Abstract

A swarm of autonomous unmanned aerial vehicles (UAVs) can provide a significant amount of intelligence, surveillance, and reconnaissance (ISR) data where current UAV assets may not be feasible or practical. As such, the availability of the data the resides in the swarm is a topic that will benefit from further investigation. This thesis examines the impact of file replication and swarm characteristics such as node mobility, swarm size, and churn rate on data availability utilizing reactive protocols. This document examines the most prominent factors affecting the networking of nodes in a mobile ad hoc network (MANET). Factors include network routing protocols and peer-to-peer file protocols. It compares and contrasts several open source network simulator environments. Experiment implementation is documented, covering design considerations, assumptions, and software implementation, as well as detailing constant, response and variable factors. Collected data is presented and the results show that in swarms of sizes of 30, 45, and 60 nodes, file replication improves data availability until network saturation is reached, with the most significant benefit gained after only one copy is made. Mobility, churn rate, and swarm density all influence the replication impact.

Acknowledgements

Above all else, I must recognize my wife's unwavering support and dedication. Her patience during the last eighteen months has been nothing short of heroic. To my boys, for all the days and nights I spent holed up in the office, thank you and I'm sorry you didn't get much say in the matter.

I would like to thank my thesis advisor, for his guidance, knowledge, patience and most of all, sense of humor. I would also like to thank my committee members, for without their dedication to teaching, this wouldn't have been possible.

Finally, I would like thank all the supervisors, mentors, and classmates that guided and supported me over years.

EFFECTS OF DATA REPLICATION ON DATA EXFILTRATION IN MOBILE AD HOC NETWORKS UTILIZING REACTIVE PROTOCOLS

I. Introduction

With UAVs becoming smaller, lighter, and easier to replace, the study of UAV swarms has gained momentum as an area of academic study. In military areas of research, UAV swarms have been popularized for their robustness, i.e. their ability to lose members and reform to continue operation. This redundancy provides a graceful degradation to the overall capabilities of the system. In the context of ISR missions, not only are the assets key to mission objectives, but more importantly, so is the data that the individual assets collect. How this information is stored and extracted from the swarm network is an area of critical on-going research. This thesis argues that file replication can increase data survivability in a system where the amount of data generated exceeds the capability to ex-filtrate the data, but extent of the benefit provided by file replication is limited by characteristics of the UAV swarm. Extensive work has been done in the last decade regarding various routing protocols in mobile ad hoc networks (MANETs), much of which stems from the seminal work of Perkins and Bhagwat[39]. Recent research has applied these concepts to collections of UAVs due to inherently mobile nature. Peer-to-peer (P2P) file sharing applications have also been covered extensively, looking at traditional peer-to-peer transfer protocols such as Ding and Bhargavas work in Peer-to-peer File-Sharing over Mobile Ad Hoc Networks [21], or even MANET specific applications such as Klemm's Optimized Routing Independent Overlay Network (ORION) [32]. Despite over a decade's worth of research, little information exists specifically on the resiliency of data in a MANET

P2P file system hosted by a UAV swarm where the goal is to maintain data until it can be requested. Furthermore, since the flight-time of each UAV is limited, a UAV rotation schedule must be enforced where UAVs enter and leave the system to maintain 24 hour operations. Additionally, some UAVs may suffer mechanical failures, unexpected operating parameters (e.g. weather, temp, etc.), or in the case of military applications, destruction from opposing forces. These factors induce churn or attrition that must factor in to the swarm's operation. Such a scenario exists where individual autonomous UAVs can form a robust MANET but lack a high-bandwidth connection back to a central control facility. Additionally, the UAV swarm itself may maintain the data on separate nodes as part of distributed artificial intelligence system, where instead of extracting the data, the system needs to maintain copies for its own use. These scenarios have applications to the military, disaster recovery operations, geological survey and others.

The complexity of MANET operation, compared to that of a traditional, fixed infrastructure network creates an abundance of factors to examine. Such factors include overhead from network routing and file system control, which impact bandwidth available for data extraction. Additional factors such as replication rate, replication strategy, file size, and number of nodes in the system all impact performance.

1.1 Research Objective

The objective of this work is to analyze the impact of data replication on availability and response times in a reactive peer-to-peer file system running on an airborne MANET. The experimental domain is a network simulator, wherein factors such as replication levels, number of nodes in the system, mobility (airspeed), and churn rate (attrition) can be varied to observe their effects on the system. The hope is that the results will shed light on the optimal configurations for future implementations. The

insight here is that increasing replication will lead to an increase in availability, but only until the overhead cost of the replication (in network bandwidth) exceeds the capacity of the ad hoc network. Furthermore, results indicate that adjusting node mobility and swarm size play a critical part in data availability.

1.2 Document Structure

The remainder of this thesis is organized as follows: Chapter II covers basic MANET principles, P2P file system principles, and an overview of current network simulators. Chapter III details the methodology used in conducting the experiments and enumerates the simulation parameters, (e.g. response variables, control variables, constant factors). Finally, Chapter IV presents the results of the experiments, while Chapter V draws conclusions and gives recommendations for potential future work.

II. Related Work

This chapter provides necessary background on ad hoc networks. In particular, it provides, a broad overview of ad hoc networks followed by a discussion of the differences between various applications of ad hoc networks in mobile ad hoc networks (MANETs), vehicular ad hoc networks (VANETs), and flying ad hoc networks (FANETs). Much of the research into ad hoc networks revolves around the different algorithms and protocols utilized for implementation. These protocols can be segregated into two primary camps, *proactive* and *reactive*. Proactive protocols act similar to traditional routing protocols where network maps are built ahead of time and reactive protocols build routing tables only on an as-needed basis. In addition, topics on the usage of virtual backbones, quality of service, and cross-layer optimization are also covered as they relate to potential future work.

Built on such proactive and reactive protocols for ad hoc networks are applications, one which is the focus of this thesis is the implementation of a peer-to-peer network file system that supports file/data replication, along with the challenges that are presented by ad hoc network implementations that do not exist in traditional infrastructure networks.

Finally, the chapter closes with a look at the current state of modeling ad hoc networks, the various simulators used, as well as a survey of simulation versus an actual network performance.

2.1 MANETs / VANETs / FANETs

MANET research was popularized in the late 1990's and has continued unabated since. Research involving ad hoc networks can be categorized three different ways, with respect to the mobility of the devices that are connected. Traditionally, the term

MANET relates to any type of node that is mobile in a 2D or 3D space. Typically, this is representative of personal computing devices such as cell phones, tablets, or other personal data assistants. A VANET refers to a network typically embedded in motor vehicles and presents a unique study landscape due to mobility constraints of traffic patterns. Boukerche et al. [11] also refers to this as V2V routing. FANETs are identical to VANETs with the exception that the focus is on the application of ad hoc networks for airborne systems. Each category possess unique challenges, thus making distinctions critical. This thesis will focus primarily on FANETs, but will use the term MANET to generalize all mobile ad hoc networks, unless noted otherwise.

For simplification, connections are modeled using the unit-disk graph (UDG) paradigm; that is each network will be represented as a disk with a radius that is equal to the range of the radio used for transmission. However, this could be expanded to take into consideration links of various weights such as frequency, bandwidth, distance, etc. We will also assume a homogeneous grouping of nodes; every node is of the same class and subject to the same constraints. Figure 1, inspired by the work of Wan et al. [53] provides an excellent visual of a unit-disk representation. Additional figures will use this figure as a baseline for continuity.

2.2 Physical Layer

A variety of wireless protocols have been selected for use in the study of MANETs. Most prominently has been the standard IEEE 802.11 protocols (Wifi), specifically the a, b, g, and n variations. The 802.11 specification supports transmission speeds from 2 - 600 MBs/sec with ranges up to 250 meters [26]. The IEEE 802.15 specification for wireless networking, better known as Bluetooth (802.15.1), is extremely useful for short range communication. It supports transfer rates from 1 to 24 MB/sec, depending on the version of the protocol used. The 802.15.4 specification introduces

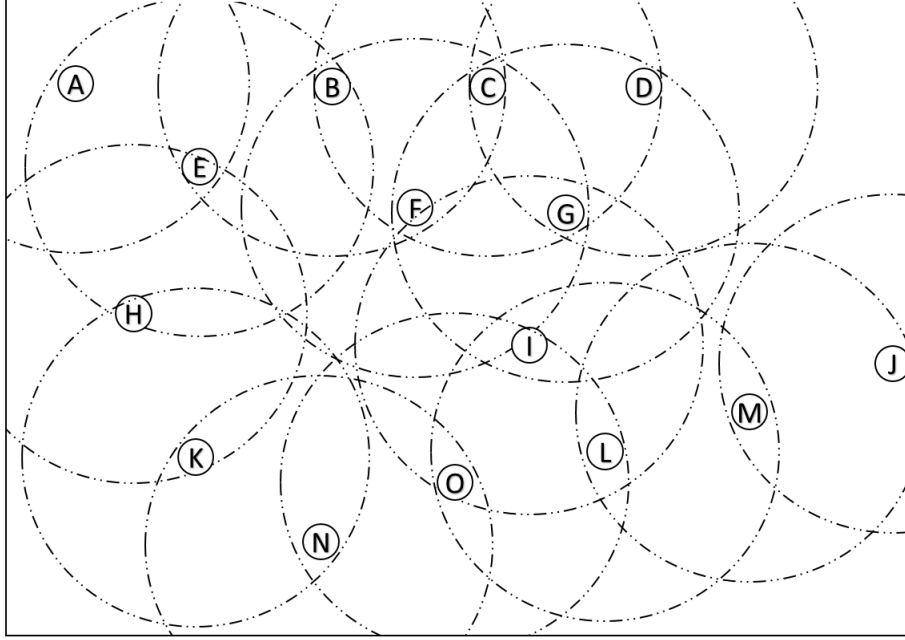

Figure 1. Model of topology of wireless ad hoc network by unit-disk graphs - Inspired by Wan et al. [53], this illustration shows each node as a solid circle labeled with a letter, and its corresponding radio range denoted by the dashed circle.

low-power specifications which may prove to be extremely useful when applied to a system of ultra small unmanned aerial vehicles (UAVs) flying in a tight cluster. Bhagwat and Segall [10] highlight the differences between design paradigms for Bluetooth networks, known as scatternets, and traditional MANETs.

2.3 Routing Protocols

Research involving MANETs has led to an abundance of various routing protocols. This section will presents prominent protocols and closely examines those that relate directly to this thesis. Perkins and Bhagwat [39] state that the challenge of routing in an ad hoc network boils down to a distributed shortest path problem, and the only primary difference between protocols is how the routing table is constructed and what information is maintained. Boukerche et al. [11] gives a survey of over 115 different routing protocols for MANETs. Here protocols are divided into nine different

categories based on the following design paradigms: Source-initiated (Reactive and on-demand), Table-driven or Pro-active, Hybrid, Geographical, Hierarchical, Multicast, Geographical Multicast and Power-Aware. While this categorization covers the gamut, most papers simply limit the grouping to Proactive and Reactive types.

The routing protocol chosen for a particular application can have a dramatic effect on overall system performance. Factors to take into account include: network size, fault tolerance, delay tolerance, mobility rate, system-knowledge (how much information does each node possess on the state of the network), node-density, and others.

According to Boukerche et al. [11], next-hop routing methods can be categorized into two groups, *link-state* and *distance-vector*. With *Link-State*, nodes maintain network topology with the cost of each link. Periodic network broadcasts update all other nodes with new information and the receiving nodes apply a shortest path algorithm to determine next hops for each destination. However, with *Distance-Vector*, each node maintains a list of distances to each destination for each neighbor. The neighbor with the smallest distance to the destination is used as the next hop. To maintain table freshness, nodes periodically broadcast their links to their neighbors.

2.3.1 Proactive Protocols.

Proactive protocols attempt to maintain an up-to-date picture of the network by updating their routing tables before they are needed. For as static network, this type of routing protocol works well and is typified by standard infrastructure routing protocols like the Routing Information Protocol. However, in a dynamic network environment where nodes are changing connections at varying rates, this type of proactive routing scheme can prove problematic. Two prominent proactive protocols,

Destination-Sequenced Distance-Vector (DSDV) and Optimized Link State Routing (OLSR) are detailed below.

2.3.1.1 Destination-Sequenced Distance-Vector.

Perkins and Bhagwat [39] chose to use a distance-vector method as an ad hoc network routing protocol because, as they stated, “Compared to the link-state method, it is computationally more efficient, easier to implement and requires much less storage space.”

Under DSDV routing, packets are transmitted to their neighbors either via media access control (MAC) address or network address. Each node maintains a routing table entry for every destination and the number of hops required to reach it. Additionally, a sequence number is associated with each entry that corresponds to the last known sequence number of the destination node. This sequence number is used to identify freshness of route information and is similar in function to that of a Lamport Clock [34]. Open Systems Interconnect (OSI) layer 2 and 3 addresses are also included in the broadcast packet.

Perkins and Bhagwat describe two different types of broadcast packets for route updates. The first, an incremental update, should be crafted to fit inside one network protocol data unit (NPDU). The second is a “full dump”, which might require multiple NPDUs [39]. The full dump broadcasts can be used when the size of the incremental packets reach the NPDU size.

While DSDV implemented a distance-vector methodology for route propagation, OLSR leverages link-state to create its routing tables.

2.3.1.2 Optimized Link State Routing.

The protocol, developed by Jacquet and Muhlethaler [28], starts with each node broadcasting “*HELLO*” messages to its neighbors (i.e. nodes that it has a direct link with). Each hello message lists the node’s neighbors and their corresponding link-state. This provides a mechanism for each node to be aware of all one-hop and two-hop neighbors. From these neighbors, each node calculates a set of multi-point relays (MPRs). Each node selected as a MPR must meet two critical conditions. First, the node must possess a bi-directional link, and second, the set of MPRs is such that it covers all two-hop neighbors. Obviously, with fewer nodes, optimality increases. This is illustrated in Figure 2.

The MPRs are used to decrease the amount of control traffic generated when propagating topology changes across the network. This is similar to the virtual backbone discussed later in the chapter, however it is calculated at each node as a local optimization, rather than a system wide distributed algorithm. Changes in topology are disseminated through topology control messages. These messages are broadcast to all neighbor nodes, but only MPRs forward the control message. Using these control messages, each node builds a complete routing table for each node in the network. Jacquet elaborates on the route calculation algorithm and provides a proof of correctness for optimality.

It is important to understand proactive protocols and to understand the benefits that reactive protocols offer in MANETs. This section provided a brief description of two prominent protocols, DSDV and OLSR. The following section provide insight into reactive protocols.

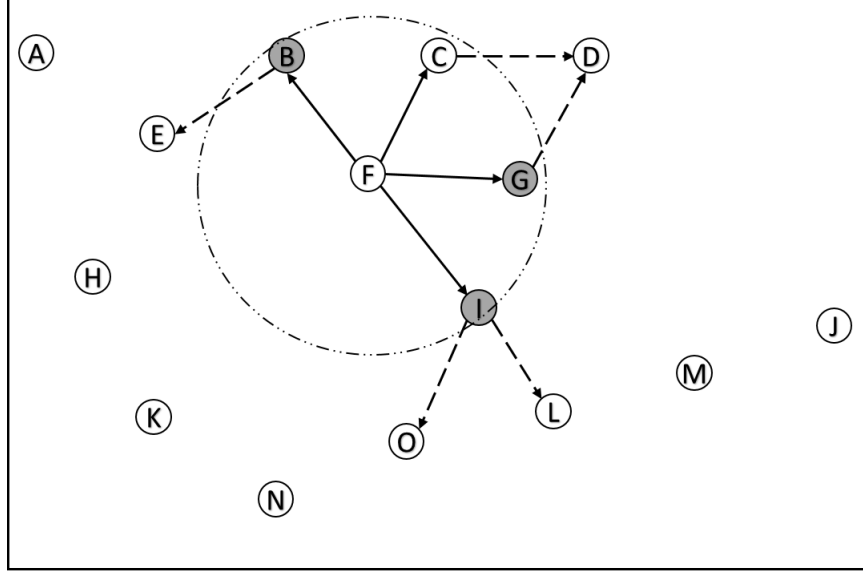

Figure 2. Illustration of MPR selection - Node F represents an arbitrary node in the system with 1 hop connections represented by a solid line. Two-hop connections from Node F are represented by dashed lines. A locally optimized MPR selection is shown as gray nodes.

2.3.2 Reactive Protocols.

Reactive protocols differ from proactive protocols in that routes are only generated “on-demand”, i.e. they only update routing information when a route does not exist, or is too old. This type of protocol has the benefit of cutting down on the number of control packets in the MANET, particularly in MANETs with high mobility, at the expense of potential delays in route acquisition. The following section will focus on Ad hoc On-demand Distance Vector (AODV), AODV variants, as well as Dynamic Source Routing (DSR). AODV is covered in-depth due to the implementation of Optimized Routing Independent Overlay Network (ORION), a peer-to-peer file transfer protocol that is discussed later in the chapter.

2.3.2.1 Ad hoc On-Demand Distance Vector.

AODV is a widely popular routing protocol. It was first proposed by Charles E. Perkins and Elizabeth M. Royer, in 1999 in their paper, “Ad hoc On-Demand Distance

Vector Routing”, with substantial assistance from Pravin Bhagwat [40]. The AODV routing protocol will be covered in-depth since it forms the foundation upon which the experiments were conducted for the current research. According to Perkins, the genesis of research into networks based on mobile nodes began with DARPA research involving packet radio networks. AODV is based on DSDV, as explained earlier, but overcomes the limitations on network size imposed by the $O(n^2)$ growth of control messages required to keep every node’s routing table current. As such, Perkins’ motivation was to “minimize broadcasts and transmission latency” [40].

