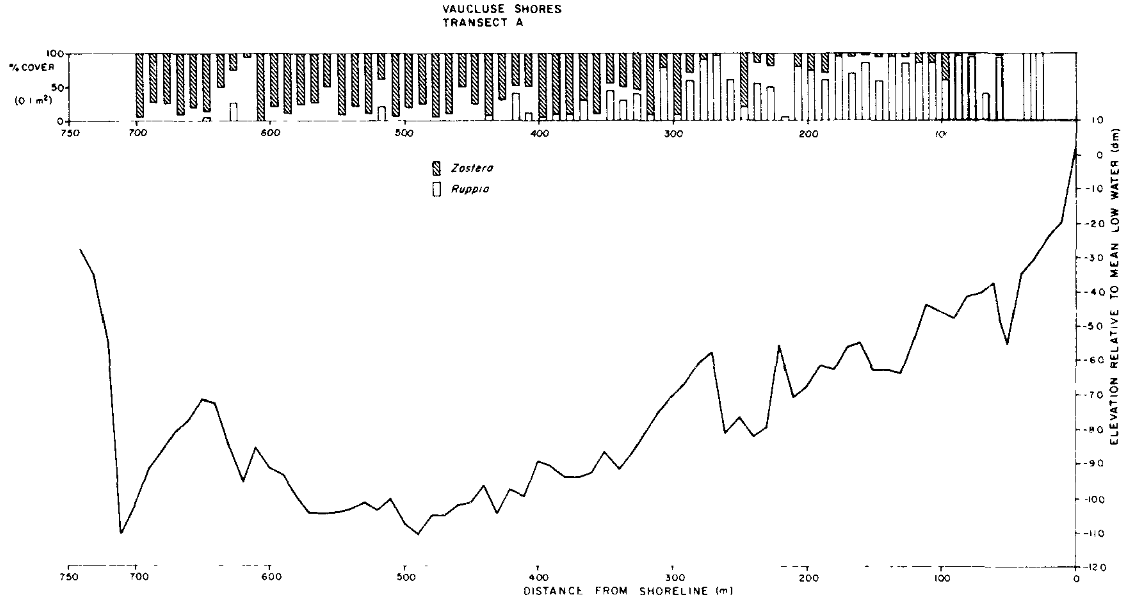

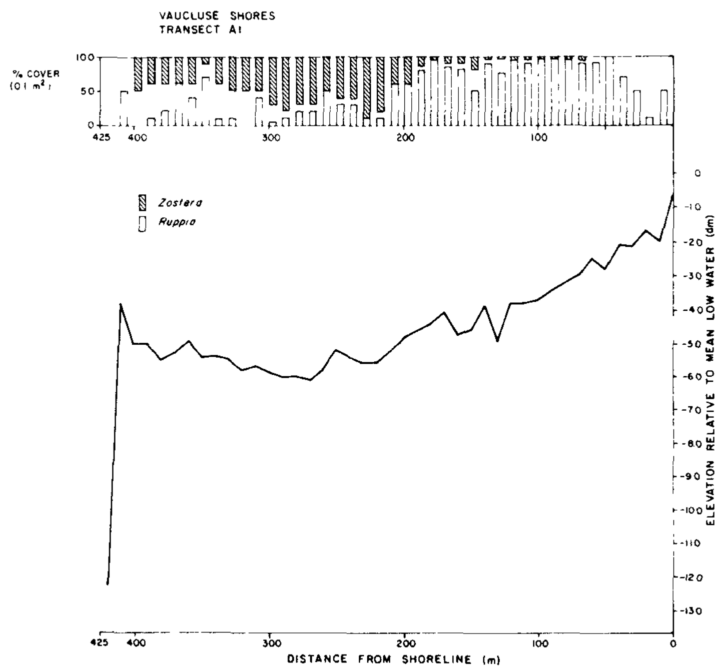

Figure 26. Depth profiles and percent cover estimates for Zostera and Ruppia at Vaucluse Shores transects.

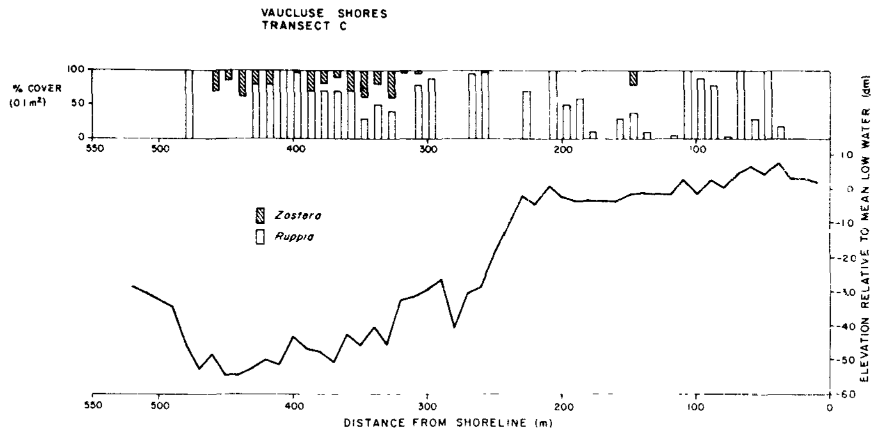

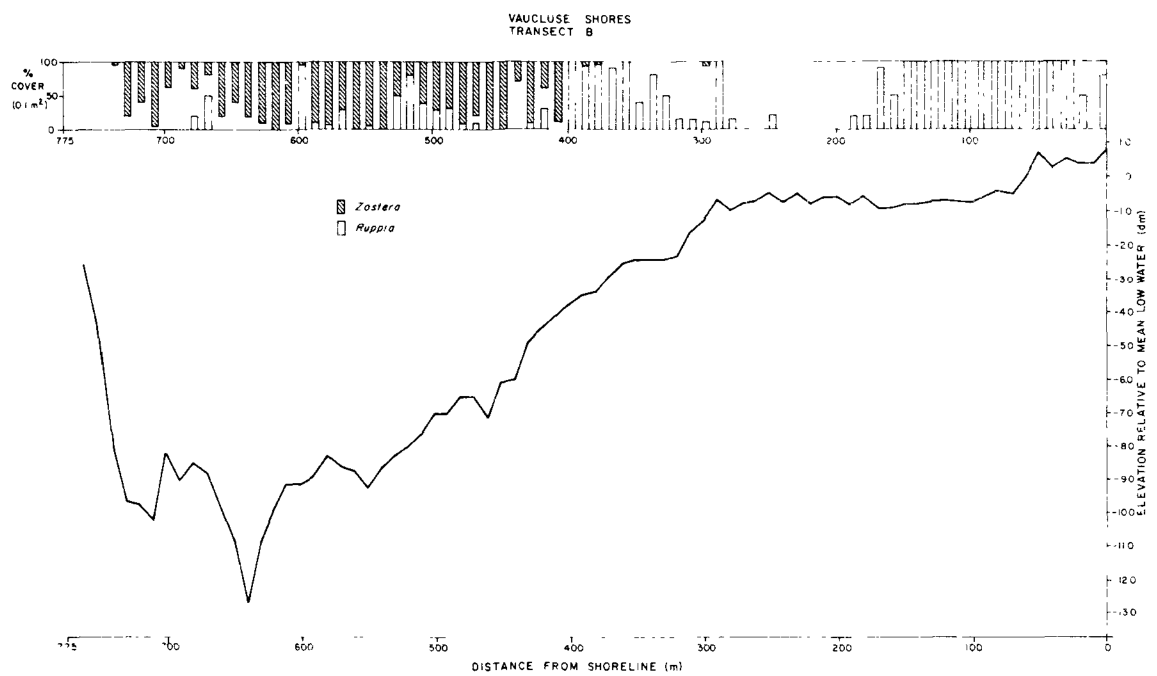

Figure 26. (Continued)

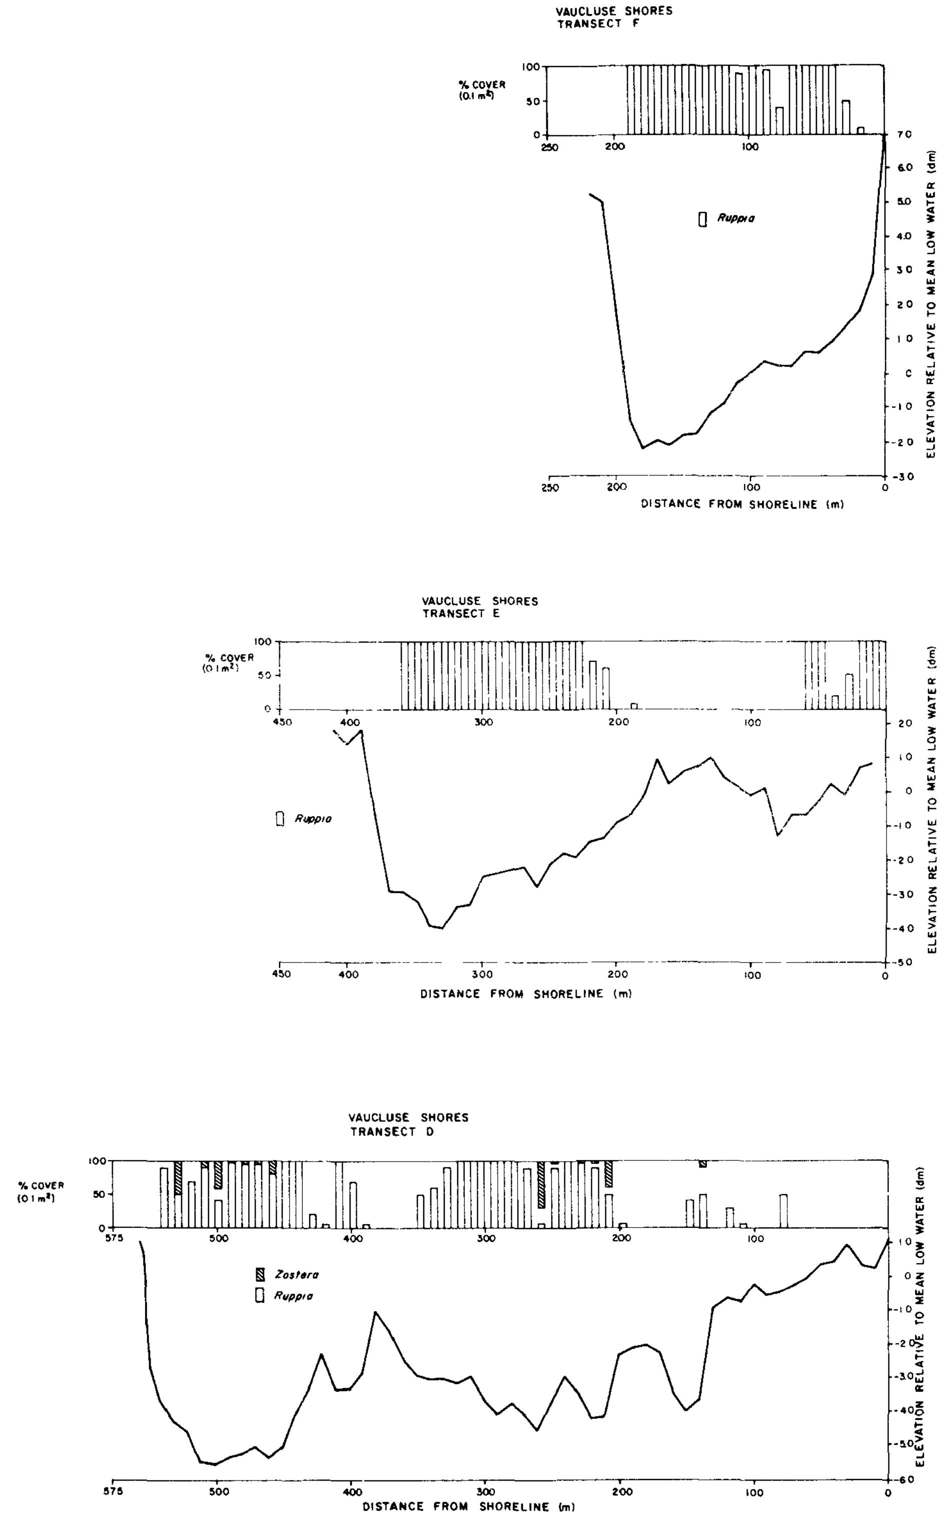

Figure 26. (Continued)

previously and illustrated in Figure 19, Zostera and Ruppia dominated at different depths. Since the greater depths occur within the southern portion of the bed, Zostera was dominant there; while in the shallow, northern portion (above transect D), Ruppia predominated. In addition, Ruppia was the only species recorded throughout the shallow inshore areas located south of transect D. For most of its length Vaucluse Shores was the only one of the six transected areas where the offshore limits of plant growth were not limited by increasing depths. Here the sand bars acted as well-defined boundaries to plant growth except along the inlet channel to the south.

Transect A1 was run from a small marsh island adjacent to the tip of the Vaucluse peninsula, south to a fixed channel marker. It illustrates to some extent the gradation from Ruppia to Zostera found throughout the rest of the bed, although the water depths here were not sufficient to exclude Ruppia from any portions of the transect. As a result the importance value for Ruppia was found to be 119.6 compared with only 80.4 for Zostera (Table 7).

Transect A crossed one of the deeper sections of the bed with a resultant zone of largely Zostera observed from 450 m to 700 m. Aerial imagery revealed a series of short, crescent-shaped bars located in the Zostera zone near transect A. These were vegetated with a mixture of Ruppia and Zostera. Portions of several of these bars were indicated at 520 m and 630 m from shore. As with the other transects, Ruppia dominated the nearshore zone of transect A, grading next to an interim zone of Zostera and Ruppia, before finally becoming a deeper zone of predominately Zostera. As the water depths shallowed on the offshore bar scattered Ruppia was observed.

Importance values calculated for transect A revealed Zostera to be the dominant species, 119.6 versus 80.3 for Ruppia (Table 7). Zostera occurred with both a greater relative frequency and relative cover. Transect A, however, was the only profile at Vaucluse Shores where this occurred.

The profile diagram of transect B indicates the broad, inshore zone of Ruppia which changed rapidly to an offshore zone of Zostera as depths increased. Importance values calculated for this transect again revealed Ruppia to be the more dominant species, 113.7 to 86.2 (Table 7).

A comparatively deep channel appeared to run in a north-south direction just inside of the offshore bar. It was vegetated primarily by dense stands of Zostera. The channel was observed to be quite wide at transect A, narrowing somewhat at transect B, and shoaling and narrowing further at transect C. Cores taken along the offshore bar between transect B and C revealed Zostera rhizomes as deep as 1 m below the sediment surface indicating recent bar movement into this channel and shoaling within this part of the bed.

Transect C was dominated primarily by Ruppia. It is here that recent changes have been observed in species dominance from Zostera to Ruppia. As mentioned above, the area was possibly in response to shoaling due to bar movement.

Transects D, E, and F illustrate the habitat found in the northern portion of the Vaucluse Shores site. Here Ruppia predominated as bottom depths rarely exceeded -5.0 dm. Zannichellia was observed throughout a small area crossed by transect F. Although it was not found in any of the other transected areas, it is widely distributed species in the Bay and is tolerant of mesohaline waters.