2.3.2.1.1 Implementation. A critical component of the AODV protocol is the concept that routes are not maintained for nodes that do not exist on an active path. Perkins refers to this as “pure on-demand route acquisition” [40]. Next, nodes are made aware of nodes in its local neighborhood by means of a periodic *hello* message. This hello message is basically a ping to all nodes that are within the transmit range (1 hop) of the source node and is not forwarded to any node beyond the receiver. The combination of *hello* messages and on-demand route acquisition creates a system of two different management requirements, one for local connectivity, and one for general topology, such as when the node is participating in an active request for a route or active file transfer.

2.3.2.1.2 Route Discovery. AODV makes use of the DSR broadcast routine (explained in a later section), with a slight alteration. Instead of propagating information about routing to the source node, each intermediary node only updates information about its neighbors. As Perkins explains, this reduction in overhead has a dramatic effect as the size of the network increases, thus making AODV more scalable [40].

The route, or path, discovery algorithm begins when a node does not currently have a route to a requested node in its route table. To begin, the node broadcasts a packet, known as a route request (RREQ), to its immediate neighbors. Each RREQ contains the *source-addr* (network address of node requesting route), *source-sequence-num* (counter that is incremented with each message), *broadcast-id* (counter that is incremented with each new RREQ), *dest-addr* (network address of node that the source is attempting to reach), *dest-seq-num* (last known sequence number of destination), and the *hop-cnt* (number of hops packet has taken).

When a neighbor node receives the RREQ, it can respond in one of three ways. First, if it has already seen the RREQ (the pairing of source address and broadcast id creates a unique key to identify), it will drop the packet and take no action. Passing that conditional, if it has a route to the destination, it can reply to the source with a route reply (RREP). Finally, if it does not have a route, it increments the packet hop count and re-broadcasts the RREQ to its' neighbors. If the node re-broadcasts the RREQ, it logs the request with the *dest-addr*, *source-addr*, *broadcast-id*, the *exp-time* (time until request expires), and the *source-sequence-num*.

This information has two purposes. The first is to drop future requests with the same id. This is critical to ensure RREQ loops are not formed. In addition to this, the information is necessary to set up the return path.

2.3.2.1.3 Reverse Path. The sequence number of the source is used to keep entries up-to-date. If a node receives a new RREQ with a higher sequence number, it updates its route entries with the address of the node that it first received the RREQ from. The expiration time out is set to a value that allows enough time for the reply to come back. While Perkins and Royer don't cover it explicitly, this parameter should be tuned to allow enough time for the reply to come back from the destination. Setting this value too high will lead to unnecessary look-ups to a

factor of $O(n^2)$, where n is the number of nodes in the system (although most realistic scenarios would not pass through every node). The net result of these RREQ forwards is that once the final destination is reached, the route back to the source has already been constructed. This can be visualized in Figure 3a.

2.3.2.1.4 Forward Path. Once the RREQ reaches a node that possess a route to the destination node, the node checks to see if the destination sequence number of the RREQ is higher than the destination sequence number stored locally. If it is, the node assumes that its route is stale, clears its entry, and proceeds with the RREQ re-broadcast. If its destination sequence number is greater than or equal to that of the RREQ, a path has been established and the process now proceeds with returning the information to the original source node as represented in Figure 3a. To accomplish this, the node with a route to the destination node replies to its neighbor from which it received the RREQ with a new RREP packet. The RREP packet contains the *Destination address*, *Source address*, *Destination Sequence Number*, *Hop Count*, and *Lifetime* (i.e., how long the route will stay active).

This RREP packet is forwarded along the reverse path that has already been created, with each node setting up a reverse pointer to the node that it received the RREP packet from (updating its route table). Since the node that received the RREP packet has new information, it updates the activity timers on the routes to keep them from being deleted. This process continues until the RREP packet reaches the source node. As the node receives additional RREP packets, it will update its route table if two conditions are met. First, if the destination-sequence number for the destination node is higher than that which is currently stored, or second, if the node receives a RREP with the same destination sequence number and a lower hop count. This algorithm works to improve the route while the information is being passed back to the source. Just like the RREQ packets, if it has a lower sequence

number, the packet is dropped to reduce unnecessary traffic. Once the RREP packet arrives at the original source destination, the route is complete and the source node can begin communication with the destination node as seen in Figure 3b.

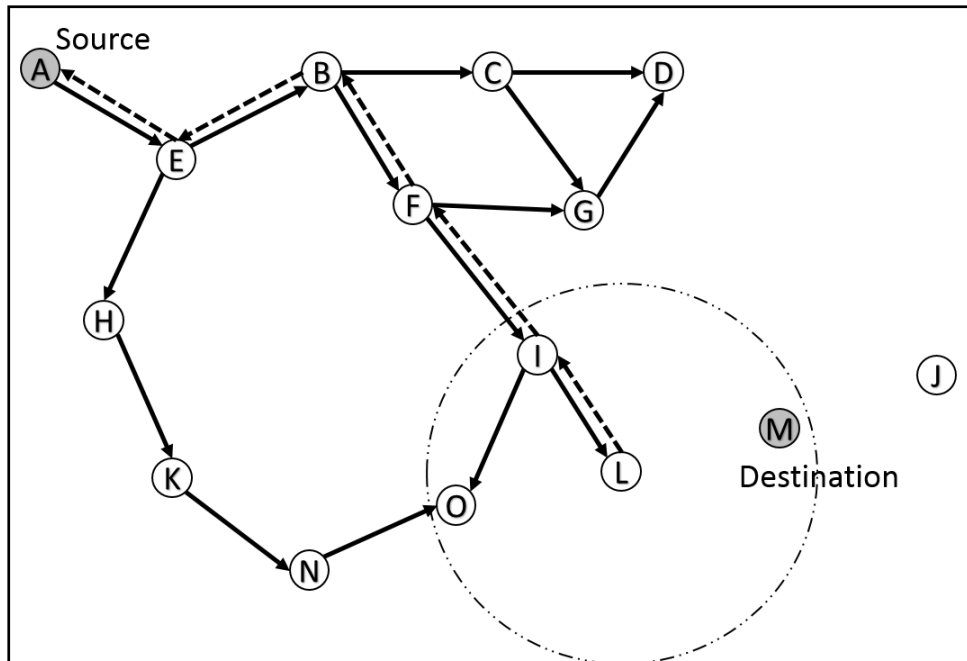

2.3.2.1.5 Route Maintenance. When there is a break in an active route, detected by either a lack of a “*hello*” message, or a link-layer acknowledgment (*LLACKS*) failure, action must be taken to update nodes on the path to the source that the route is no longer tenable. This is done through sending an RREP packet with an incremented sequence number and a hop count set to ∞ [40].

While Perkins does not cover this topic at length in his paper, the fact that the route table only contains entries for a short duration provides an interesting area of study. This duration, or *activity timeout* is a tuned parameter that needs to be adjusted to ensure optimal performance. Expected node mobility and network traffic should be evaluated to help determine appropriate values. As node mobility increases, the frequency of link-layer failures increases (assuming non-static mobility pattern). A link-failure message is sent back to the source node where it will initiate a new RREQ, again flooding the system. If the network is active, valid route entries will be refreshed often, limiting the scope of the RREQ flood.

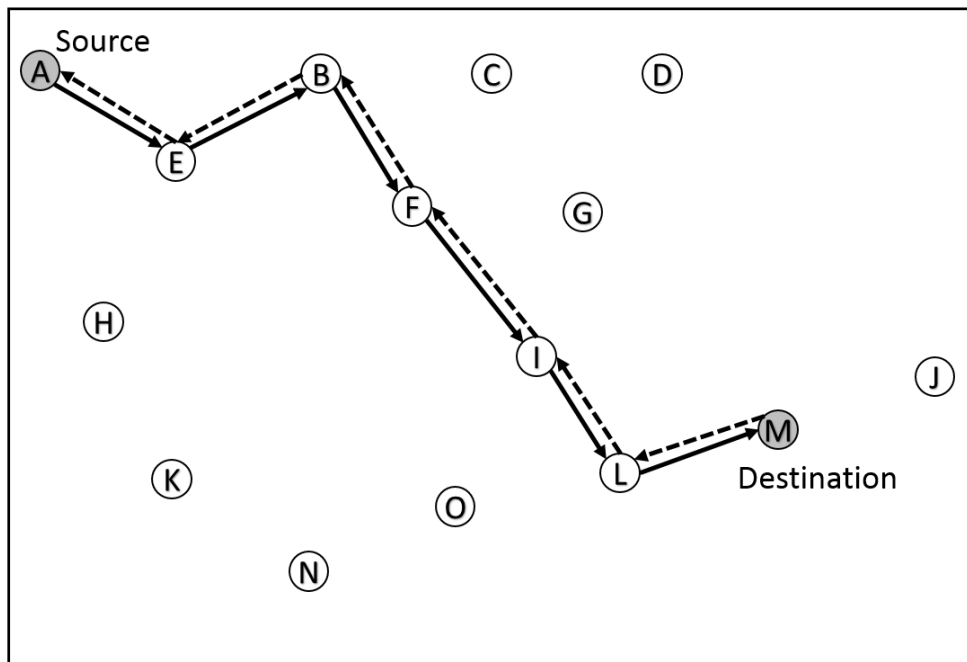

2.3.2.2 Ad hoc On-demand Distance Vector Variants.

Several papers introduce variations on AODV in attempts to increase the protocol’s utility in various situations. The following paragraphs cover a few of the significant AODV based protocols.

2.3.2.2.1 Channel Assignment Ad hoc On-demand Distance Vector Routing. Gong and Midkiff [22] assert that since the 802.11 protocol doesn’t work well in a multi-hop wireless environment (based on the work of Xu and Saadawi),

(a) Reverse Path Formation

(b) Forward Path Formation

Figure 3. Forward and reverse path formation in AODV - The reverse path is constructed in figure 3a. RREQ packets (solid line) are broadcast at each node if it has not yet seen the RREQ and it does not have a valid route to the requested node. If a node contains a valid route, it sends a RREP along the reverse path, establishing a forward path. Figure 3b shows the completed communication channel with the destination node.

a method for handling channel selection is required to reduce interference between neighboring nodes. Unfortunately, as Gong points out, it is not possible to eliminate all interference since the distributed channel assignment problem is *NP*-complete. Channel Assignment AODV (CA-AODV) mirrors AODV with the exception that it carries additional information in the RREQ and RREP packets to support multiple channels. At each hop, if a neighbor node has been already assigned a channel, a new one is randomly selected. During the RREP, if a channel is already in use at the next hop (due to an already existing route), the next node along the RREP (1 hop closer to the source) is informed and it selects a new channel for the route being established. Figure 4 can help aid in the understanding of this processes; you can see that node A already has a route to node M, utilizing node I on Channel 2. Node D is requesting a route to node N that passes through node I. Since node G does not have an active route to node N, it randomly assigns one of its available channels (in this case, 2) to the route. The RREQ proceeds to its destination, node N then initiates the RREP process as in AODV. Node I, aware that it currently is using channel 2, informs node G through the RREP packet to choose a different channel. When node G receives the packet, it chooses a new available channel (in this case, for the route. It is important to note that changing of the selected channel is only important during the RREP, as the RREQ packet is flooded, and many nodes will not be part of the forward route.

2.3.2.2.2 Ad hoc On-Demand Multipath Distance Vector Routing.

Zapata [58] present a variant to the traditional AODV routing protocol that calculates multiple disjoint and loop free paths as part of the initial route creation phase. The author's reasoning for this process is sound. The largest drawback to reactive protocols is the network traffic generated during a flood request to establish a new

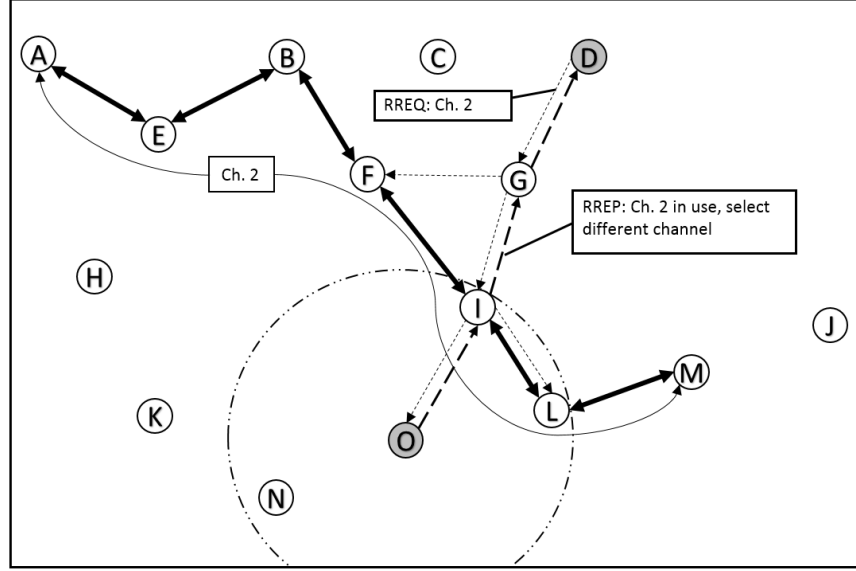

Figure 4. Channel selection in CA-AODV - An active route exists between nodes A and M. Node D requests a route to node N on channel 2 as well. Node I informs node G to select a different available channel during the RREP process to de-conflict the channel assignment.

route. With a multi-path algorithm, a new route request only has to be performed when all current established routes fail, thus reducing the number of flooded RREQs.

2.3.2.2.3 Ant-Colony-Based Routing Algorithm. Ant-Colony-Based Routing Algorithm (ARA) is an extension of the AODV protocol, but implements components of Ant Colony Optimization (ACO) algorithms. For the unaware, an ACO algorithm uses “pheromone” trails to find an optimal solution to a given problem using multiple agents. Over time, these multiple agents converge on an optimal solution. This is achieved by the ant agents depositing a set amount of pheromone on the edges selected for use in route to the destination and again on the way back. This pheromone evaporates at a set rate so that paths that aren’t taken will decrease in pheromone levels, and paths that are utilized will be reinforced and its pheromone levels will increase, thus increasing the future likeliness of selection.

In the case of ARA routing, specially crafted packets are the “ants” and each node updates the packets, as well as certain local variables based on the status of these

ant packets. The length of the path that the ACO algorithm is optimizing in this case is hop-count, however, it can be extended to any other applicable metric, such as capacity, congestion, power, or combinations thereof. Caro refers to two different types of ants, FANTs and BANTs which are analogous to the RREQ and RREP packets of AODV [15]. A key departure is that these packets are routed based on pheromone levels of neighbor nodes, with some stochastic randomization included to increase breadth of the search space and not get trapped in a localized optimization. Once a FANT reaches its destination, it reinforces nodes along the reverse path headed to the source with additional pheromones. This makes these nodes more likely to be selected as intermediaries for future packets. Link failures are handled in a similar way to AODV. *Route_Error* messages are generated if a node doesn't receive confirmation that the next hop received the packet. It sets the pheromone level for the failed node to 0 and sends *Route_Error* message to the previous node to process. This chain is continued until the *Route_Error* message reaches the source node, at which time it will generate a new request for a route.

2.3.2.3 Dynamic Source Routing.

DSR, developed by Maltz, Broch, and Johnson, was designed to have very low overhead to support high mobility and is very similar to AODV with few exceptions [29]. The primary difference is that it maintains multiple routes for each destination. When a RREQ is forwarded, the intermediate node appends its IP address to the packet. When the packet reaches the destination, it replies along the route, including the list of all the addresses that the packet went through [2]. As Ade states, maintenance of the route is performed through confirmations that the packet was received either at the link or network layer. If the source detects a broken link, it can either use a different cached route or request a new route. The other difference is that

the protocol uses source routing instead of the routes from the intermediate node. In their initial design, [29] make the assumption that all radios operate in promiscuous mode; that is every packet is delivered to the network layer, regardless of the MAC layer addressing. This allows nodes to “overhear” packets destined for them even if they are addressed to another node in the route before them in a process known as “Automatic Route Shortening” [29]. This also allows the node to update its routing table with information from the packet, even though it is not part of the active route.

2.3.3 Hybrid Protocols.

Research has also looked at combining proactive and reactive protocols into a hybrid approach. While these protocols tend to increase the complexity of implementation, they hope to exploit advanced algorithm techniques to achieve more efficient routing mechanisms. Two examples of hybrid protocols are AntHocNet, which is a specific protocol and virtual backbones, which describes a class of hybrid protocols.

2.3.3.1 AntHocNet.

AntHocNet was introduced by [15], which “combines reactive route setup with proactive route probing, maintenance and improvement”. It uses a multi-path algorithm based on principles of standard ACO algorithms such as ARA. The AntHocNet protocol begins with a *reactive route setup* phase. During this phase, forward ants dubbed “*reactive forward ants*” are broadcast towards a destination and “*backward ants*” are returned as in other ACO protocols. AntHocNet then departs from other ACO algorithms through the use of “*proactive forward ants*” that are used to monitor and improve current routes while data is being transmitted. Instead of sending *Route_Error* messages back to the source in the event of a link failure, as in ARA,

AntHocNet attempts to perform local repair or warn earlier nodes in the path of the problem. Caro calculates route selection probability P_{nd} as

$$P_{nd} = \frac{(T_{nd}^i)^{\beta_1}}{\sum_{j \in N_d^i} (T_{jd}^i)^{\beta_1}}, \beta_1 \geq 1 \quad (1)$$

where T_{nd}^i is the pheromone value (quality of solution) of reaching node d from node i through node n . N_d^i represents the set of neighbors of i to which a path to d is known. Caro uses β_1 as a tuning parameter that can be leveraged to adjust the exploratory behavior of the ants. Each ant is marked as $F_d^s(k)$, where k is the replica number of the same ant initiated from source node s with destination d . If F_d^s reaches a node with no entries for node d , it will broadcast F_d^s to all neighbors, otherwise, it will unicast F_d^s to nodes in its route table for node d .