A relic bar, which used to form the northern limit of the SAV bed, was observed to come ashore just north of transect E. It can be seen in the profiles at approximately 360 m along transect D and 150 m along transect E. A small channel was observed between this bar and the larger bar which now forms the offshore limits of the bed. Zostera was observed throughout this channel as it continued north some distance above transect E. Evidence again indicated that this entire upper portion of the Vaucluse Shores bed was rapidly shoaling due to the southward bar and spit migration. Eventually, it should become too shoal even for Ruppia to exist, thus illustrating the dynamic nature of the SAV beds found along this eastern shoreline of the Bay.

DISTRIBUTION OF SAV ALONG VIRGINIA'S TIDAL SHORELINE

Virginia is endowed with over 5300 km (3,300 miles) of tidal shoreline in which much of the adjacent littoral zone has the potential for supporting submerged aquatic vegetation. As described previously, this shoreline can be divided into two regions. The first consists of the mesohaline and polyhaline areas of the Chesapeake Bay and its major tributaries (James, York, Rappahannock, Potomac, etc.). The second includes the oligohaline and freshwater portions of the major tributaries. Historically, the first region with its Zostera and Ruppia beds has received the greatest attention since it has been found in this study to have SAV covering over 8400 hectares (20,750 acres) of shallow bottom in densities ranging from very sparce (<1 per m^2) to very dense (>1000 m^2). These areas are of extremely high value to the coastal ecosystem and their locations and relative densities have been described previously in this report.

However, continuum exists between these higher salinity areas (15-25 $^o/oo$) and the tidal, freshwater areas of the major rivers. Figure 4 and Appendix C present the data obtained from the field sampling along this continuum. Time did not permit an exhaustive field survey of all portions of Virginia's tidal rivers and Bay shoreline but enough data were obtained from selected areas to provide a description of the distribution and abundance of SAV's throughout tidal Virginia.

Species Associations

Table 8 lists a total of 20 species of submerged aquatics and their percent occurrence at the 93 locations which contained vegetation. Since

TABLE 8. PERCENT OCCURRENCE OF SAV SPECIES AT 93 STATIONS THROUGHOUT TIDAL VIRGINIA

Species	Percent Occurrence
Zannichellia palustris	42
Ceratophyllum demersum	35
Najas minor	23
Vallisneria americana	13
Elodea canadensis	13
Nitella sp.	12
Najas quadalupensis	12
Zostera marina	12
Ruppia maritima	12
Potamogeton pectinatus	6
Callitriche verna	6
Potamogeton perfoliatus	6
Potamogeton cripus	5
Myriophyllum spicatum	3
Potamogeton filiformis	3
Chara	2
Najas flexilis	2
Elodea nuttallii	1
Potamogeton nodosus	1
Potamogeton foliosus	1

this was not a random sampling of locations along Virginia's shoreline, it cannot be considered truly representative of the relative abundance of each particular species throughout Virginia. Certainly Zostera and Ruppia would have to be considered the overwhelmingly dominant species found in Virginia's tidal waters. They are nearly the only species found in the mesohaline and polyhaline regions (except for Zannichellia) and form extensive beds many thousands of m^2 in size. However, except for an occasional area of Ruppia, they are not found where salinities are consistently below 10 ppt (VIMS, Data Base). For the purposes of minimizing redundance only those areas of Zostera and Ruppia where transects were made are included in Appendix C. All other locations where Zostera and Ruppia were found are marked on the appropriate topographic sheets included in Appendix B. It is apparent from this study as well as previous work (Orth, 1976, 1977b) that Zostera and Ruppia both co-occur in varying amounts in nearly all the mesohaline and polyhaline grass beds.

A dendogram of plant species associations calculated for the data in Appendix B is presented in Figure 27. This inverse, hierarchical classification (Boesch, 1977) shows three primary plant associations: A, B, and C. (Table 9), with Callitriche verna associated with both B and C.

TABLE 9. ASSOCIATIONS OF SAV IN VIRGINIA'S TIDAL WATERS

A	B	C
Zostera marina	Potamogeton crispus	Najas minor
Ruppia maritima	Potamogeton perfoliatus	Najas quadalupensis
	Potamogeton pectinatus	Ceratophyllum demersum
	Vallisneria americana	Elodea canadensis
	Zannichellia palustris	Nitella
	Callitriche verna	Callitriche verna
	Chara*	Potamogeton foliosus*
	Myriophyllum spicatum*	Najas flexilis*
		Potamogeton filiformis*
		Potamogeton nodosus*
		Elodea nuttalli*

*Less than 5 percent occurrence.

Those species which occurred in less than five percent of the field survey stations were omitted from the calculations. However, for completeness they have been reintroduced to the appropriate associations based on the locations of the few stations where they occurred and other nearby associated submerged vegetation.

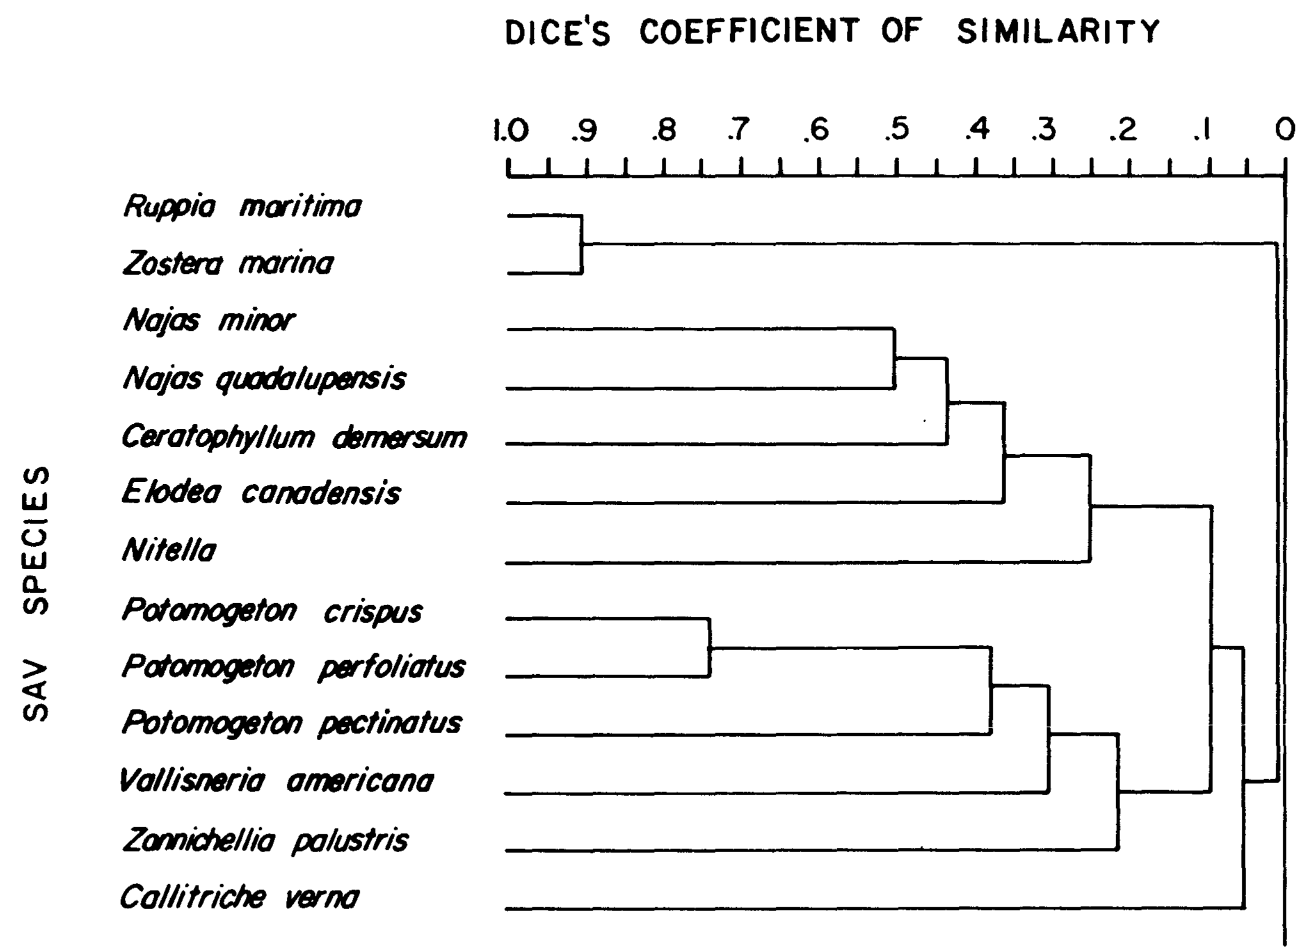

Figure 27. Dendrogram of SAV species associations in the lower Chesapeake Bay and its tributaries.

These three plant species assocations may best be explained by their locations and the salinity tolerance of each of the species. Species association A, composed of Zostera and Ruppia, is tolerant of the highest salinities found in the Bay, and therefore, they are found dispersed along the lower Bay shoreline as well as the lower portions of the major rivers.

It is interesting to note that although Ruppia is much more tolerant of freshwater than Zostera (Stevenson and Confer, 1978), it is not found to any significant extent in Virginia rivers upstream from those areas where it co-occurs with Zostera. Kerwin (1966) reported finding Ruppia in the Poropotank River, a tributary of the York River located approximately 14 km above the most upstream areas where large Zostera and Ruppia beds have been recorded (i.e. Claybank). Surveys of the Poropotank conducted for this study revealed no Ruppia, although numerous other species (Ceratophyllum demersum, Potamogeton pectinatus, etc.) were found (Appendix C).

Species association B listed in Table 9 includes those species common in waters where salinities are generally 15 ppt or less. In Virginia these species have been found to occur in varying amounts in each of the major rivers, however, the largest beds occur along the Potomac River in the vicinity of Upper Machodoc Creek. In the other rivers these species tend to occur only in small pocket areas at the head of numerous marsh guts where they are generally not distinguishable from the air.

Zanichellia is generally more widespread than any of the other species in this group and occurs further downstream in areas of higher salinity. Although it grows mixed with the others in the group it also occurs in monospecific stands at the heads of many small creeks.

Vallisneria americana is found in greatest abundance along the Potomac River, especially in the vicinity of the Rt. 301 bridge (See Mathias Point Topographic Sheet, Appendix). It is also found in small amounts in each of the other rivers and occurs both above and below the upper limits of saltwater intrusion. Potamogeton perfoliatus, P. pectinatus and P. crispus are also most abundant along the Potomac River in the vicinity of Upper Machodoc Creek. Although appropriate salinity regimes (5-10 ppt) are found in each of the other major rivers, suitable shoal areas for the formation of large SAV beds are not present. Callitriche verna is another species which is found in the narrow transition zone between fresh and brackish water. It was observed at the heads of the Poropotank River adjacent to large areas of Taxodium distichum dominated swamps and at the heads several creeks along both the Rappahannock and Potomac River.

Association C includes those species that are commonly found in fresh-water areas. The decrease in the salinity tolerance from association A to B to C has resulted in an increase in diversity, with association C having the greatest species richness. Ceratophyllum demersum appears to be the most common, as it occurred at 35 percent of the sampling stations. It was generally observed floating throughout the heads of many freshwater creeks and in many areas formed dense stands especially along the Chickahominy River. Najas minor was also common throughout the Chickahominy

River as was Najas quadalupensis. N. minor was also observed along the Rappahannock River.

Species Distribution

The distribution of the 20 species of submerged vegetation found in this study have been described to some extent in the preceeding section and have been mapped and discussed in other sections of this report. It was felt by the authors, however, that a summary of how these species were distributed along Virginia's tidal rivers and Bay shoreline would be of value. Therefore the following section describes segments of Virginia's shoreline and the vegetation that was documented to occur or was most likely to occur there.

The upper portion of Virginia's side of the Potomac River, from the Chain Bridge in Washington, D.C. to Mathias Point Neck, contained few areas of SAV. Although little field work was conducted here during this study, aerial reconnaissance combined with previous field investigations in this region have failed to reveal any significant areas of SAV. However, based on the dominant marsh vegetation (i.e. Nuphar, Peltandra, Pontederia) found in the numerous creeks along this section of the river, small areas of Ceratophyllum demersum, Vallisneria americana and Najas are likely to exist, especially at the creek heads and in small marsh guts.

From Mathias Neck Point to Mattox Creek numerous areas of SAV were present. These included species such as Zannichellia palustris, Potamogeton crispus, Potamogeton perfoliatus and Vallisneria americana which were found along the shoreline of the lower portions of the major creeks. Scattered Zannichellia was common at the heads of these creeks, especially Upper Machodoc, Rosier, Monroe and Mattox. Myriophyllum spicatum occurred in isolated areas but had its densest concentration at the head of Rosier Creek.

From Mattox Creek downstream to Smith Point at the mouth of the Potomac few SAV existed. The absence of SAV along this section of the Potomac may be due to its greater degree of wave exposure which could preclude the development of SAV. The creeks, which had suitable habitat, were also lacking in submerged vegetation. Zannichellia and Ceratophyllum demersum were recorded at the head of Nomini Creek while Zannichellia and Myriophyllum were found at the head of Lower Machodoc Creek, but in neither area did they occur in significant quantities. Other creeks downstream from these two, such as the Yeocomico River, were generally devoid of submerged vegetation. It would not be unusual, however, especially in early summer, to find scattered small amounts of Zannichellia at the heads of these creeks. Large beds of SAV located at the mouth of the Coan River were observed in historical aerial photographs. Because of the high salinities in this region, they were probably composed of a mixture of Zostera marina and Ruppia maritima. They have not been present since at least 1971, however.

The section of Chesapeake Bay shoreline between Smith Point at the mouth of the Potomac River and Windmill Point at the mouth of the Rappahannock River was vegetated with numerous beds of Zostera and Ruppia. These have been mapped and described previously in this report. The numerous creeks found along this region (e.g. the Wicomico River) contained beds of Zostera and Ruppia along their lower portions. They may also have contained scattered Zannichellia near their heads, although none were observed in this study.

The Rappahannock River had a species distribution similar to that of the Potomac River, a progression form head to mouth of associations C to B to A (Table 9).

Although little field work was conducted in the most upstream tidal portions of the Rappahannock (above Rt. 301 bridge), scattered Ceratophyllum is likely to be found there associated with the areas of freshwater marsh and tidal swamp. Ceratophyllum was observed south of the bridge at the head of Elmwood Creek. From here downstream to Tappahannock no SAV were observed along the Rappahannock River shoreline. Several of the larger creeks, such as Cat Point, Mount Landing and Piscataway, did contain dense beds of SAV at their heads. Included were such species as Ceratophyllum, Najas, Callitriche verna and Vallisneria americana. Downstream portions of these and other creeks in this region contained scattered Zannichellia.

Large beds of SAV at one time (prior to 1971) extended as far upstream along the Rappahannock River shoreline as the town of Moratico. These were vegetated with Zostera and Ruppia. However by 1978, most of this shoreline was completely unvegetated.

Zannichellia was present along this region but only within the small tributary creeks, especially at their heads where salinities were reduced. Priest (personal communication) reported Zannichellia found at most of the heads of the small creeks from this middle region of the river downstream to the Rappahannock River's mouth. The only Zostera and Ruppia beds observed within the river system were sparce areas occurred near the mouth of the Corrotoman River.