During the course of route formation, if a node receives multiple ants of the same generation (think same broadcast-id and sequence number from AODV), it will compare the ants current hop count and travel time and forward it on if it is within a certain acceptance factor of the best ant recorded of that generation. This supports both multi-path routing and limiting control traffic by discarding ants following bad routes. As Caro points out, the problem with this policy by itself is the formation of kite-shape paths due to the automatic acceptance of the first ant to reach the node. This is seen by the thick lines in Figure 5 where node E is requesting a path to node G. To correct for this kite behavior, an additional tuning parameter is evaluated that takes into account the first node selected from the source, with preference given to paths that take different routes. This aides in the building of uniquely disjoint paths to improve route selection options in the event of a link failure, as illustrated by the dashed lines in Figure 5. These paths, while less optimal, improve resiliency.

Once the forward ant reaches the destination node, the reverse ant is sent back to perform further pheromone updates. The amount of pheromone added is based

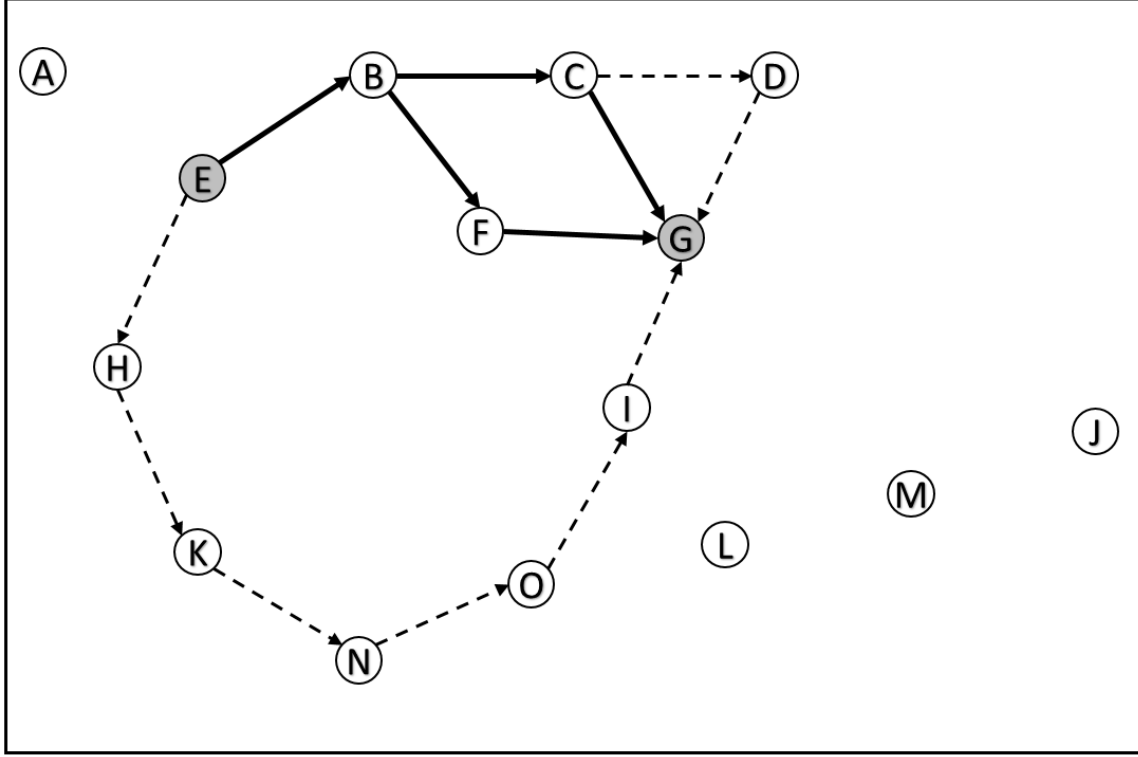

Figure 5. AntHocNet Multi-Path Selection - Solid lines indicate typical ant pathing behavior. Dashed lines are the result of adding an additional tuning parameter to favor disjoint points at nodes with a low hop count.

on the estimated time to reach the destination node, and a system-wide average estimation of the time to complete one hop. According to Caro, the use of a system-wide constant instead of a local calculation prevents route oscillation due to changing local conditions such as congestion and channel access activities [15].

Once a route has been established, data packets can be sent to the destination nodes. This is done in a similar fashion to the forward ants. Since each node maintains multiple routes for each node, each hop is again selected stochastically where

$$P_{nd} = \frac{(T_{nd}^i)^{\beta_2}}{\sum_{j \in N_d^i} (T_{jd}^i)^{\beta_2}}, \beta_2 \geq \beta_1 \quad (2)$$

The key difference is that a higher exponent is utilized to perform a more greedy selection in regards to better paths [15]. With proactive ants being utilized, this

process has the effect of automatic load balancing as congested nodes will decrease in pheromone levels with respect to equally feasible neighbors.

2.3.4 Virtual Backbones.

Virtual backbones present an opportunity to reduce the amount of control traffic necessary to operate an ad hoc network. Of particular note is Das's use of a minimally connected dominating set (CDS) as a virtual backbone to function as a back-up route for packets, and as well as the primary means to compute and update routes for packets, i.e. its a control subgraph [20]. However, some protocols such as DSR and AODV dynamically calculate routes on an as needed basis, and as such, virtual backbones have less utility. None-the-less, it was a topic of active research in the ad hoc community network for over a decade, with the most recent research focus centered around evolutionary algorithms such as Ant Colony Optimization [35, 38, 53].

The formation of a virtual backbone is grounded in the graph theory concept of dominated sets. As such, Wan et al. describe a dominated set as follows:

Given a graph $G = (V, E)$, a dominating set $V' \subset V$ such that each node in $V - V'$ is adjacent to some node in V' , with a connected dominating set being a DS which also induces a connected sub graph [53].

While the construction of a CDS can be done in polynomial time, finding a minimally connected dominating set (MCDS) is known to be NP-Hard. Furthermore, since we are dealing with a dynamic environment, an approximation algorithm that finds a MCDS quickly is preferred as enumerating all possible solutions is not feasible based on the time constraints of the problem domain $O(2^n)$. Further complicating the problem is the distributed nature of the nodes, which imparts a latency delay for any communication between nodes.

Much research has been done in the area of MCDS problems. Butenko looks at the MCDS problem from a different stand-point in which nodes attempt to remove themselves from the CDS (pruning) using a modified leader election algorithm [13], while others look at the problem from a centralized/decentralized standpoint [24, 5, 53].

Algorithm 1 illustrates an Ant Colony Optimization implementation of a virtual backbone. This algorithm is based of the work of Jovanovic and Tuba [30] and was utilized in coursework complementary to this thesis to build a prototype simulator using the Unity3D engine.

2.3.5 Quality of Service.

All of the routing algorithms presented thus far fail to recognize the importance of quality of service (QoS) for multimedia applications such as video streaming and Voice over Internet Protocol (VoIP) communication. If a UAV swarm has video capability or is supporting another system that does, it is reasonable to assume that there may be a requirement to establish a live feed through the swarm back to some centralized location. Furthermore, while obvious that our UAVs do not have pilots, the potential exists for the swarm to act as a relay for VoIP communication from other sources. While this thesis is not taking QoS into consideration, it has been a central theme to a number of research papers generated over the last decade [8, 16, 36, 31, 48].

Tanenbaum and Van Steen [50] lists a number of factors that must be considered when discussing QoS in the general sense. These factors include, required bit rate, session set-up delay, end-to-end delay, jitter (delay variance), and round-trip delay.

While buffering is a useful technique for handling QoS with video applications, it is not appropriate for services that require packets to arrive in the correct sequence with the correct timing (such as VoIP transmissions). As Tanenbaum and Van Steen

Algorithm 1: ACO Based Psuedo Code

```
Initialize source node =  $j_0$ ;  
while time allows (delay termination) do  
  foreach ant  $i$  do  
    while CDS is incompleted ( $|V_{Out}| > 0$ ) (feasibility) do  
      Step 2: poll list of neighbors (next state generator)  
      foreach neighbor( $j$ ) =  $k$  do  
        if  $k \notin EdgeList$  then  
          increment nodeCounter;  
          add  $k$  to edgelist  
      select node  $k \in EdgeList$ : based on(weight) (selection) ;  
      if  $rand > weight$  then  
        exploit:  
        select  $n_i$  with MAX  $\tau_i \cdot degree_i^k$ ;  
      else  
        explore:  
        select  $n_i$  with probability  $\frac{\tau_j \cdot degree_j^k}{\sum_{i \in EdgeList^k} \tau_j degree_i^k}$ ;  
      Reinforcement: Local Level;  
      move to next node:  $j \leftarrow k$  ;  
      update message counter;  
      update return route matrix with pointer to node  $n_{j-1}$ ;  
    forward result to supervisor;  
    if Best solution then  
      while not at  $j_0$  do  
        update Global level  $\tau_j$ ;  
        Reinforcement: (dependent on specific optimization goal)  
        Evaporation: (dependent on node mobility)  
         $j \leftarrow n_{j-1}$  (based on route matrix);  
  Output: Best solution found(solution);
```

[50, 162] point out, the use of forward error correction (FEC) can assist with this. FEC entails encoding extra information in each packet so that if packets are lost in route, they can be reconstructed using the other packets. FEC is also used in the form of erasure coding (EC) in distributed file management systems such as Tahoe-LAFS as part of its replication scheme. Altman and De Pellegrini [4] examine the impact of FEC and Fountain Codes in a Delay Tolerant ad hoc Network. While FEC and EC concepts relate to routing, they are better discussed in the context of file management, and thus outside the scope of this section. Bagwari et al. [7] evaluate the impact of additional nodes in an AODV network and its impact on QoS and concluded that increasing the number of nodes from 45 to 60 increases the overall QoS of the network as measured in packets received, packets dropped, and overall network load.

2.3.6 Analysis of differences in routing protocols.

Now that a number of protocols and concepts have been examined, comparisons between protocols can help show how the routing algorithms impact the performance of the system. Of course, as protocols have been developed over the last one and half decades, a number of papers have been published documenting such comparisons [2, 15, 25, 46].

While not providing any data for analysis, Ade and Tijare [2] provides a useful comparison of features regarding the predominant protocols - DSDV, DSR, AODV, and OLSR. This comparison of traits is summarized in Table 1.

Sharma [46] compares the performance of AODV, DSR, and AntHocNet and concluded that AntHocNet suffers in cases of high mobility and small node buffer sizes. The paper states that the proactive use of ants induces large overhead delay and reducing the number of proactive ants reduces the quality of route information.

Restricting ant usage to purely reactive behavior eliminates control overhead, but doesn't result in significant gains over AODV and DSR.

Gunes et al. [25] compared ARA to AODV, DSR, and DSDV, evaluating several different factors against changing pause durations. While this information is useful for UAV swarms that have hover capability such as quad-copters, it could be extended to UAVs without hover capability flying in tight orbits over a geographic area where their orbits do not change the topology. Obviously, in the later scenario, the data link layer would require longer range capability than what is provided by 802.11. Additional research would need to be conducted of course, since the simulation results can not be extended beyond the hardware technology simulated. None-the-less, Gunes finds that as Pause Time increases from 100 to 900 seconds, the protocols perform in the following descending order based on delivery rate: DSR, ARA, AODV, DSDV. However, as Pause Time reaches 900 seconds, all protocols perform universally well [25].

Caro analyzes the performance of AntHocNet with respect to its father, AODV, in regards to both node speed and pause time [15] using the Qualnet simulation framework. The data shows that AntHocNet outperforms AODV by roughly 5% at 10 m/s and increases this performance by 2% as node mobility increases to 50 m/s . Over the same mobility space, the data shows that AntHocNet reduces the mean end-to-end packet delay by 10-20 ms . When node pause time is considered, AntHocNet has a 5 - 7% advantage in packet delivery ratio, but this advantage quickly tapers off as node pause time increases past 240 seconds. In the simulation set-up, Caro explains that they intentionally used a sparse network to highlight the strengths of the AntHocNet approach where, in a dense network, the traditional reactive procedures of AODV would be more effective [15]. The use of spares network would appear to be the reason for the contrary results reported by Sharma [46].

Table 1. Routing Protocol Feature Comparison [2]

Property	DSDV	DSR	AODV	DSR
Multicast Routes	N	Y	N	Y
Distributed	Y	Y	Y	Y
Unidirectional Link Support	N	Y	N	Y
Multicast	N	N	Y	Y
Periodic Broadcast	Y	N	Y	Y
QoS Support	N	N	N	Y
Reactive	N	Y	Y	N

2.4 Peer-to-Peer File Systems

This thesis looks at file systems in the strict context of a sensor platform and not a traditional distributed database. That is to say, each node generates its own files and only cares about replicating whole files to other nodes for the purpose of redundancy. Therefore, issues of concurrency are irrelevant since we are dealing with a write-once, read-once paradigm. Once the file is extracted from the UAV swarm, there is no need for it to reside in the system any longer. This paradigm is a vastly different scenario than most peer-to-peer file systems, and factors heavily into this thesis's experimental design decisions.

While there exists a large number of peer-to-peer file systems, some are useful for application in a MANET, while many are not. A large factor determining usability is the amount of control traffic required to keep the file system operational. Due to the unique nature of MANET infrastructure, this overhead can quickly overtake available bandwidth, therefore scalability is an issue.

Early peer-to-peer (P2P) applications such as Napster, leveraged a central server to manage client connections. The server kept track of which files where on which clients, but it did not store the files themselves. It served as a broker, pointing the requesting client to providing client. Gnutella on the other hand, worked in a purely

decentralized fashion, not relying on a central server. BitTorrent takes a hybrid approach where files are shared by multiple users and are tracked on different servers. Special files, .torrent, are listed in some publicly available locations. The .torrent file maintains information about the file to be shared, as well as the tracking server that manages all the nodes sharing the file. The tracker servers act in a similar fashion to the Napster broker, helping nodes connect to each other. BitTorrent allows multiple connections to be setup with different nodes, increasing transfer rate.

An extension of the completely decentralized approach was the inception of the Distributed Hash Table or distributed hash table (DHT).

2.4.1 Distributed Hash Tables.

Distributed Hash Tables are used often in distributed systems to form an overlay network without regard to network topology. DHTs brought about a performance increase over pure distributed systems, such as Gnutella due to their $O(\log n)$ look-up operations, as compared to Gnutella's $O(n)$ [17]. Despite the improvement over Gnutella, Tanenbaum states that the lack of topology information can lead to “performance problems” [50, 188]. Vranicar [52] highlights four implementations of a DHT file system in his Master's thesis, which provides a good introduction to DHTs. These file systems include *Chord*, *Tapestry*, *Pastry*, and *Content Addressable Network*.

2.4.1.1 Chord.

Chord works by assigning every node and file in the network a randomly chosen identifier out of an m -bit identifier field, with m usually being 128 or 160 bits [50, 188]. A sufficiently large key space is required to ensure the avoidance of hash collisions. Files then are assigned to the node whose key has the smallest identifier where $id \leq k$. This identifier is the *successor* of k . As Tanenbaum elaborates, the main issue is key-

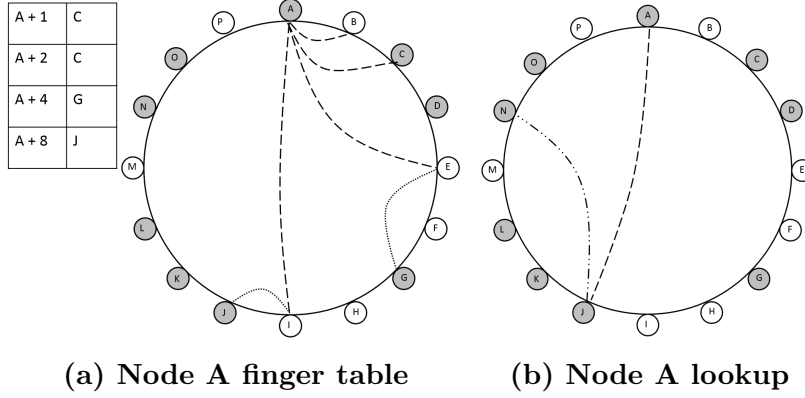

Figure 6. Distributed Hash Table Lookup Process - Figure 6a shows node A’s finger table. Figure 6b performing a lookup for node N. Since node N doesn’t fall within node A’s finger table, it requests a look-up from the last node that node A does maintain a record for. Node J will respond to node A’s request since node N would fall within node J’s table. Gray nodes identify active nodes in the DHT.

lookup, which Chord speeds up through the use of a “finger table”. Each node stores a table of size $\log n$ with respect to the number of the nodes in the system. During a lookup operation, this finger table allows a search of the network by, in the worst case, halving the distance to the successor node that contains the data. Figure 6, inspired from Stoica et al. [49] and Tanenbaum and Van Steen [50], illustrates how a finger table with $\log(n)$ entries is used to look up keys at a distance greater than $n/2$.

When a node is added to the system, it queries a random node and performs a lookup on the successor of its key+1 ($succ(p+1)$). Once this query is complete, the node inserts itself between two existing nodes and the three nodes update their respective successor and predecessor pointers and finger tables accordingly.

Crammer and Fuhrmann analyzed the performance of Chord in a MANET. In their research they evaluated the file-system using three different routing protocols: OLSR, DSR, and AODV. Their conclusion, tested on network sizes from 10 to 100 nodes, was that Chord is ill-suited for use in a MANET. As a surprise, it was not due to network congestion, but due to the node mobility and the system assuming that

the nodes have left the network, resulting in “incorrect application behavior” which lowered network consistency [19].

2.4.1.2 Pastry.

Pastry was presented at the beginning of the millennium as a large scale peer-to-peer overlay network [43]. To route requests to the correct node, each Pastry client maintains a routing table which is similar in functionality to the Chord finger table. This table has entries for $2^b - 1$ items for each N row of the table, where N is the number of clients and b is configuration parameter. The neighborhood set lists nodes and addresses of nodes in close proximity based on a system defined metric. The neighborhood set is not used for actual routing, but for determining certain local properties. The leaf set, however, holds entries for nodes that are the numerically closest, both $|L/2|$ above and below the current node. L is a configuration parameter that is normally set to 16 or 32. During a lookup, the algorithm first checks to see if the request is handled by a node in the leaf set. If that fails, the routing table is utilized and the request is forwarded on. Rowstron’s experiments show that Pastry does in fact scale well with an average number of hops following a $O(\log(N))$ function.

Zahn et al. integrated Pastry into an AODV based MANET in a version they coined “MADPASTRY” [57]. In their application they introduce the concept of node clusters with the same prefix to approximate the concept of locality. Their findings show that their implementation performed as well as a Gnutella-style agent, but with only a fraction of the traffic (unfortunately, figures were not cited). Despite this, their analysis also stated that in tests with fast moving nodes, the routes are broken too often for MADPASTRY to handle [57].

2.4.1.3 Tapestry.

Another implementation of a DHT for file management is the Tapestry system proposed by Zhao et al. [59]. Zhao asserts that by using Decentralized Object Location and Routing (DOLR), mobile and replicated end-points can properly handle message passing, even in the presence of system instability. Nodes in the system are assigned *nodeIDs* and application end-points are assigned *Globally Unique Identifiers* or GUIDs. These identifiers are selected from 160-bit space using some form of secure hashing such as SHA-1 [59]. As Zhao states, one key difference between protocols like Pastry and Tapestry, compared to first generation P2P systems like Gnutella or Freenet, is that the DHT protocols can guarantee that files can be found in the system as long as they exist, where Gnutella and Freenet can make no such guarantee. An interesting aspect of Tapestry is that it is designed to work with multiple applications, rather than each application forming its own overlay network. To achieve this, each message is assigned an application identifier, or A_{id} . This A_{id} is then used to route the message to the correct process once the packet arrives at the destination.

Tapestry makes use of the following API to integrate applications with the overlay (as written by Zhao [59]):

1. $\text{PublishObject}(O_G, A_{id})$: Publish, or make available, object O on the local node. This call is best-effort and receives no confirmation.
2. $\text{UnpublishObject}(O_G, A_{id})$: Best-effort attempt to remove location mappings for O .
3. $\text{RouteToObject}(O_G, A_{id})$: Routes messages to location of an object with GUID O_G .

4. RouteToNode(N, A_{id}, Exact): Route message to application A_{id} on node N . “Exact” specifies whether the destination ID needs to be matched exactly to deliver payload.

Routing follows a Classless Inter-Domain Routing (CIDR) like-system where messages are forwarded to neighbor links whose nodeID is closer to the root of the identifier. Each node then maintains a look-up table called a “neighbor map” that splits nodes into levels based on the number of digits that match in the id prefix [59].

Zhao covers a number of issues pertaining to availability and redundancy, mainly centered around the volatility of node connectivity. Using acknowledged control messages, careful handling of node insertions and removals, and periodic beacons, Zhao claims a near 100% matching of node routing messages to objects.

Zhao does not explicitly cover the use of Tapestry in a MANET setting, however, since Tapestry takes network distance into account, it could prove suitable for use in a MANET. The major drawback is the overlaying of a logical network on top of the physical network which is constantly changing. Unfortunately, research into this topic remains elusive and presents the opportunity for future work.

2.4.1.4 Content Addressable Network.

A Content Addressable Network (CAN) functions slightly differently from DHTs. In a CAN system, nodes divide a logical coordinate space that takes the form of a d dimensional torus (the edges of the plane wrap around). As nodes enter the system, they divide the plane into smaller sections of responsibility known as “virtual coordinate zones”. Each node maintains a routing table to contains entries to all nodes that are adjacent to the section it is responsible for. Routing then is simply performed by drawing a line from the source node to the destination. Figure 7 demonstrates this routing mechanism [42].

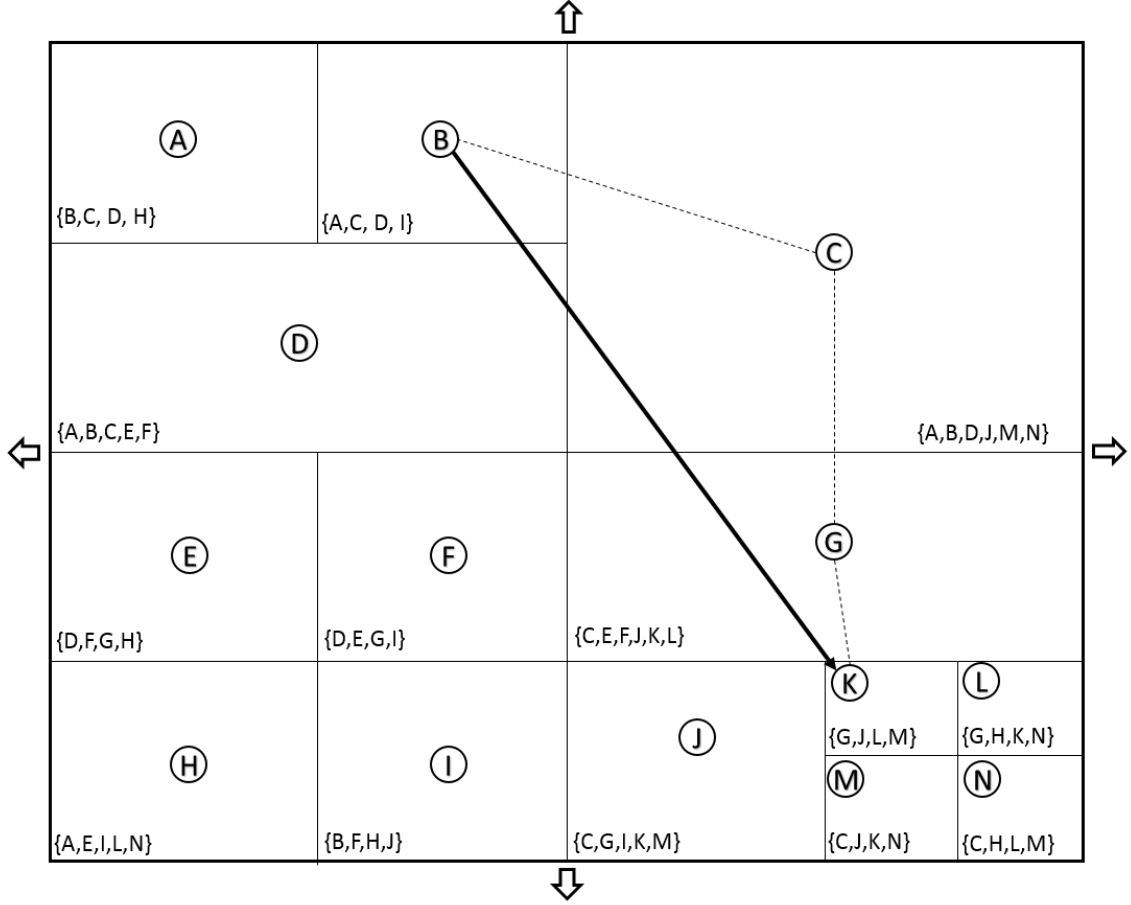

Figure 7. Content Addressable Network Grid - Nodes divide a grid into areas of responsibility for maintaining routing information. The grid represents a torus, so edges wrap around to zones on the opposite edge with each node's neighbor set contained in the braces. A notional route of node B looking for data that would reside on node K is shown by the dotted line.

Ratnasamy cites traditional routing mechanisms in his work, discussing the downsides of using mechanisms such as the Distance Vector and Link State routing algorithms, citing the need to disseminate local topology information, but doesn't consider reactive protocols such as AODV and OSLR in his analysis.

Shah et al. examine the performance of merging P2P networks, comparing CAN and Chord. Their work, using the NS-2 simulator, shows CAN outperforming Chord in a MANET setting by 5 - 10% on most metrics [45]. Their work is interesting to examine given the event that there exist two or more disjoint peer-networks joining together. Such would be the case in the event that you had two separate UAV swarms

converging in a single area. A notional scenario additional resources being required to monitor a particular area and a portion of a system was diverted to increase capability.

2.5 Combining P2P and MANETs

It is important to note several commonalities shared by both MANET routing and P2P file applications. In both system, no single entity acts as a central server, therefore node cooperation is implied and flooding of requests is required. The flooding mechanism creates scalability problems, as it is an exponential function. Furthermore, the central challenge to both systems is finding routes efficiently despite a constantly changing topology [21]. While the mechanism for the topology changes are different (physical location changes in MANETs, and turn-on/drop-offs in P2P systems), the impact is similar. The Ding paper also points out several differences that are important to note. First, MANET routing occurs at the network and data-link layers, while P2P applications work at the application layer of the OSI model. Another key difference is the inherent power constraint possessed by MANET nodes that is not found in typical P2P application hosts. In fact, many research articles have centered around finding optimal routes using power consumption as a metric [44, 54, 3, 47].

2.5.1 Integration Paradigms.

When discussing the performance of a P2P system, the critical metric is the complexity of the lookup or query operation. This lookup metric determines the overall scalability of the system. The complexity model includes message traffic at both the routing and application layers. Ding and Bhargava [21] divide MANET file system implementations into five different categories based on the query routing mechanism (lookup protocol): *Broadcast over broadcast*, *Broadcast*, *DHT over broadcast*, *DHT over DHT*, and *DHT*. The five paradigms are visualized in Figure 8. In the figures,

circles represent nodes in the system, and gray circles are peers in the P2P overlay. Shortest routes between source and destination are denoted by a dotted line, while solid lines mark paths of the routing algorithm. The differences between these groups is discussed below.

2.5.1.1 Broadcast over broadcast.

One of the easiest approaches to deploy a P2P network in a MANET is to implement a broadcast based P2P application on top of a broadcast based routing mechanism. Figure 8a illustrates this methodology. While it is easy to implement, it suffers from the double broadcast, ensuring that scalability is not an option ($O(n^2)$ complexity). Not only does this create additional control overhead, it requires more energy as well. Also, the disconnect between logical routing and physical routing means that the shortest logical route might mean traversing the entire width of the physical network. In a highly dynamic environment such as a MANET, this should be minimized as much as possible.

2.5.1.2 Broadcast.

If the application and network layers can be combined, many of the drawbacks of the Broadcast over Broadcast methodology can be overcome. While broadcast messages still flood the network, routes will now be the shortest physically, greatly reducing the complexity to $O(n)$, as visualized in Figure 8b. An example of this would be the ORION protocol merged with AODV (discussed in a later section).

2.5.1.3 DHT over broadcast.

Implementing a DHT based P2P application on top of a broadcast routing mechanism can reduce the control overhead at the application layer at the expense of

implementation complexity. Figure 8c illustrates this implementation. As stated previously, query operations in a DHT are $O(\log n)$ but this is multiplied by the $O(n)$ constant of the network layer, producing a query operation that is $O(n \log n)$.

2.5.1.4 DHT over DHT.

In this scenario, as shown in Figure 8d, a DHT based P2P application sits on top of a DHT based routing mechanism. An example of this would be Chord running on a proactive protocol like Virtual Ring Routing (VRR) [14]. VRR differs from traditional table that it only maintains entries for its neighbors. VRR maintains a routing table for both its physical neighbors and its virtual (logical) neighbors. Then with a DHT encoding scheme, it routes messages to the physical neighbor that gets the message closest to its logical neighbor. When implemented correctly, this results in a $O((\log n)^2)$ complexity.

2.5.1.5 DHT.

Similar to the cross-layer broadcast implementation, a unified DHT system combines the routing and application layers to greatly reduce control traffic as seen in Figure 8e. In this system, both network ids and file names are hashed within the same key space. When a file is generated, the key value is stored at the node with the closest id. The DHT system results in a lookup complexity of $O(c \log n)$, where c is the average hop count per lookup [21].

This thesis does not give working examples of all the paradigms listed above, but details three useful implementations below.

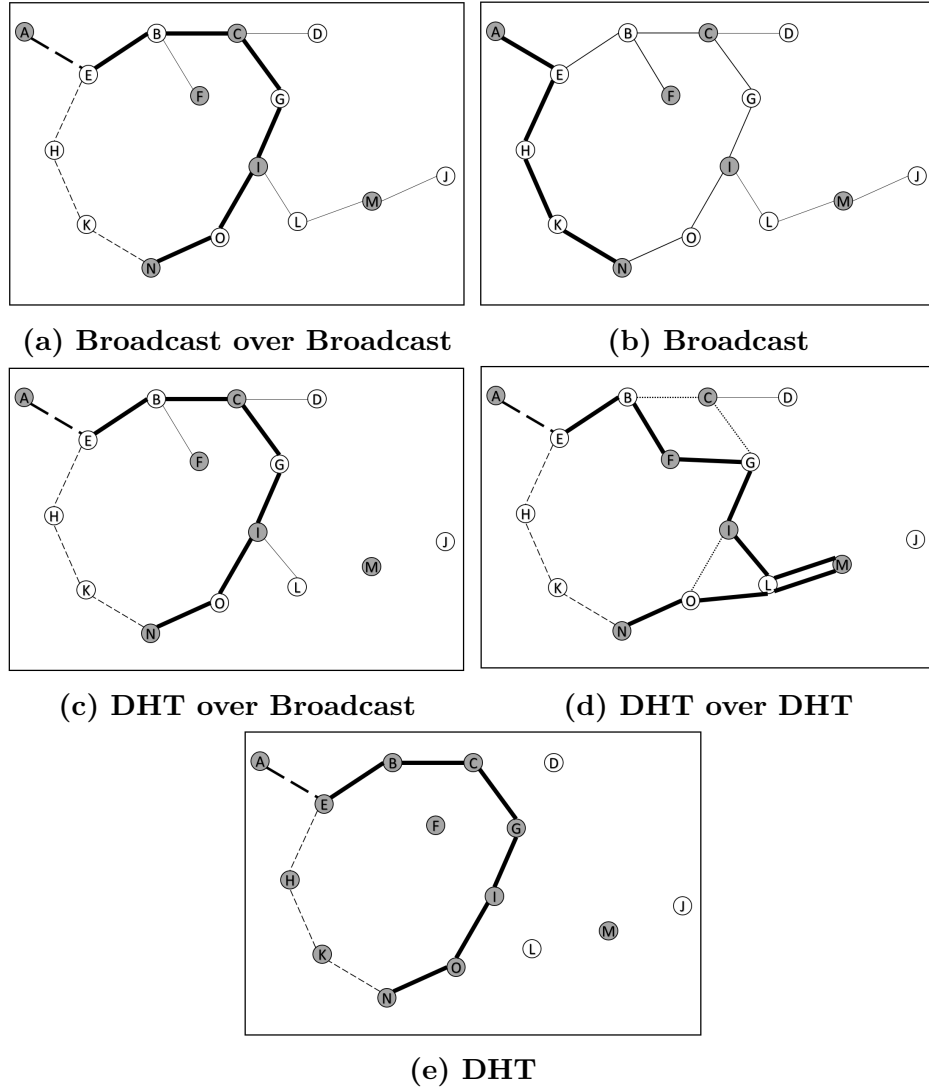

Figure 8. MANET File System Implementations - Adapted from Ding and Bhargava [21], Figures 8a - 8e demonstrate the various implementations of file systems in a MANET. White nodes are nodes participating in the system, while shaded nodes are nodes participating in file system. Thin lines denote broadcast messages, thick lines denote selected route while dotted lines represent shortest physical route.

2.5.2 Optimized Routing Independent Overlay Network (ORION).

The ORION protocol was presented by Klemm at el. as new approach to P2P operation in MANETs [32]. ORION takes principles of AODV and other reactive routing protocols and introduces it to the application layer. Instead of maintaining static connections between peers, as in traditional P2P systems such as PASTRY and Gnutella, connections are setup on-demand. Klemm states that while ORION introduces potential for redundancy between the application and network layers, it is possible to combine the two for cross-layer optimization. As such, ORION can be implemented as either a *Broadcast over Broadcast* or *Broadcast* paradigm as listed above. There are two principle divisions of ORION's tasks, search and transfer.

2.5.2.1 ORION Search Protocol.

Each node in ORION hosts a local repository for files to share from its local file system. The assumption is made that each file is uniquely identified. For its application in the UAV Swarm problem domain, this is an important and reasonable assumption. If each UAV is a separate sensor platform, it is reasonable and logical that each file generated would be tagged with information about the UAV that generated it; the time, location, and sensor type. This information would naturally be utilized as a basis for search queries such as finding all imagery data of location x between times $y1$ and $y2$, with obvious extensions to audio, video, infra-red, or any other sensor utilized.