The shoreline between the Rappahannock and York Rivers contained extensive beds of Zostera and Ruppia, especially in the region of Mobjack Bay. These have been mapped and described previously. The Piankatank River did contain submerged vegetation at its head in contrast to the other creeks in this region. Here species tolerant of oligohaline and freshwater conditions occurred. They included Nitella, Callitriche, Najas, Ceratophyllum and Elodea. Callitriche continued upstream from the Piankatank into an area of tidal swamp known as Dragon Run. Nitella formed scattered dense pockets in shallow areas just downstream from the swamp, while the other species formed small fringes or pocket areas associated with the adjacent marsh vegetation. In the middle reaches of the Piankatank Zannichellia was observed (Priest, personal communication) while at the near of the river's mouth scattered sparce beds of Zostera and Ruppia were found.

The York River contained extensive areas of oligohaline and freshwater marshes and swamps along its two tributaries, the Mattaponi and Pamunkey Rivers. However, large amounts of organic matter were present in these waters, and as such, the areas appeared unsuitable for SAV. Ceratophyllum, which is tolerant of low light conditions, was the most common species found associated with these wetland areas, but it was widely scattered and in sparse amounts.

Downstream from the confluence of the Mattaponi and Pamunkey Rivers, at West Point, to the town of Gloucester Point, no SAV was found along the York River shoreline. Several of the larger creeks along this section (e.g. Ware Creek, Poropotank River) did, however, contain small, dense beds of submerged vegetation at their heads. Here numerous low salinity and freshwater grasses occurred including Ceratophyllum, Elodea, Nitella, Vallisneria, etc. Downstream portions of these and other creeks, where salinities were higher, contained Zannichellia but in sparse amounts.

From Gloucester Point and Yorktown, downstream to the mouth of the York River, scattered beds dominated by Zostera and Ruppia occurred. The small creeks along this section of the river were generally devoid of vegetation in their upstream portions. The region from the mouth of the York River south to New Point Comfort at the mouth of the James River contained extensive beds of Zostera and Ruppia which have been mapped and described previously in this report. The two large creeks found along this region, the Poquoson and Back Rivers, have Zostera and Ruppia near their mouths, but little submerged vegetation within the creeks themselves.

The upper James River contained extensive areas of tidal freshwater marsh and swamp from the Chickahominy River upstream to its fall line in Richmond. Although no field work was conducted in this region during this study, aerial reconnaissance combined with previous field investigations here have failed to reveal significant areas of SAV. It would not be unlikely to find scattered Ceratophyllum, as well as other freshwater species associated with these wetland areas, however.

The submerged vegetation found within a portion of the Chickahominy River, a major tributary of the James, has been described in detail earlier in this report. Generally, it consisted of fringe and pocket areas of Ceratophyllum and Najas associated with the adjacent Peltandra dominated wetlands. Although only a portion of the Chickahominy was mapped for this report, the remainder of the river system contained a similar distribution of SAV species.

From the Chickahominy River downstream to the mouth of the James River few SAV species were found. Several of the creeks along this region contained submerged vegetation in very sparse amounts. Ceratophyllum was recorded at the head of Grays Creek, while Zannichellia was found in Skiffes Creek, Mill Creek and the Warwick River. In no place did they occur in more than trace amounts.

The submerged vegetation found along Virginia's eastern shore has been mapped and described previously in this report. The SAV consisted of large beds of very sparce to very dense areas of Ruppia and Zostera located at the mouths of the numerous creeks found along this region, as well as adjacent to the necks of land separating these creeks. The greatest concentrations of SAV were found in the vicinity of Hungar's and Cherrystone

Creeks. The Vaucluse Shore area located at Hungar's Creek has been described in detail earlier. Other creeks further north along this shoreline contained large areas of SAV but in much reduced densities. No SAV was observed at the heads of these creek systems, although it would not be unlikely if scattered *Zannichellia* did occur.

Along the Maryland-Virginia border little SAV occurred in the vicinity of the Pocomoke River. Further west in the shoal areas behind several of the Bay islands including Tangier and Great Fox, large beds of SAV were found. Here, as along the rest of the eastern shoreline of Virginia *Zostera* and *Ruppia* predominated.

APPENDIX A

GENERAL GUIDELINES FOR MISSION PLANNING AND EXECUTION FOR OBTAINING AERIAL PHOTOGRAPHY OF SAV

1. Tidal Stage - Imagery will be acquired at low tide, ± 1.5 feet, as predicted by the National Ocean Survey (NOS) tables. Record tidal stage.

2. Plant Growth - Imagery will be acquired when growth stages ensures maximum delineation of SAV, and when phenologic stage overlap is greatest. Record plant growth stage (dormant, juvenile, mature, etc.).

3. Sun Angle - Imagery will be acquired when surface reflection from sun glint does not cover more than 30% of frame. Sun angle should generally be between 20° and 40° to minimize water surface glitter. At least 60% line overlap and 30% side lap will be used to minimize image degradation due to sun glint. Record sun angle and time of day of imagery acquisition.

4. Turbidity - Imagery will be acquired when clarity of water ensures complete delineation of grass beds. Record water turbidity conditions.

5. Wind - Imagery will be acquired during periods of no or low wind (no maximums have been established). Off-shore winds are preferred over on-shore winds if wind conditions cannot be avoided. Record wind speed and direction.

6. Atmospherics - Imagery will be acquired during periods of no or low haze and/or clouds below aircraft. There should be no more than scattered or thin broken clouds, or thin overcast above aircraft, to ensure maximum SAV to bottom contrast. Record cloud cover and haze conditions.

7. Sensor Operation - Imagery acquired will be vertical with less than 5 degrees tilt. Scale/altitude/film/focal length combination will permit resolution and identification of one square meter area of SAV (surface). Record film/filter/camera/focal length combination and imagery scale.

8. Plotting - Each flight line will include sufficient identifiable land area to assure accurate plotting of grass beds. Record compass direction and aircraft speed and altitude.

APPENDIX B

APPENDIX C

DISTRIBUTION OF SAV PRESENTING STATION NUMBER, DATE OF SAMPLING, LOCATION OF STATION, SPECIES PRESENT AT THAT STATION AND THEIR RELATIVE ABUNDANCE AND GENERAL OBSERVATIONS AT THE STATION (SEE FIGURE 4 FOR STATION LOCATION)

Station	Date	Location	Species	Relative abundance	Observations
1	7-12-78	Salters Creek	none	–	No SAV observed in creek. *Sa* dominated marsh along shoreline.
2	7-12-78	Hampton River	none	–	No SAV observed from inside mouth to head of River. *Sa* marsh fringe.
3	9-14-78	Long Creek	none	–	No SAV observed from inside mouth to head of marsh channel. *Sp*, *Jr* marsh.
4	9-12-78	Plum Tree Island	*Zm*	*Zm* dominant	Transect site; sparse *Zm* along bottom which rapidly drops off in depth.
5	9-19-78	Plum Tree Island	*Rm*, *Zm*	*Rm* dominant *Zm* dominant	Transect site; broad SAV bed extending from *Sa* marsh shoreline.
6	9-15-78	James River-Warwick River	*Zp*	*Zp* occasional	Sparse *Zp* at head of river; no SAV observed in downstream areas.

(continued)

APPENDIX C (continued)

Station	Date	Location	Species	Relative abundance	Observations
7	9-14-78	James River-Skiffes Creek	*Zp*	*Zp* occasional	Sparse *Zp* at head of creek; no SAV observed in down-stream areas.
8	7-7-78	James River-College Creek	none	-	No SAV observed in creek system.
9	7-7-78	James River-Mill Creek	*Zp*	*Zp* dominant	*Zp* in shallow embayed area near mouth of creek, fringing along *Sc*, *Pv* marsh.
10	7-7-78	James River-Powhatan Creek	*Nm*	*Nm* dominant	Scattered along small marsh gut near head of creek; associated marsh vegetation *Pd*, *Pv*, *Sa*; only SAV area observed in creek system.
11	6-23-78	James River-Grays Creek	*Cd*	*Cd* occasional	No SAV found throughout most of creek. *Cd* observed floating near head of creek; associated marsh vegetation of *Pd*, *Ta*.
12	8-24-78	Chickahominy River-Nayses Bay	*Cd*, *Nm*, *Ec* *Va*	*Cd* dominant *Nm* dominant *Ec* frequent *Va* occasional	Large SAV bed approximately 300 m in width covering shallow bay; *Cd* and *Nm* dominant with other species observed occasionally throughout.

(continued)

APPENDIX C (continued)

Station	Date	Location	Species	Relative Abundance	Observations
13	8-24-78	Chickahominy River- Gordon Creek	*Cd*, *Ng*, *Ec*, *Nm*	*Cd* dominant *Ng* abundant *Ec* frequent *Nm* occasional	Small bed of SAV at head of freshwater marsh gut.
14	8-24-78	Chickahominy River- Gordon Creek	*Cd*, *Nm*, *Nf*	*Cd* dominant *Nm* abundant *Nf* abundant	Narrow (2m) SAV fringe along edge of *Pu*, *Za*
15	8-24-78	Chickahominy River- Gordon Creek	*Nm*, *Cd*, *Ng*, *Nf*	*Cd* abundant *Ng* frequent *Nf* occasional *Nm* dominant	Narrow fringe (2m) of SAV along freshwater marsh of *Pd*, *Ne*
16	8-24-78	Chickahominy River- Gordon Creek	*Nm*	*Nm* dominant	Narrow fringe (1m) of *Nm* along edge of mixed tidal swamp and marsh at head of creek channel.
17	8-24-78	Chickahominy River	*Nm*	*Nm* dominant	Scattered small patches ($1m^2$) of *Nm* along shoreline of large, shallow embayed area; depth <1m at low water.
18	8-24-78	Chickahominy River- Blackstump Creek	*Nm*	*Nm* dominant	Narrow fringe of *Nm* along creek channel bordering freshwater marsh.
19	8-24-78	Chickahominy River- Blackstump Creek	*Nm*, *Cd*, *Ng*	*Nm* dominant *Cd* frequent *Ng* occasional	Dense bed of SAV at head of creek channel; adjacent marsh of *Za*, *Pv*, *B*, *Ta*.

(continued)

Station	Date	Location	Species	Relative Abundance	Observations
20	6-23-78	Chickahominy River-Yarmouth Creek	*Nm*, *Cd*, *Ec*, *N*, *Ng*	*Nm* dominant *Cd* abundant *Ec* frequent *N* frequent *Ng* occasional	SAV bed fringing on band 1-2m wide along *Nl*, *Pd* marsh.
21	6-23-78	Chickahominy River-Yarmouth Creek	*Cd*, *Ec*, *Nm*, *Ng*	*Cd* dominant *Ec* dominant *Nm* abundant *Ng* occasional	SAV bed fringing in band 1-2 m wide along *Nl*, *Pd* marsh.
22	6-23-78	Chickahominy River-Yarmouth Creek	*Cd*	*Cd* dominant	*Cd* fringing in band 2m wide along *Nl* marsh; also growing between *Nl*.
23	6-23-78	Chickahominy River-Little Creek	*Cd*, *Ec*, *Ng*	*Cd* dominant *Ec* abundant *Ng* occasional	1-2 m wide bed along edge of channel fringing *Pd*, *Nl* marsh.
24	6-23-78	Chickahominy River-Little Creek	*Cd*	*Cd* dominant	1 m wide fringe along edge of *Pd*, *Nl* marsh.
25	7-11-78	Chickahominy River-Sunken Marsh	*Nm*, *N*	*Nm* dominant *N* occasional	*Pd* marsh channel with intermittent, narrow (1m) band of SAV along edge of marsh.
26	7-11-78	Chickahominy River-Old Neck	*Nm*, *N*, *Ng*,	*Nm* dominant *N* occasional *Ng* occasional	Freshwater marsh gut with narrow (1 m) band of SAV along channel edge.
27	7-11-78	Chickahominy River-Big Marsh Point	*Nm*, *N*	*Nm* dominant *N* occasional	Narrow (<1m) fringe of SAV along *Pc*, *Pv* marsh.

(continued)

Station	Date	Location	Species	Relative Abundance	Observations
28	7-11-78	Chickahominy River	*Nm*, *N*	*Nm* dominant *N* occasional	Scattered small patches of SAV along *Nl* marsh.
29	7-11-78	Chickahominy River-Uncles Neck Creek	*Nm*, *Cd*	*Nm* dominant *Cd* frequent	Narrow SAV fringe (1-2 m wide) along edge of *Pd*, *Za* marsh; silt bottom; deep channel with no vegetation present.
30	7-11-78	Chickahominy River-Uncles Neck Creek	*Va*, *Nm*, *Cd*	*Va* dominant *Cd* frequent *Nm* abundant	Small marsh gut with SAV covering bottom at head of channel; *Cd* and *Nm* along sides; *Va* in center; associated marsh vegetation *Pd*.
31	8-2-78	York River-Ware Creek	*Cd*, *N*, *Ng*, *Ec*, *Va*, *Po*	*Cd* abundant *N* frequent *Ng* frequent *Ec* occasional *Va* occasional *Po* occasional	SAV along channel bottom at head of creek; adjacent marsh of *Pd*, *Pv*, *Za*.
32	8-15-78	Pamunkey River-Cook Landing	*Cd*, *Nm*	*Cd* dominant *Nm* frequent	Small freshwater marsh gut with scattered SAV along channel edge.
33	8-16-78	Pamunkey River-Big Creek	*Cd*	*Cd* dominant	Narrow fringe of *Cd* along edge of *Pv* marsh.
34	9-5-78	Mattaponi River-Carbin Creek	*Cd*, *Pi*, *En*	*Cd* dominant *Pi* occasional *En* occasional	Sparse fringe of SAV along shoreline at head of creek.

(continued)

APPENDIX C (continued)

Station	Date	Location	Species	Relative Abundance	Observations
35	9-5-78	Mattaponi River-Burnt Mill Creek	*Cd*, *Zp*, *Ng*	*Cd* dominant *Zp* frequent *Ng* occasional	Fringe of SAV along edge of freshwater marsh.
36	7-5-78	Poropotank River-Guthrie Creek	*Zp*	*Zp* dominant	Shallow marsh gut at head of creek; *Zp* found scattered on channel bottom (<1m); associated marsh vegetation *Za*, *Sa*.
37	7-5-78	Poropotank River	*Pc*	*Pc* dominant	Main branch of river at head; dense stands of *Pc*, *Zm* wide along channel; associated vegetation is wooded swamp with abundant floating *L*.
38	7-5-78	Poropotank River	*Cd*, *Ec*, *Zp*	*Cd* abundant *Ec* abundant *Zp* occasional	Small freshwater marsh gut near head of river; narrow (.5m) SAV fringe along *Pd* marsh.
39	7-5-78	Poropotank River	*Cd*, *Zp*	*Cd* abundant *Zp* occasional	Scattered patches of SAV along edge of freshwater marsh in small gut; associated vegetation *Pd*, *Pv*, *Za*.
40	7-5-78	Poropotank River-Poplar Spring Branch	*Pc*, *Cd*, *Zp*	*Pc* dominant *Cd* frequent *Zp* occasional	Dense bed of *Pc* at head of creek branch covering channel bottom; associated marsh vegetation *Pd*, *Pv*, *Za*; *Cd* generally only along edge of marsh.