Each node also possess a response table and file routing table, similar to the tables utilized by AODV, to manage current routes and RREQs. A Least Recently Used replacement policy controls the size and memory consumption of the tables [32].

One primary difference between AODV and ORION, is that when files are requested, the source is not looking for a particular node, it is looking for files that

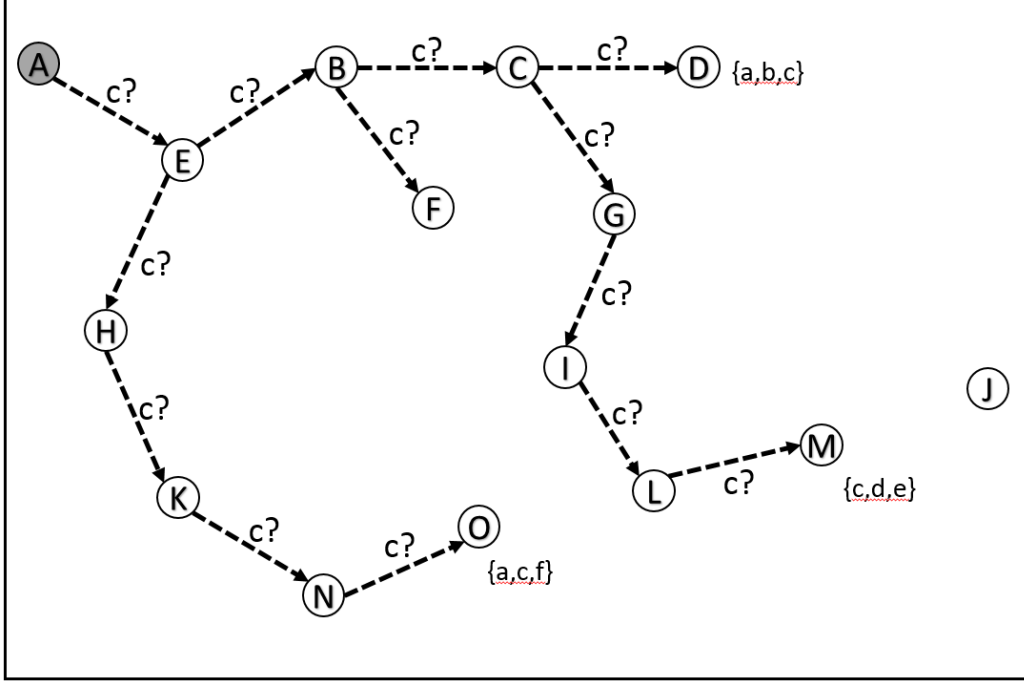

Figure 9. ORION Query Broadcast - Node A initiates a query broadcast for file “c”. Only nodes that do not contain the file re-broadcast the query. Nodes that receive queries only track the first arrived request with the same sequence ID. Notional file tables for nodes D,M, and O are shown in braces.

match its query criteria. To accomplish this, a QUERY message is broadcast in a similar fashion to AODV’s RREQ. Nodes that own files that match the source node’s query criteria reply with a RESPONSE message. Again, in line with AODV, each message contains a SRC and SEQ field that is used to uniquely identify each request and prevent loops. Figures 9 and 10 illustrate this process.

Figure 9 shows node A initiating a QUERY message, looking for file “c”. Node A broadcasts a QUERY packet to its neighbors and they re-broadcast the QUERY. Nodes that receive QUERY broadcasts only track the first arrived request with the same sequence ID to prevent loops in the system. Furthermore, if a QUERY is requesting a specific file, nodes only have to re-broadcast if they do not possess the queried file. Using this broadcast attenuation technique can be useful for reducing the traffic needed for re-querying during a failed transfer.

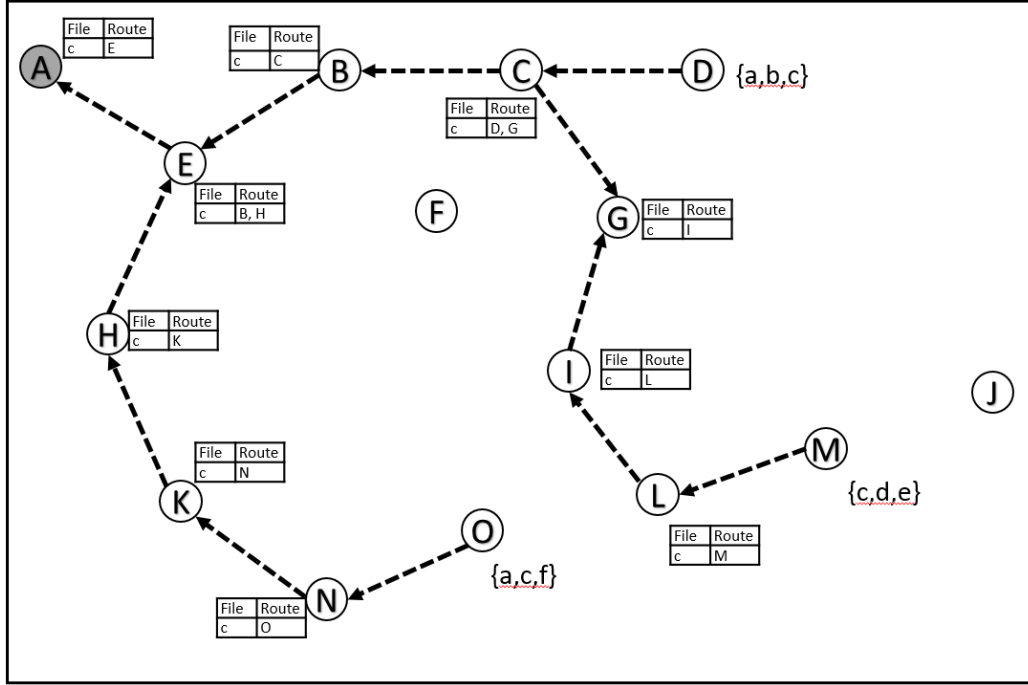

Figure 10. ORION Query Response - Nodes that possess file “c” respond to requests along the reverse path. Nodes add responses to their routing table for file “c”.

Figures 10 illustrates the process of nodes replying with a RESPONSE message. Nodes that possess file “c” responds along the reverse path. Of course, this is a simplified model, as the ORION protocol specifies that queries can be anything and nodes can reply with any number of files that match the query criteria. If a node receives a RESPONSE packet that contains a file listing that it already possesses, it simply strips that file from the response before forwarding it along the reverse path.

2.5.2.2 ORION Transfer Protocol.

Due to the volatility of connections in a MANET, it is critical that control of the transfer process resides at the requester (source) [32]. Since one assumption for ORION is that nodes are homogeneous, and that the maximum transfer unit (MTU) doesn’t vary between communicating nodes, files can be broken up into block sizes

that fit inside of a single packet. The source node, having a route to the desired file and file information from the original QUERY message, initiates a DATA_REQUEST message for a single block to the corresponding node in its file routing table. When the request reaches the provider node, it responds with a DATA_REPLY message that contains the file block.

ORION uses a local resolution for link-failure, which is a departure from the AODV's source initiated link-failure resolution protocol. In the event that a node cannot fulfill the request for the file (it has no remaining entries in its file table) it sends a ROUTE_ERROR message back to the source node. At this point, the source node can either abort the transfer or initiate a re-query. The only difference between a re-query and a regular query message is that the source node is aware the file exists in the network, and can request it by name instead of providing keywords.

The final piece of ORION's transfer protocol is loss recovery and packet scheduling. To handle the inevitability of drop packets, the transfer protocol uses a list of pending block requests. When a file is first requested this list is initialized with all the block required to complete the transfer ($blocks = \frac{filesize}{MTU}$). To prevent unnecessary block requests, the source node keeps track of the average round trip time and uses a round-robin approach to requesting blocks. Therefore, all blocks in the file will be requested before re-tries are attempted. Conducting the file requests in this round-robin fashion allows time for the delayed blocks to still reach the source node before being requested again.

2.5.3 ORION+.

ORION+ is an extension of the ORION protocol that was developed by Ahmed Abada [1]. ORION+ attempts to improve the performance of ORION by using proactive unicast messages to calculate link quality. According to the author, this

has the benefit of re-ordering routes based on quality instead of the first in approach. Additionally, bad routes are determined before they are needed. ORION+ provides no benefit if there is only one route to the requested file or the topology is changing at a significant rate [1].

2.5.4 Mobile Peer-to-Peer (MPP) protocol.

While the author of ORION cites that it can be implemented as a cross-layer solution, MPP is designed from the start to be exactly that [23]. However, the DSR protocol is integral to MPP, such that every node participating in a MPP mesh must be running DSR [1] where ORION will work on top of any protocol.

MPP has two types of transfer schemes, static and dynamic. With the static mode, nodes involved in a file transfer file requests are cached for later use. When a link breaks, the protocol will look up an alternate source from this cache. The static mode is very similar to the ORION methodology. As Gruber points out, the static system works well in systems with fewer nodes, low mobility, or small file sizes [23].

The dynamic mode of the protocol uses an first-come first-serve methodology where the first route back from a file request is used. Any additional routes that arrive afterward are discarded. In the event of a link failure, a new file request is issued, thus re-flooding the network. The dynamic mode has the effect of using the best source for the file until the link breaks (at the expense of more frequent network flooding).

2.5.5 Availability Schemes.

Since a central part of this thesis is looking at the effect of redundancy, it is worth our time to look briefly at some principles of replication. Tanenbaum and Van Steen [50] states that redundancy, which is a key attribute to availability, can come from

two sources: replication and erasure coding. Replication, the most obvious solution, entails creating duplicate copies on multiple nodes. When node availability decreases, replication loses its ability to guarantee redundancy.

Erasure coding is the procedure of segmenting files into multiple fragments. Each fragment contains additional information about the file, such that if multiple fragments are missing, the file still can be reconstructed. Tanenbaum defines the redundancy factor as $r_{ec} = \frac{n}{m}$, and the number of required m fragments to reproduce the file is computed as

$$1 - \epsilon = \sum_{i=m}^n \binom{n}{i} a^i (1 - a)^{n-i} \quad (3)$$

where m = number of fragments, a is the average node availability, ϵ is the required file unavailability. The formula for calculating the replication rate for straight file replication is

$$1 - \epsilon = 1 - (1 - a)^{r_{rep}} \quad (4)$$

Taking these two formulas, Tanenbaum produces the ratio of $\frac{r_{ec}}{r_{rep}}$. When this ratio is compared over the average percentage of node availability, straight file replication requires twice as much redundancy as erasure coding to achieve the same guarantee of file availability [50]. While this reduction isn't that dramatic in a traditional wired system, in a UAV swarm this represents a reduction in broadcast transmissions (network congestion) and power consumption.

In traditional systems, file popularity is also an important concept. Intuitively, the more popular a file is, the higher the replication rate should be. Increasing the number of copies based on popularity ensures that the file is available as needed, but also reduces the query time. Vranicar [52] uses Beehive [41] in this study of data availability, but this system proves to be an unnecessary complication in our stated problem domain. First, as Tanenbaum states, popular and uniform distribution

policies end up being very similar when looking at the average number of nodes that need to be queried [50]. Second, in our system, once a file is retrieved there is no further need for it. The file is extracted by the node with long-haul communication, and as such, is really the only true consumer of files. In this sense, each node isn't really a "peer", but simply a resource for the extraction node to utilize, so popularity is null and void. However, if data availability is essential for operation of the swarm, then a popularity based model could prove useful.

Chen looks at replication and MANETs with the goal of optimizing file availability by reducing query delay. The optimization is done by calculating node meeting frequency and using this parameter to adjust which nodes receive replications [18]. While an interesting proposition, Chen's work does not take into account the issues of placing increased demand on select nodes. The increased utilization will increase network traffic to this node, potentially slowing routes requiring this node. Additionally, the rise in traffic could increase the power consumption forcing it to be replaced at more frequent intervals. For these reasons, a simple replication is better suited for this thesis's problem domain.

2.6 Simulation Environments

Since forming an actual network of UAVs is impractical for most research purposes, most researchers turn to simulation as a means to study the various interactions of interest. Discrete event simulators favored in the research papers present thus far include QualNet, OPNET, GloMoSim, NS-2/3 and OMNeT++. While there are many others, NS-3 and OMNeT++ are the main focus of this paper due to open-source availability. Additionally, Koksall evaluated many simulators, and recommends OMNeT++ and NS-2 as the best choices for researchers (NS-3 was not available at time of his publication) [33].

2.6.1 Network Simulator Version 2/3.

Network Simulator Version 2(NS-2), begun as a project out of UC Berkly in 1997. For over a decade it received continued support from various sources due to its open-source nature. NS-2 modules are written in C++ and it uses the OTcl language for simulation scripting. NS-2 was the de facto simulator of choice for many research papers. Network Simulator-3 is an open source discrete-event network simulator that is the successor to NS-2. NS-3 was initially released in 2008 (and still in active development) to improve the core architecture of NS-2 and provide a pure C++ scripting environment where NS-2 was much more complex, dividing code between C++ and OTcl. Its software core leverages object-oriented concepts such as smart pointers and template programming to improve performance over NS-2. NS-3 also has a dedicated data-collection framework which provides robust data collection capabilities. Unfortunately, the only application layer P2P module available to NS-3 is Pastry (at the time of this writing). Any additional file systems would need to be coded as a separate module. NS-3 provides limited support for direct code execution, allowing the simulation to interact with real programs and system processes as part of the simulation. Additionally, NS-3 can also interact with real system process in a real-time mode for testing of operational systems by supporting Berkley sockets and POSIX threads [55] as well as provide the capability for evaluating packet traces with network monitoring utilities such as Wireshark.

2.6.2 OMNeT++.

OMNeT++ is a discrete-event simulator that is utilized to run a variety of simulation scenarios. For network simulation and experimentation, the INETMANET modules of OMNeT++ and Denacast P2P module are required. Denacast is an Oversim (P2P simulation module) [9] adaptation to support MANET operation. Khan con-

ducted a performance evaluation of several network simulators and found OMNeT++ to be much more efficient than NS-2/3. In his simulations, he found NS-2/3 to run near 100% cpu utilization vs. OMNeT++ and GloMoSim's 10-20% rate [51].

2.6.3 Comparison of Performance.

Weingärtner et al. [55] conducted several comparison studies of multiple simulators to evaluate their performance. To do this, they coded a reference simulation for each simulator, opting to not use prepackaged module to ensure an apples-to-apples evaluation was conducted. For purposes of simplicity, a network topology of a $\sqrt{n} \times \sqrt{n}$ grid of nodes was chosen as their test topology, with n ranging from 4 to 3025. As an initial test, they measured the number of dropped packets recorded by the simulator when each transfer was hard-coded with a set drop probability.

Weingärtner et al. [55] shows that each simulator performed within a reasonable measure of each other for the purpose of comparing performance, with SimPy being the biggest out-lier. Satisfied with the baseline comparison, Weingartner ran several tests, calculating the computational time required vs. node count and the coded dropped packet rate. Their tests show SimPy took significantly longer to run simulations, linearly increasing with node count. NS-2 is second to last, increasing at a much slower rate. The rest of the simulators show much better performance, running their test cases in less than 200 secs for node counts up to 3025. When comparing run time against dropped packet count, from 0 to 50 % packet drop rate, OMNeT++ and NS-3 performed similarly well, while NS-2 took roughly 4 times as long, and SimPy taking 10 times longer to conduct the same simulation [55]. At higher rates of dropped packets, each simulator took roughly the same amount of time.

With regard to memory utilization, Weingartner's results show a linear increase up to 3025 nodes. The JiST simulator uses roughly double the memory, capping out

at 140 MB. Weingartner evaluated memory consumption with respect to drop rate probability and as expected, as packet loss goes up, less memory is required to track current packets. It is important to note that the test case for this test was simple, and more memory is expected to be utilized in a real network simulation. Based on these results, both NS-3 and OMNeT++ are acceptable choices for this thesis's experimentation.

2.7 Summary

This chapter covered some of the core considerations in regards to operating a Peer-to-Peer network in a MANET environment. A general overview of MANETs was presented, followed by a quick description of the data-link layer protocols associated with wireless communication. Extensive coverage of various routing protocols was given to emphasize the importance of the network layer in intra-MANET communication. Routing protocols covered included proactive varieties such as DSDV and OSLR, reactive protocols including AODV (and variants) and DSR. In addition, brief coverage of hybrid protocols, virtual backbones, and quality of service considerations was presented as well.

Chapter 2 also covered traditional P2P architecture, providing insight into how distributed systems are set up to transfer information in a traditional network, and the challenges introduced by attempting to use the same methodology in a MANET. The chapter then transitions to analyzing the five major paradigms for implementing a P2P application in a MANET. Additionally, treatment was given to the MANET P2P protocol that will be implemented as part of the experimentation in Chapter IV (ORION), as well as the MPP protocol for comparison.

Finally, this chapter covered several simulation environments available for researchers, compared performance, and assess validity. Next, Chapter III will present the methodology in conducting the experiment.

III. Methodology

The objective of this experiment, is to ascertain the impact of replication on data availability (as measured by mean query and transfer success rate and mean time for request/delivery of information) in a mobile ad hoc network. Specifically, the experiment is designed to measure the ability to extract information from a remote location given a narrow-band communication channel and a given attrition/replacement rate of unmanned aerial vehicles (UAVs) in the swarm. In particular, this experimental domain implements the Ad hoc On-demand Distance Vector (AODV) routing protocol as the underlying ad hoc network and implements the Optimized Routing Independent Overlay Network (ORION) protocol as its file replication/transfer mechanism.

Data will be collected from the simulation based on the ability of the swarm to fulfill the request for information compared against the output provided by various configurations. This experiment provides a combinatorial evaluation over four input parameters. The evaluated parameters include: the number of nodes (i.e. UAVs in the swarm), airspeed, replication level, and churn (i.e. attrition) rate. For each configuration, twenty runs will be performed over 10 minutes of simulation time (i.e. 2-4 thousand samples). The primary focus is on query and transfer success rates, while secondary consideration is given to the speed at which the two primary objectives are accomplished.

The replication amount/rate is important to study due to the increased traffic generated from creating multiple copies on different nodes and how this impacts total transfer time and availability. The hypothesis here is that as replication amount increases, data availability (as measured by successful transfers) will increase until network saturation is reached, at which point success rates will decrease and response times will increase. The aim of this experiment is to identify the conditions under which this trade-off between robustness and over-saturation occurs. Once a certain

level of replication is reached, transfer times will start to increase due to the amount of traffic required to replicate the files, thus reducing available system bandwidth to complete the file request. The key insight of this work is that increased replication is expected to decrease transfer time initially due to the probabilistic decrease in hop count from request origination to file source(s). In this way, multiple nodes will be able to respond to the file request, thus ensuring a response to file requests and consequentially improving data availability. Network utilization itself is not measured explicitly as it has been covered extensively by Vranicar [52]. Interestingly, because the only traffic generated in this system is either from the routing protocol or from the application created for this experiment, we can attribute any change in response time to the level of replication being employed by the swarm.

As noted by Andel and Yasinsac [6], many research papers suffer from a lack of reporting on parameter specification. Andel and Yasinsac [6] examined many of the publications on mobile ad hoc networks (MANETs) and found a gamut of issues. At the time of their writing, 85% of the publications were not independently repeatable, 87.9% did not specify the version of simulator used, 30% did not specify simulator package, 43% lacked transmission range specification, 65% did not list the number of simulation runs, 87.5 % did not use confidence intervals, 71.6% did not list the type of traffic utilized, and 61.5% did not use a mobility model [6]. Thus this chapter also provides the information necessary to ensure the experiments are repeatable and verifiable.

3.1 Experimental Design

The purpose of the experiment is to measure the impact of replication count on an ad hoc peer-to-peer file system in relation to the availability of randomly selected

files and the end-to-end total transfer time. Several different control factors will be evaluated, including: swarm size, node mobility (i.e. speed), and rate of churn.

3.1.1 Apparatus.

Since the experiment is conducted in a discrete time network simulator, it necessary to discuss the system utilized for the experiment, (i.e. software and hardware).

3.1.1.1 Software.

OMNeT++ was selected for its open-source availability, robust network and mobility models, efficiency, and ease of experimental integration. Final simulations were performed on version 4.6, using INET (network simulation module) version 2.99.

Verification of simulator performance is critical when conducting experimentation modeling real world scenarios. Bredel and Bergner [12] examine the performance of the 802.11g wireless model in OMNeT++ and compare it to a real physical system. They conclude that OMNeT++’s model performs very well over long observation times with average measurements. They point out that discrepancies exist in packet scheduling so care should be taken when analyzing “rare network events” [12]. Ivanov et al. [27] examine the performance of NS-2, assessing its modeling of network connectivity, packet delivery and latencies. Their work concludes that NS-2 does an adequate job of modeling a multi-hop network in an indoor setting, but produced mean latencies that were lower than real-world performance. The authors state that this is most likely from two primary sources: lack of runtime overhead from the OS and errors in dynamic data rate modeling (NS-2 uses static data rates). Their tests, which consisted of measuring packets delivered as part of an MPEG-4 video stream across 4 hops, found that the packet delivery ratio error averaged 0.3 to 1% of the real world system. This work can be extended to NS-3 since the core models have

not changed between versions 2 and 3. These two works, when combined with the comparison analysis of Weingärtner et al. [55], lends credibility to the results of both simulation environments (NS 2/3 and OMNeT++), with the understanding that no simulation will ever be 100% accurate.

3.1.1.2 Hardware.

The simulations run on a 64-bit Intel Sandybridge i5-2500k quad-core processor running at 3.7Ghz with 16 GB DDR3 RAM (pc-1600) on a ASUS ROG Maximum IV motherboard, and a Samsung Solid State Drive (rated at 500MB/s read/write). The test system OS is Windows 8.1 Pro with all foreground applications and unnecessary services closed to prevent potential interference with testing.

3.1.2 Simulation Design.

The simulation scenario is defined by a set of nodes (i.e. UAVs) randomly moving in a 1000 meter square bounded space using OMNeT++’s “mass-mobility” mobility model. Upon reaching the edge of this region, the nodes are reflected back in at the complementary angle. Each node, except the exfiltration (i.e. sink) node, will generate a file at a set interval as to mimic nodes collecting some form of data (e.g. imagery). Once the files are generated, they will attempt to replicate the file to its closest neighbors based on the configured replication rate parameter, which varies between 0 and 4. Periodically, the sink node (representing the node that possesses the lower-bandwidth, long haul communication capability) will request one file at random from the network as a whole. If a query response is not received within 1 second, the master node marks that file as unattainable and moves on to the next file. The time to wait value was chosen empirically to maximize the number of samples collected by the system, and should be adjusted to accommodate systems with higher

latency. Once the master node receives a response to the broadcast query (or times out), it will request the file in accordance with the ORION protocol as detailed in Chapter 2. Upon completion or failure of a query and transfer, the simulation adds the requested file to a taboo list, thus ensuring the file is not requested again. The simulation repeats the process until the simulation terminates at 600 seconds. In the event that all generated files have been queried, the master node will sleep for an interval equal to that of the file generation rate, giving the swarm time to generate and replicate new files. Pending requests that occur when the simulation terminates are discarded, resulting in a negligible loss that is not expected to have a significant impact on results.

Transfer failures occur as either a timeout or a route error. In a timeout situation, the file transfer request exceeds a set value of time allowed to complete the request. For this experiment, this is set to 5 seconds. On the other hand, a route error is generated when a node fails to receive a request acknowledgment from the next hop. When a route error occurs, the unreachable node is removed from the receiving node's file source list, and sends a route error message to the previous node in the return path. Subsequent route errors being performed recursively along the return path if no other routes are available at each intermediate node.

If churn (i.e. nodes entering and leaving the system randomly) is enabled, a percentage of nodes will be turned off for a set duration to simulate hardware faults, UAV crashes, etc. During this window, the nodes will not reply to queries or transfers until it is re-enabled. However, the node will continue to move (an effect that is not expected to have a significant impact on results). When a node is selected to be disabled, it turns off for a period of 30 seconds, meaning that it cannot act as a node in the network, losing any previous data and routing info. This value was chosen

to be relatively large in network time to highlight the effect that churn has on the system.

Since the focus of this thesis is on data availability resulting from replication (rather than from layers 1,2, and 3 of the Open Systems Interconnect (OSI) model), an idealistic radio model was chosen to represent the physical layer communication of the network. This choice was made for simplicity and to limit the number of factors in experimental design.

3.2 Assumptions

Several assumptions were made in the design of this experiment: Nodes are replaced at the same rate of attrition (i.e. churn rate), byzantine faults [50, 325] do not exist, communication channels are secure and available, hardware errors do not exist within the nodes unless that node is selected for attrition, individual nodes are fully cooperative, nodes are homogeneous (i.e. equally compatible/capable), each file is unique (data consistency checks are not required), each node possesses sufficient storage capability, and finally, once a file has been extracted from the swarm, it will not be requested again.

With that in mind, we can turn our attention to examining the response variables that the experiment will measure.

3.2.1 Response Variables.

The experiment is conducted as a discrete time simulation with the following parameters (Table 2).

- **Query Success Rate** (*querySuccRate*)- Measured as a ratio of the number of queries completed versus the number initiated.

- **Query Response Time** (*queryTime*) - Measured in milliseconds, this measures the amount of time it takes for the source node to receive a response to a request for a file. It includes the time required for the system to locate a file and send the first response back to the source node. While multiple nodes may be able to respond (due to replication), only the first response is measured.
- **Transfer Success Rate** (*xferSuccRate*) - Measured as a ratio of number of completed file transfers over the number of file queries.
- **Transfer Completion Time** (*xferTime*) - Measured in milliseconds, this measures the amount of time it takes to complete a file transfer, not including the initial query.
- **Hop Count** (*hopCount*) - Covariant, this measures the average number of nodes query and transfer packets travel through from source to destination.

3.2.2 Independent Variables.

Due to the number of factors that can be varied in a simulation environment, this experiment performs a full factorial experiment [37] over the following four factors (Table 3).

- **Replication Rate** - The number of times an individual file is replicated to other nodes across the system. Replication rate will remain constant value for each run, but will be varied from 0 - 4 on different runs.
- **Number of Nodes** - The number of *UAVs* in the system under test. The node count will remain constant during individual runs, independent of replication rate. Node counts of 30, 45, and 60 are applied to simulate a small, medium, and large UAV swarms.

- **Speed** - The rate of motion (i.e. UAV speed) is held constant for each run, but is varied to 2, 8, and 15 meters per second between runs to evaluate the effect of speed on network performance.
- **Churn Rate** - The churn rate factor how often nodes are removed from the system and replaced with a new, blank node. To simulate nodes entering and leaving the system for logistical reasons (e.g. fuel or maintenance) or catastrophic reasons (e.g. crashing). Churn rate values will be set to a constant 0, 5, or 10% for each run and will not effect the number of nodes.

3.2.3 Control Factors.

Across all runs of the experiment, several factors are held constant to limit the scope of the experiment. While variations in these values would certainly impact the system performance, they are not the focus of this research. (Table 4) summarizes the experiment's constant factors.

- **Mobility Model** - This factor describes how nodes move in the simulation space. For this experiment, the Mass-mobility model included in OMNeT++ is used rather than the typical random waypoint model used to simulate pedestrian traffic. The Mass-mobility model's continuous travel pattern more accurately reflects the movement of a UAV swarm.
- **Movement Space** -Represented as a two-dimensional Cartesian coordinate grid measured in meters, the simulation space is set to 1,000 meters for all simulation runs. This value, along with number of nodes, dictate connection density.
- **Wireless Model** - The simulation model used to represent the physical characteristics of the wireless transmission. For the purpose of this experiment,

the IdealRadio Model included in OMNeT++ is chosen. It is not affected by random errors, signal-to-noise loss ratios, and other anomalies.

- **Transmit Rate** - The data rate at which the simulator makes network connections. OMNeT++ supports a variety of wireless protocols natively. This experiment assumes an 802.11 wireless network with a bandwidth of 11Mbps.
- **Transmit Range** - The range at nodes are able to establish network connections. Keeping with the 802.11n standard, a value of 250m was chosen.
- **Routing Protocol** - AODV was chosen as the layer 3 routing protocol for all runs in this experiment.
- **File Size** - The size of the data file to be transferred. This value is set to 100KB across all runs as not to affect transfer times.
- **File Generation Rate** - The rate at which files are created on each node, and is also used to determine how long the master node will sleep for in the event that it has no new files to query. Throughout all runs, a generation rate of 3 seconds is used with node start times staggered randomly between 0 and 200ms.
- **Churn Duration** - The amount of time that nodes selected for attrition will remain disabled. A value of 30 seconds is applied in all runs.
- **Query Timeout** - The amount of time before a query is considered to have failed. A duration of 1 is utilized for all runs of this experiment.
- **Data Packet Timeout** - The amount of time before a transfer is considered to have failed. A transfer timeout of 2 seconds is used for all runs.
- **Requery Attempts** - The number of times the transfer protocol will attempt to transfer the file if a previous transfer fails. A value of 5 was selected based

on testing to provide reasonable results without attempting to overcome all network failures.

3.2.4 Data Collection and Reduction.

Data is collected via a comma delimited log file. Each measurement taken or calculated is recorded as both raw and summary data.

3.3 Summary

This chapter documented the experiment design and implementation that will be used to evaluate the effects of file replication on data availability in ad hoc networks. Specifically, this experiment is designed to evaluate the effects of replication count, node count, node speed, and churn rate on a simulated ad hoc network's ability to access information in the network. Chapter IV presents the data collected from this experiment and provides insight into factor interaction.

Table 2. Response Variable Summary

<i>Response variable</i>	<i>Normal operating level and range</i>	<i>Measurement precision</i>	<i>Relationship of response variable to objective</i>
<i>querySuccRate</i>	0-100 %	calculated ratio	Measured as a ratio of number of queries for files to the number of responses.
<i>queryTime</i>	0-100 <i>ms</i>	1 <i>ms</i> steps, measurement based on simulation clock. Prior research serves as baseline	It includes the time it takes for the system to find a file in the network and then send the first response back to the source node. Since multiple nodes may have a copy of the requested file, only the first response back is measured.
<i>xferSuccRate</i>	0-100 %	calculated ratio	Measured as a ratio of number of requests for a file to number of completed file transfers.
<i>xferTime</i>	0-5000 <i>ms</i>	1 <i>ms</i> steps, measurement based on simulation clock.	Amount of time it takes to complete a file transfer. It does not include the time for the initial query.
<i>hopCount</i>	0-10	averaged value	average number of nodes a query or transfer travels through.

IV. Results and Analysis

The primary objective of this research is to evaluate the impact of file replication on availability, with a secondary look at the impact on transfer and query rates in a simulated mobile ad hoc network (MANET). The following results of the simulation and analysis will be examined as an aggregate collection, then a deeper look will be given by breaking out the results based on the simulation factors. As a last look, results with respect to time will be investigated to investigate the possibility of measurement time playing a factor in results. The granular breakdown is done to provide a deeper analysis of how the simulation factors impact the overall results. The data presented in this chapter was analyzed using the “R” statistical program. Line graphs have been chosen to represent the data with confidence intervals for each data point. These graphs are generated using the ggplot library [56].

4.1 Aggregate Values

When measuring availability, this thesis looks at two primary components, first whether or not the system can locate the file in the network, and second, the ability of the system to successfully transfer the file (ex-filtration). Query success rate measures the first component, and transfer success rate measures the second factor. Since the main goal of this thesis is to evaluate the impact that file replication has on availability, query and transfer success rate will be examined first as an aggregate collection of factors. The time to execute queries and transfers, secondary objectives of this thesis are also presented. Inspecting the results with respect to node count, mobility and churn rate will be broken out further in the chapter.

4.1.1 Query Success Rate.

Figure 11 illustrates query and transfer success rates based on the replication count. Looking first at the query success rate, the top left chart clearly shows that replication induced a significant effect on the ability of the unmanned aerial vehicle (UAV) swarm to locate a file. Increasing replication from 0 copies of the file to 1 copy, the mean query success rate increased from of a baseline 76.3% to 85.4%, for a mean query success rate increase of 9.1%. Increasing the replication rate to a factor of 2 resulted in a much smaller increase of 3.13% (85.4 to 88.6 success rate) from a replication level of 1. Further increasing the replication factor to 3 only results in a gain of 1.17% over a replication factor of 2. Finally, a replication factor of 4 actually decreases the query success rate by 0.62% from the value obtained by the replication factor 3 measurements.

4.1.2 Transfer Success Rate.

Knowing that the file exists is one part of the equation. Successful extraction of the file from the swarm, after ascertaining its existence, is the other part. The top-right illustration in Figure 11 displays the combined results of all factors for transfer success rates based on replication levels. As expected, the transfer rate closely follows the query success rate pattern, but at a lower rate of success. The baseline (replication factor of 0) mean transfer success rate is 62.65%. Increasing the replication factor to a value of 1 results in a mean transfer success rate increase of 10.81%. Adding an additional replication (replication factor of 2) increases the mean transfer success rate from 73.46% to 77.12% (increase of 3.65%). A replication factor level of 3 nets an additional 1.18% increase in transfer success rate over the replication level 2 measurements. Finally, as with the query success rate, the measured transfer success rate decreases when the replication factor is set to a value of 4. Additional

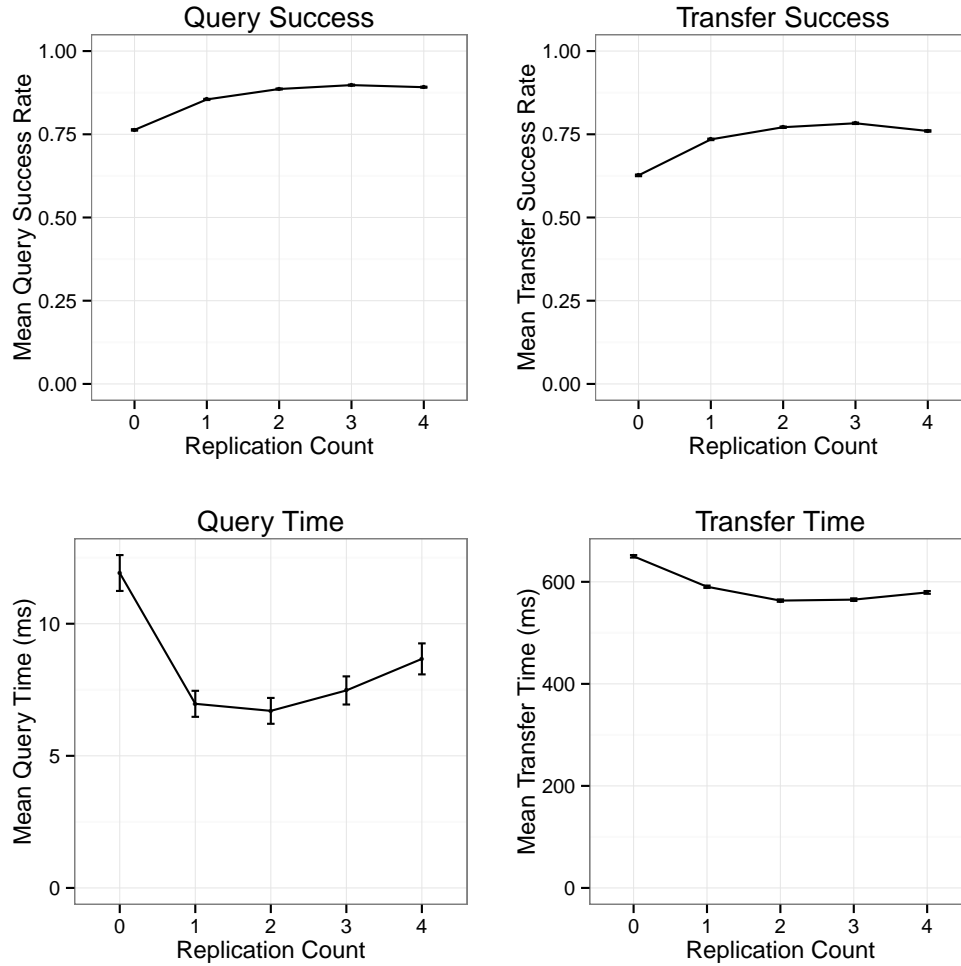

Figure 11. Query/Transfer Success Rates and Mean Time (All Nodes) - This group of charts shows the overall aggregated means across all node counts, speeds, and churn rates for each replication factor with 95% confidence intervals overlaid. The upper-left illustrates mean query success rate while the upper-right shows mean transfer success rates. On the bottom, the left charts the mean query time for each replication factor while the right shows mean transfer time. The aggregate data shows a general improvement in availability as replication goes up to a factor of 3, but starts to decrease at a factor of 4, with the inverse being true for query and transfer times.

replication resulted in a mean transfer success rate decrease of 2.31% to (from 78.31 to 76.0%).