(continued)

APPENDIX C (continued)

Station	Date	Location	Species	Relative Abundance	Observations
41	7-14-78	York River-Aberdeen Creek	*Zp*	*Zp* abundant	Scattered *Zp* along *Sa* marsh shoreline at head of creek.
42	7-14-78	York River-Timberneck Creek	none	-	No SAV observed in creek system.
43	9-15-78	York River-Sarah Creek	none	-	No SAV observed in creek system.
44	8-15-78	Brown's Bay-A	*Zm*, *Rm*	*Zm* dominant *Rm* abundant	Transect site; broad SAV bed approximately 400 m wide of mixed *Zm* and *Rm*; adjacent marsh of *Sa*.
45	8-15-78	Brown's Bay-B	*Zm*, *Rm*	*Zm* dominant *Rm* dominant	Transect site; broad SAV bed approximately 400 m wide of mixed *Zm* and *Rm*; adjacent marsh of *Sa*.
46	8-16-78	Ware Neck-B	*Zm*, *Rm*	*Zm* dominant *Rm* dominant	Transect site; broad SAV bed approximately 400 m wide interspersed with submerged, parallel bars.
47	8-16-78	Ware Neck-A	*Zm*, *Rm*	*Zm* dominant *Rm* dominant	Transect site; broad SAV bed with inshore shallow zone of largely *Rm*; deeper offshore zone dominated by *Zm*.

(continued)

APPENDIX C (continued)

Station	Date	Location	Species	Relative Abundance	Observations
48	8-17-78	East River-B	*Zm*, *Rm*	*Zm* dominant *Rm* dominant	Transect site; broad SAV bed approximately 350m wide; shallow inshore zone of *Rm* grades to deeper offshore zone of *Zm*
49	8-17-78	East River-A	*Zm*, *Rm*	*Zm* dominant *Rm* dominant	Transect site; broad SAV bed approximately 300m wide; shallow inshore zone of *Rm* grades to deeper offshore zone of *Zm*.
50	9-7-78	Horn Harbor-B	*Zm*, *Rm*	*Zm* dominant *Rm* frequent	Transect site; broad SAV bed dominated by *Zm* extends approximately 300m offshore of sandbar; inshore of bar is area of silty bottom that is sparsely vegetated.
51	9-6-78	Horn Harbor-A	*Zm*, *Rm*	*Zm* dominant *Rm* occasional	Transect site; 300m wide SAV bed extending offshore from *Sa* marsh; zone of mixed *Zm* and *Rm* near shore grades to *Zm* only offshore.

(continued)

Station	Date	Location	Species	Relative Abundance	Observations
52	8-1-78	Vaucluse Shores	*Zm*, *Rm*, *Zp*	*Zm* dominant *Rm* dominant *Zp* rare	Transect site; extensive SAV bed inshore of large sandbar; width varies from 200m at north end to 700m at southern end; *Rm* dominates shallow areas with *Zm* dominating deeper zones; sparse *Zp* at north end.
53	6-21-78	Piankatank River-Carver's Creek	*Ec*, *Pc*, *Zp*, *Pc*, *Cd*	*Ec* abundant *Pc* abundant *Zp* abundant *Pc* frequent *Cd* occasional	Small freshwater marsh gut; SAV in dense bed covering bottom from inside mouth to head of creek.
54	6-21-78	Piankatank River	*N*	*N* dominant	Scattered patches *N* throughout shallow (<1m) embayed area; silty bottom.
55	6-21-78	Piankatank River	*Cv*	*Cv* dominant	Narrow bed 1-2m wide along edge of channel bordering mixed freshwater marsh/ wooded swamp community.
56	6-21-78	Piankatank River	*N*, *Cv*, *Nm*, *Ng*	*N* dominant *Cv* dominant *Nm* frequent *Ng* occasional	Bed 2m wide along edge of *Pd* marsh; average water depth 1m.
57	6-21-78	Piankatank River	*N*	*N* dominant	Scattered patches *N* along edge of freshwater marsh.

(continued)

APPENDIX C (continued)

Station	Date	Location	Species	Relative Abundance	Observations
58	6-7-78	Rappahannock River-Lancaster Creek	*Zp*	*Zp* dominant	Scattered *Zp* along shoreline; adjacent marsh of *Sa* and *Sc*.
59	6-9-78	Rappahannock River-Moratico Creek	*Zp*	*Zp* dominant	Scattered *Zp* along two small brackish marsh guts.
60	6-9-78	Rappahannock River-Moratico Creek	*Zp*	*Zp* dominant	*Zp* along marsh channel at head of creek; adjacent marsh of *Sa*, *Sc*, *Bh*.
61	6-15-78	Rappahannock River-Farnham Creek	*Zp*	*Zp* dominant	Sparse *Zp* fringe along edge of brackish marsh.
62	6-15-78	Rappahannock River-Farnham Creek	*Zp*	*Zp* dominant	Scattered *Zp* bordering brackish marsh.
63	6-20-78	Rappahannock River-Suggetts Point	*Pc*	*Pc* dominant	*Pc* in *Sp* marsh ditch that is slightly perched with restricted tidal flushing.
64	6-20-78	Rappahannock River-Neals Point	*C*, *Rm*	*C* frequent *Rm* frequent	Sparse coverage of SAV along small, marsh creek channel.
65	6-21-78	Rappahannock River-Richardson Creek	*Cv*, *Zp*	*Cv* abundant *Zp* frequent	Head of creek branch with fringe of SAV along edge of marsh; adjacent marsh of *Pv*, *Ta*.
66	7-18-78	Rappahannock River-Totuskey Creek	*Zp*	*Zp* dominant	Sparse *Zp* along two brackish marsh guts near mouth of creek.

(continued)

APPENDIX C (continued)

Station	Date	Location	Species	Relative Abundance	Observations
67	7-13-78	Rappahannock River-Totuskey Creek	*Cv*	*Cv* dominant	Intermittent fringe of *Cv* along edge of freshwater marsh and tidal swamp.
68	6-6-78	Rappahannock River-Belleview Creek	*Zp*	*Zp* dominant	Scattered *Zp* along *Sc* dominated marsh gut.
69	6-8-78	Rappahannock River-Piscataway Creek	*Cd*, *Cv*, *Va*	*Cd* abundant *Cv* frequent *Va* frequent	Fringe of SAV along edge of *Pv*, *Pd*, *Nl*, *Ta* marsh.
70	6-8-78	Rappahannock River-Piscataway Creek	*Va*, *Cd*, *Ec* *Pn*	*Va* dominant *Cd* abundant *Ec* frequent *Pn* frequent	Dense SAV stands across bottom of main channel at head of creek; adjacent marsh of freshwater species including *Pv*, *Pc*, *Nl*, *Za*.
71	7-19-78	Rappahannock River-Jugs Creek	*Ec*, *Zp*	*Ec* frequent *Zp* frequent	Scattered SAV along edge of channel at mouth of creek.
72	7-20-78	Rappahannock River-Little Carter Creek	*Zp*	*Zp* dominant	Scattered *Zp* along edge of brackish marsh.
73	7-20-78	Rappahannock River-Little Carter Creek	*Cd*, *Nm*, *Zp*	*Cd* abundant *Nm* abundant *Zp* frequent	SAV along edge of marsh at head of creek channel.
74	6-21-78	Rappahannock River-Hoskins Creek	*Va*, *Cd*	*Va* dominant *Cd* frequent	SAV of mostly *Va* along channel bottom at head of creek; adjacent marsh of *Pv*.