4.1.3 Query Time.

The lower left graph of Figure 11 shows the impact of replication on mean query time. Its quite obvious that replicating files once has a significant impact on mean query time, decreasing mean query time by 41.53%. Further replication however, has no statistically significant effect. It should be noted that while this reduction is significant based on percentage, this impact is trivial in a system where large files are transferred, as a query only requires 1 packet to be broadcast, versus the many packets required to transport the data. However, if many smaller files are to be transferred (suggesting more queries will be performed), this measurement becomes more significant

4.1.4 Transfer Time.

A secondary objective of this thesis is to examine the impact of file replication on mean transfer time of queried files. The bottom-right graph illustrates the effect of replication on transfer time. As can be seen, increasing replication from 0 to 1 improves (decreases) mean transfer time by 59.60 ms. The mean transfer time is further reduced by an additional 27.16 ms. Further increases in replication fail to result in a significant decrease in transfer time, and in fact start to increase the transfer time as replication count is increased to 4. The lack of improvement with increased replication would suggest that the amount of network traffic required to achieve this level of replication impacts the speed of the file transfer protocol. The delay is assumed to be the result of UDP packet retransmissions due to network broadcast congestion.

Additionally, packet queue lengths are suspected of contributing to this delay, but analysis of packet queues are outside of the scope of this research.

4.2 Results by Node Count

Now that the combined measurements have been examined, results based on swarm size (with values of 30, 45, and 60) will be examined to ascertain what impact swarm size (or node count) has on performance. It should be noted that node speed (mobility) and churn rates are aggregated in these measurements.

4.2.1 Query Success Rate.

Looking at mean query success rate (top-right, Figure 12), it is clear that the 30 node swarm is at a significant disadvantage in completing query requests with respect to larger swarms. At the baseline value of zero replication, the 30 node swarm possesses a mean query success rate approximately 20% lower than the medium and large swarm. The difference between values is most likely caused by the average node density of the coverage area. Smaller networks are more likely to become disconnected and therefor less likely to be able to successfully complete the requested query. The smaller swarm shows an increased improvement in query completion over the medium and large node swarms as the replication factor is increased to 1. Further increases in replication show slight gains in query success rate at replication factors 2 and 3 and performance starts to decrease when replication is set to 4 for all swarm size sample groups. Analysis of Variance (ANOVA) of the complete data set shows that all factors have a statistically significant impact on query success. The ANOVA data can be seen in Table 5. However, as shown in Table 5, the size of the swarm has the most dramatic impact (based on the F-statistic values).

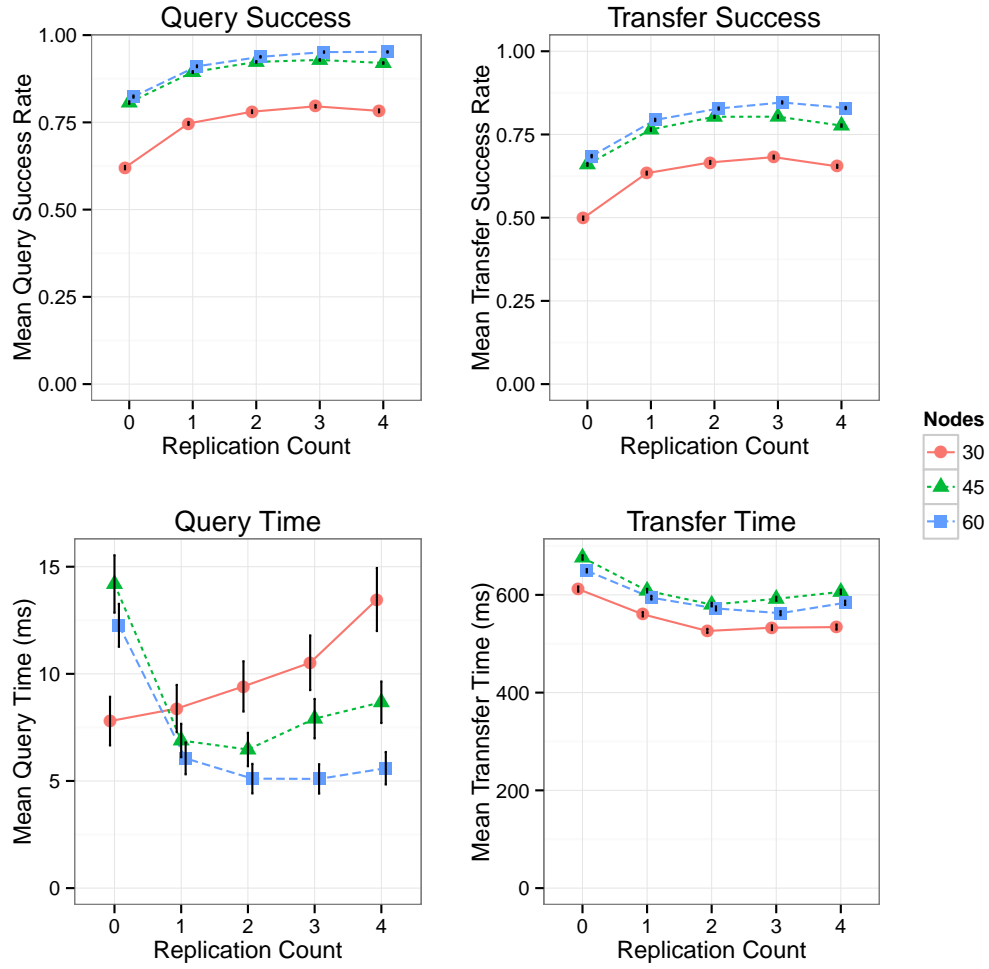

Figure 12. Query/Transfer Success Rates and Mean Time by Nodes - This figure is the same format as 11, but mean values are separated by the node count factor. The 30-node swarm maintains an approximate 20% reduction in query and transfer success. The lower left shows the small swarm not following the general trend of the larger node swarm.

Table 5. ANOVA for Query Success

	Df	Sum Sq	Mean Sq	F value	Pr(>F)
Replication	4	1856	464.06	4255.34	0.00000
Speed	2	152	76.11	697.93	0.00000
Nodes	2	3946	1972.87	18090.87	0.00000
Churn	2	3429	1714.41	15720.85	0.00000
Residuals	740103	80711	0.11		

4.2.2 Transfer Success Rate.

Similar results are demonstrated in mean transfer success rate values, albeit at a reduced success rates. The top-right and bottom-right charts of Figure 12 shows an almost identical trend line between nodes for mean transfer success and mean transfer time for all node counts, implying that changes in replication count impact all swarms similarly, regardless of swarm size. Turning to ANOVA analysis of transfer success rates (Table 6), we can see a slightly different picture than what transpired with query success rates. The ANOVA data shows that when it comes to successfully completing transfers, node mobility plays a more important role than node count. Surprisingly, the replication factor, while still statistically significant, is least important when examining all factors together.

4.2.3 Query Time.

A particular measurement of interest when looking at the data broken out by node count is the mean query time. With respect to the 30 node swarm, mean query time monotonically increases when replication count is increased, where as in the larger swarms, query time first decreases up to a replication count of 3 and then starts to trend upward. The upward trend is more pronounced in the lower node count swarms. It is suspected that the difference with the small swarm is that since such a smaller number of queries are successful, the query time measurement is skewed by a difference in amount of measurements taken. It is also presumed that queries that were successful took place in a cluster of nodes where increasing replication would generate a localized network saturation, thus increasing the delay in sending responses.

Table 6. ANOVA for Transfer Success

	Df	Sum Sq	Mean Sq	F value	Pr(>F)
Replication	4	2386	596.48	3416.84	0.00000
Speed	2	5630	2815.21	16126.52	0.00000
Nodes	2	3605	1802.30	10324.19	0.00000
Churn	2	3443	1721.28	9860.07	0.00000
Residuals	740103	129200	0.17		

4.2.4 Transfer Time and Hop Count.

The smaller swarm has the benefit of having to search fewer nodes, and therefore increasing the probability that the file is found in fewer hops (failures do not play a factor here). However, since only successful queries are evaluated, the smaller swarm is more likely to have network disconnects at longer hop counts. In the larger swarms, it is more likely the file is located at a greater number of hops from the source (most likely due to more successful queries being measured). Increasing replication decreases the mean hop count and therefore decreasing mean query and transfer times. However, just as was shown before, once replication reaches a point of network saturations, response times increase and override the gains achieved by reducing the hop count. Figure 13 shows these two measurements side by side. Figure 13a shows the effect of replication on mean hop count. Increasing the replication factor reduces the mean hop count almost uniformly across node count samples. Figure 13b shows the corresponding transfer time tracking very closely to the mean hop count.

4.2.5 Total System Packets.

While looking at the experiment data separated by node count, it would be worthwhile to comment on the total number of application level packets used at the various levels of replication. Figure 14 shows the linear increase in the mean sum of application packets generated by each configuration. Obviously, at a replication factor of zero, relatively few packets being generated. Any variance in the number of pack-

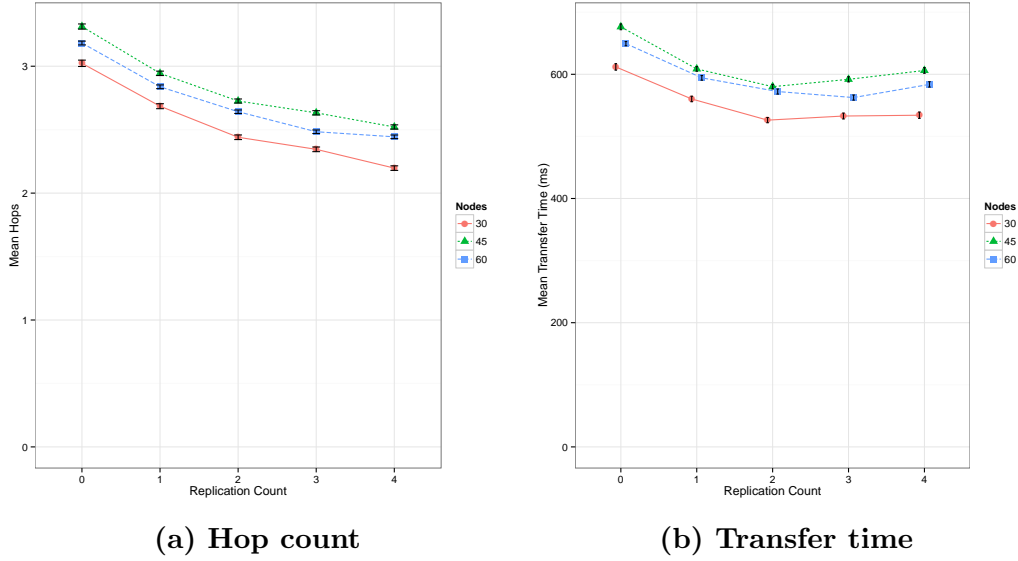

Figure 13. Mean Hop Count and Transfer Time by Node Count - Increasing replication decrease the mean hop count for each sample group. The transfer time follows the hop count trend until a factor of 3 is reached.

ets is caused by how the system is designed to initiate queries. To maximize the number of data points, as soon as a query and transfer is complete, the next one is initiated; therefore in systems where network dynamics induce slower requests, fewer measurements will be made, and therefore fewer packets generated. As the replication factor is increased, the amount of packets increases based on the number of nodes in the swarm, the number of packets required to query and transfer the file for each replication, and additional packets for retransmission as needed.

4.3 Results by Mobility

The following section examines the experiment sample data based on node speed (mobility). It is important to note that node count and churn rates are aggregated in these measurements.

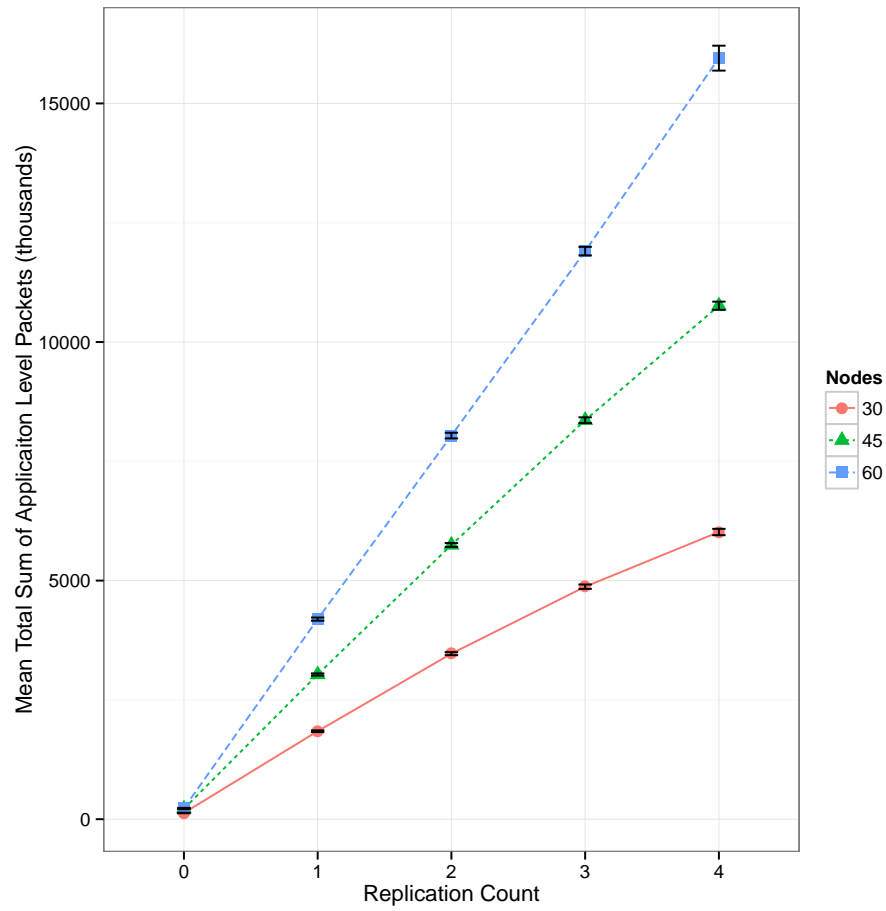

Figure 14. Mean Total Sum of Application Level Packets - The total number of application level packets increases linearly with respect to node count as replication level is increased.

4.3.1 Transfer Success Rate.

Another factor to examine is how node mobility affected availability. Looking at the top-left chart in Figure 15, it is apparent that varying node mobility has little impact on the mean query success rate. In contrast, varying node mobility did in fact have a significant impact on transfer success. At the lowest speed factor (2 m/s), increasing replication monotonically increases the mean transfer success rate. Again, as expected, the largest increase being realized with the first and second replication factor increase. The 8 and 15 m/s factor samples show a more pronounced increase in success rate as replication is increased from 0 to 3 in the 8 m/s sample group and 0 to 2 in the 15 m/s sample group, above which, increasing replication reduces mean success rate by 3.05 and 6.16%, respectively. Logic would suggest that the increase in mobility resulted in an increase in the number of retransmissions required due to broken links. The data here suggests that a similar trend would be seen in the 2 m/s mobility group at a higher replication count, however this would need to be measured in a separate experiment. Finally, an interesting observation is that in the slowest sample group, the mean transfer success rate tracks very closely with the mean query success rate, whereas in the faster mobility groups, mean transfer success is significantly impacted due to the increase in mobility.