(continued)

APPENDIX C (continued)

Station	Date	Location	Species	Relative Abundance	Observations
75	6-22-78	Rappahannock River-Mount Landing Creek	*Va*, *Cd*	*Va* dominant *Cd* frequent	SAV along edge of *Pv*, *Ta*, *Nl* marsh at head of creek.
76	8-3-78	Rappahannock River-Cat Point Creek	*Cd*, *Nm*, *Ng*	*Cd* abundant *Nm* abundant *Ng* occasional	Fringe of SAV along small marsh gut; adjacent marsh of *Pv*, *Sc*.
77	8-3-78	Rappahannock River-Cat Point Creek	*Cd*, *Pi*	*Cd* dominant *Pi* occasional	SAV in dense stands across channel bottom at head of creek.
78	9-27-78	Rappahannock River-Quioccasin Creek	*Cd*	*Cd* dominant	Fringe of *Cd* along *Sc*, *Za* marsh shoreline at head of creek.
79	7-5-78	Rappahannock River-Farmers Hall Creek	*Cd*, *Va*	*Cd* abundant *Va* abundant	Pocket of SAV at head of creek branch; adjacent marsh *Pv*, *Pd*.
80	7-17-78	Rappahannock River-Hutchinson Swamp	*Cd*	*Cd* dominant	Scattered *Cd* at head of small creek; mixed fresh-water marsh species.
81	7-31-78	Rappahannock River-Elmwood Creek	*Cd*	*Cd* dominant	*Cd* at head of creek branch fringing along *Za*, *Pv* marsh.
82	7-19-78	Potomac River-Yeocomico River	none	-	No SAV observed from mouth to head of tidal river system.
83	7-19-78	Potomac River-Lower Machodoc Creek	*Zp*	*Zp* dominant	Sparse coverage of *Zp* along shoreline.

(continued)

APPENDIX C (continued)

Station	Date	Location	Species	Relative Abundance	Observations
84	7-19-78	Potomac River-Lower Machodoc Creek	*Zp*, *Ms*	*Zp* dominant *Ms* frequent	Narrow fringe of SAV along shoreline at head of creek.
85	7-19-78	Potomac River-Nomini Creek	*Zp*, *Cv*	*Zp* abundant *Cv* frequent	Scattered *Zp* along shoreline of head of creek; sparse *Cv* much of it floating; adjacent marsh of freshwater species; no SAV observed in downstream sections of creek.
86	7-18-78	Potomac River-Mattox Creek	*Pc*, *Va*, *Zp*, *Pr*	*Pc* dominant *Va* abundant *Zp* frequent *Pr* frequent	Broad (10m) SAV bed along sandy shoreline; depth approximately 1m.
87	7-18-78	Potomac River-Mattox Creek	*Zp*	*Zp* dominant	Small area of *Zp* scattered along shoreline; depth <1m.
88	7-18-78	Potomac River-Mattox Creek	*C*, *Zp*	*C* abundant *Zp* frequent	Scattered SAV along shoreline; associated marsh of *Sa*, *Sc*.
89	7-18-78	Potomac River-Mattox Creek	*Zp*, *Pr*, *Pc*	*Zp* abundant *Pr* abundant *Pc* frequent	SAV bed 5-10m wide along shoreline; located behind sand spit at mouth of creek.
90	7-18-78	Potomac River-Monroe Creek	*Zp*, *N*	*Zp* dominant *N* frequent	Head of creek; intermittent dense fringe of *Zp* along marsh; *N* locally abundant.

(continued)

APPENDIX C (continued)

Station	Date	Location	Species	Relative Abundance	Observations
91	7-18-78	Potomac River- Rosier Creek	*Pc*, *Ps*, *Ec*, *Zp*, *Va*, *Pr*	*Pc* dominant *Ps* abundant *Ec* occasional *Zp* occasional *Va* occasional *Pr* occasional	Broad SAV bed (10-20m wide) along shoreline of embayed area; water depth 0.5-2.0; *Ps* dominates in areas.
92	7-18-78	Potomac River- Rosier Creek	*Ms*, *Zp*	*Ms* dominant *Zp* frequent	Marsh channel at head of creek; dense stands of *Ms* across width of creek; adjacent marsh of *Za*, *Pd* *Ta*, *Sc*.
93	7-18-78	Potomac River- Rosier Creek	*Zp*, *Ms*	*Zp* abundant *Ms* frequent	Sparse occurrence of SAV along shoreline; *Zp* more abundant fringing along edge of *Sa* marsh.
94	7-18-78	Potomac River- Rosier Creek	*Ps*, *Zp*, *Pr*. *Ec*	*Ps* dominant *Zp* frequent *Pr* occasional *Ec* occasional	Intermittent SAV fringe along shoreline of creek; 0.5-2.0m water depth, *Zp* locally abundant.
95	7-18-78	Potomac River- Upper Machodoc Creek	*Pc*, *Zp*, *Va*, *Po*, *Pr*	*Pc* dominant *Zp* frequent *Va* frequent *Po* frequent *Pr* occasional	SAV bed 10-20m wide along shoreline near mouth of creek; sandy bottom with 1-2m depth.
96	7-18-78	Potomac River- Upper Machodoc Creek	*N*, *Zp*	*N* dominant *Zp* frequent	Small (<1m) patches of SAV fringing *Sa*, *Sc* marsh.

(continued)

APPENDIX C (continued)

Station	Date	Location	Species	Relative Abundance	Observations
97	7-18-78	Potomac River- Upper Machodoc Creek	*Zp*	*Zp* dominant	Scattered patches of *Zp* along edge of *Sa*, *Sc* marsh.
98	7-18-78	Potomac River- Upper Machodoc Creek	*Zp*	*Zp* dominant	Sparse coverage of *Zp* along sandy shoreline.
99	7-18-78	Potomac River- Upper Machodoc Creek	*Zp*	*Zp* dominant	Large areas of scattered *Zp* along shallow flats on both sides of channel near head of creek branch.
100	8-9-78	Potomac River- Rt. 301 Bridge	*Pr*, *Va*	*Pr* dominant *Va* abundant	Broad fringe of SAV along shoreline; grades from *Pr* near shore to *Va* in deeper areas offshore.

APPENDIX D

DATA DERIVED FROM TRANSECT ANALYSIS AT SEVENTEEN LOCATIONS PRESENTING DATE AND TIME OF TRANSECT SAMPLING, DISTANCE FROM SHORELINE (m), ELEVATION (dm), PERCENT COVER OF ZOSTERA AND RUPPIA ($0.1m^2$), BOTTOM TYPE AND GENERAL OBSERVATIONS

TABLE D1: PLUM TREE ISLAND-TRANSECT A[1]

Date	Time[2]	Distance[3] from shore-line (m)	Elevation[4] (dm)	% Zm ($0.1m^2$)	% Rm ($0.1m^2$)	Bottom Type	Observations[5]
9-12-78	1045	0	+ .7	-	-	Peat	Eroded peat block from adjacent marsh.
"	1046	10	- 2.4	-	-	Fine Sand	Bare sand, no vegetation.
"	1048	20	- 2.6	-	-	"	
"	1050	30	- 3.5	20	-	"	Zm appears at 26m.
"	1052	40	- 3.7	30	-	"	Zm scattered.
"	1053	50	- 4.8	60	-	"	Zm common last 10m.
"	1054	60	- 6.1	-	-	"	Bare sand sparse Zm in vicinity.
"	1055	70	- 6.6	-	-	"	Sparse Zm.
"	1056	80	- 7.9	-	-	"	Patches of Zm nearby.
"	1057	90	- 9.2	-	-	"	Scattered Zm.
"	1100	100	- 9.6	10	-	"	Small patch Zm.
"	1101	110	-11.0	0	-	"	No Zm observed in vicinity.
"	1103	120	-11.1	trace	-	"	A few sprigs Zm only.