4.3.2 Query and Transfer Time.

The mean amount of time required to complete a successful query is visualized in the bottom-right of Figure 15. Increasing replication count from 0 to 1 slightly reduced the mean query time of the 2 m/s sample group, but had no significant impact beyond that. At the higher speeds, increasing replication rate had a larger impact on mean query time, reducing mean query time by 1.52ms, 6.48ms, and 9.66ms for the 2, 8, and 15m/s sample groups, respectively, as replication increases from 0 to

1, but again we see that further increases start to negatively impact the mean query time. What is apparent from this chart is that node mobility has a clear and distinct impact on mean query time, much more so than replication rate. It is suspected that packet routing plays a key factor in this delineation, but further research is required to make certain of this suggestion. As for the mean transfer time, increasing mobility has little impact below a replication factor of 1. As replication is increased beyond 2, mean transfer time is impacted negatively, albeit slightly. It should be noted that unlike the samples separated by node count, mean query and transfer times are inversely ordered in the mobility grouped samples. Counter to intuition, the faster moving swarm has a slight advantage in terms of transfer speed (when only considering completed transfers). The reason for this becomes apparent when the mean hop count for each group is examined.

4.3.3 Hop Count.

Figure 16a shows that increasing the mobility of the swarm has the positive effect of reducing the mean hop count for each transfer. The mean transfer time can be viewed with respect to the mean hop count in Figure 16b. The 15 m/s swarm has the lowest mean hop count per replication factor, while the 2 m/s swarm has the highest mean hop count.

It is prudent at this point to discuss how the mean hop count is calculated. For each measurement transfer (does not include transfers between nodes for replication) that takes place, each file block that is received tracks the number of hops it traveled to get from source to sink. When the completed transfer is recorded, the number of total hops is divided by the number of blocks, giving a mean hop count for that transfer. Only the first data packet for each block is counted, as duplicate packets are discarded if the block has already been received. Also, if a transfer is not completed

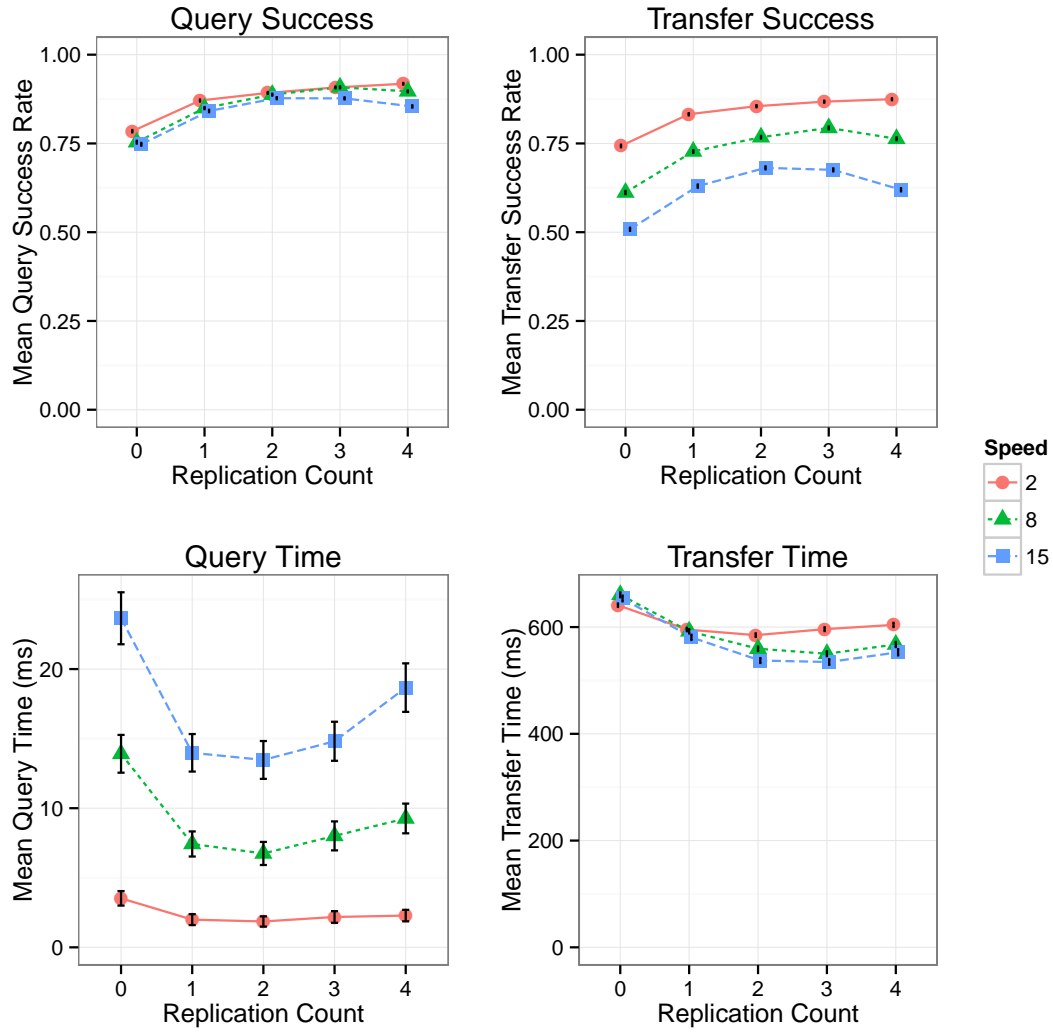

Figure 15. Query/Transfer Success Rates and Mean Time by Speed - The top-left chart shows a close grouping of values, indicating that node mobility does not play a significant role in query success. The top-right and bottom-left charts show a clear separation of trend lines, showing that contrary to query success, node speed does factor into transfer success rates and mean query times.

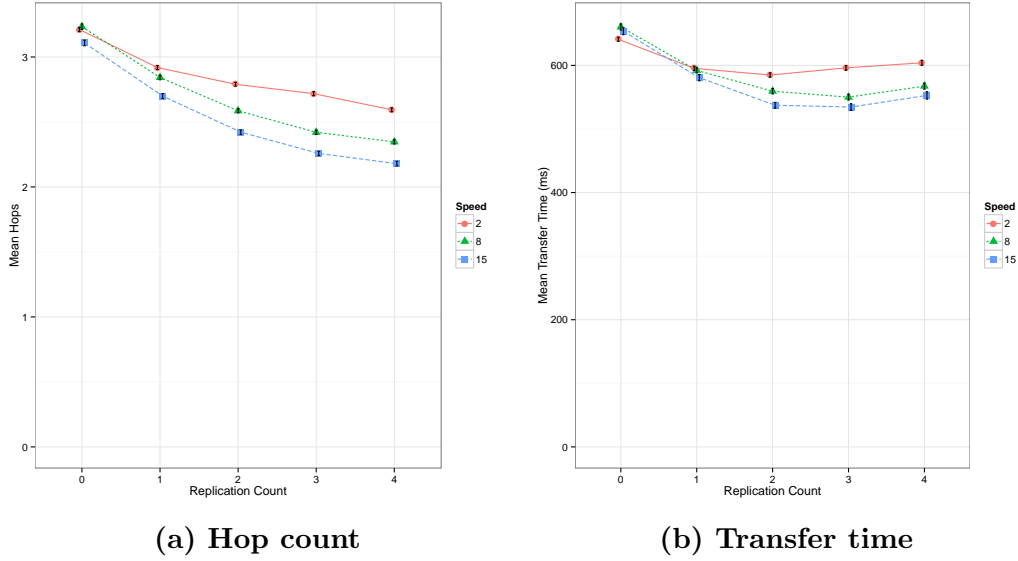

Figure 16. Mean Hop Count and Transfer Time by Speed - Increasing replication decrease the mean hop count for the sample groups based on mobility . The transfer time follows the hop count trend until a factor of 3 is reached.

successfully, it is re-attempted up to 4 additional times before being considered a failure. System implementation is a possible explanation as to why the higher mobility swarm possesses a lower mean hop count, even at a replication factor of 0. At higher levels of replication, it is suspected that in the higher mobility swarms, the faster mobility results in a quicker diffusion of replicated files, increasing the likelihood that a node containing the requested file is closer to the requester (sink).

4.4 Results by Churn

A critical piece of of this experiment is to determine how replication affects availability given different levels of attrition. To achieve this, nodes were “turned off” for a set duration of time. The number of nodes turned off was a percentage of the swarm size. While turned off, all of the disabled nodes’ data tables were erased so when they are re-enabled, it was the equivalent of being replaced with new nodes. Below is the results of the experiment when examined with respect to churn rate.

The churn rate is maintained at a steady rate for the duration of the experiment, with nodes being “turned on” before new nodes are chosen to be disabled.

4.4.1 Query Success Rate.

The top-left graph in Figure 17 shows the mean query success rates grouped by churn rate. Obviously, when the churn rate factor equals 0, the system has a very high probability of successfully querying a particular file. Increasing the replication level from 0 to 1 slightly increases the query success rate by 1.66%. The impact of replication on node availability when zero churn is present is dampened by the fact that the larger swarms (45 and 60 nodes) already had relatively high success rates at a 0 replication level (80.76 and 82.38%, respectively) when higher churn rates are factored in. As churn rate increases, the baseline mean query success rate is lowered to 73.7% at a 5% churn rate, and 59.88% mean query success rate at 10% churn rate.

As replication is increased by a factor of one, query success rates improve by 1.66, 13.14, and 15.02% for the 0, 5, and 10% churn rates, respectively. As expected, the higher churn rates realize a greater improvement in availability as measured by mean query success rate. These gains have diminishing returns as replication is increased further. With 0 churn, increasing replication does not significantly improve mean success rate. Gains taper off once a file is replicated twice in the 5% churn samples and at a factor of 3 in the 10% churn grouping.

4.4.2 Transfer Success Rate.

Mean transfer success rate trends follow very closely to the mean query success rate trends when grouped by churn rate. Again, we see transfer rates improving as the replication factor is increased only to start degrading once reaching a certain replication factor. When there is zero churn in the system, mean transfer success

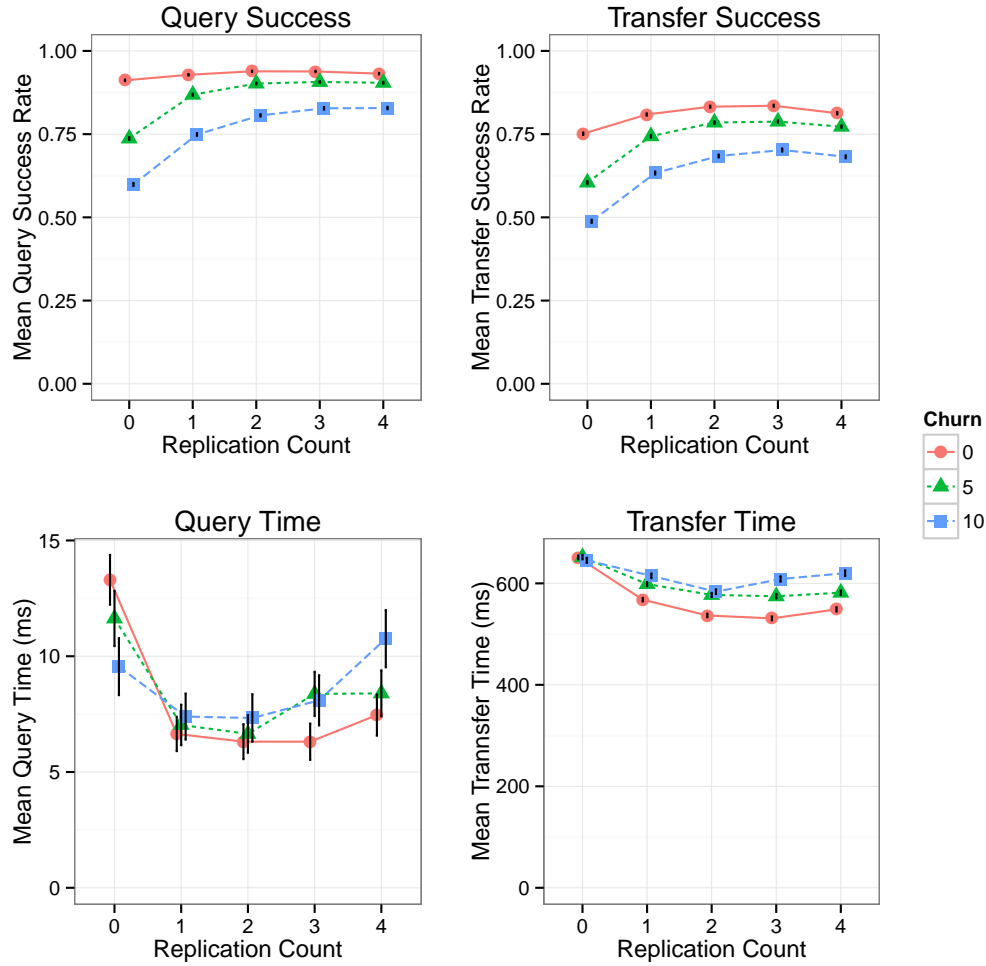

Figure 17. Query/Transfer Success Rates and Mean Time by Churn -Churn rate has an impact on query and transfer success rates as indicated by the top figures, while less of an impact is seen in query and transfer times (bottom charts).

rates increase from 75.13% to 83.25% at a replication factor of 2, 83.54 at replication factor 3, and starts to degrade at a factor of 4 only completing 81.3% of transfers. Likewise, at a churn rate of 5%, the baseline transfer success is 60.45%, increasing to 78.77% at a replication factor of 3 and degrades to 77.2% at a replication factor of 4. In a system with a 10% churn rate, without replication, the experiment measures a mean transfer success rate of 48.83%. Mean transfer success rate improves 14.47% when replication factor is set to 1 and peaks at 70.24% at a replication factor of 3, before decreasing roughly 2% at a replication factor of 4.

4.4.3 Query Time.

As seen in the bottom-left graph in Figure 17, increasing replication dramatically impacts the query time in the sample group with zero churn, reducing mean query time by 50% (13.3 to 6.64). However, after this initial increase, further replication does not change query time by any level of statistical significance. Similar reductions in mean query time are exhibited in the 5 and 10% churn sample groups at a lower improvement rate (39.4 and 22.5%, respectively). In the higher churn sample groups, increasing replication beyond a factor of 1 leads to a trend in increasing mean query time, with a more pronounced effect in the 10% churn sample group. Again, this data points to network traffic overriding any gains seen by reducing hop distance between requesting and source node. Overall, while statistically significant (analysis of variance (ANOVA) shows a p-value of $< 2e-16$), churn rate is not as significant factor when examined in the context of the overall system.

4.4.4 Transfer Time and Hop Count.

In regards to mean transfer time, it is clear from the lower-right chart in Figure 17 that churn has extremely limited impact when zero replication is being performed. Intuitively, the low impact is a result of the fact that transfer times are only calculated on successfully completed transfers. As before, if we examine mean transfer time concurrently with mean hop count as in Figure 18, we can see that mean hop is the driving force behind transfer times. In fact, with the exception of the replication factor of 4 data points, the two charts show almost identical trend lines, giving further support to the hypothesis that hop count drives transfer speed until it is overcome by network congestion. In all churn sample groups, hop count monotonically decreases as replication count increases, for a net reduction of 0.895, 0.776, and 0.623 mean hops in the 0, 5, and 10% churn groups (respectively). Of note is that fact that in the

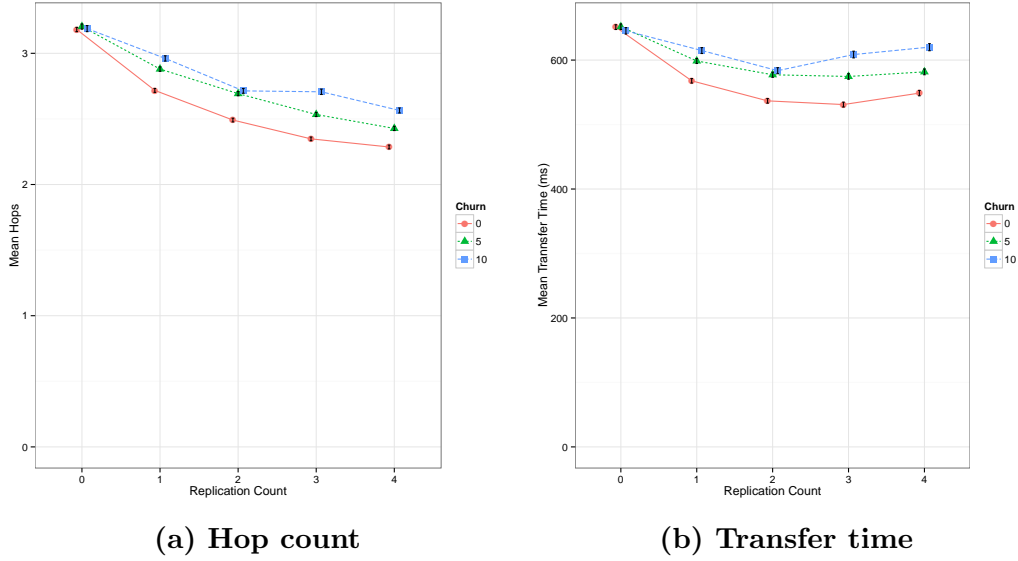

Figure 18. Mean Hop Count and Transfer Time by Churn - Lower levels of churn result in lower hop counts (18a) and therefore lower transfer times (18b), except when overcome by network traffic.

10% churn group, a larger reduction in transfer time as replication is increased to a factor of two, whereas the lower churn rates see their largest reduction at a replication factor of 1 (12.78% for zero churn, and 8.14% for 5% churn).

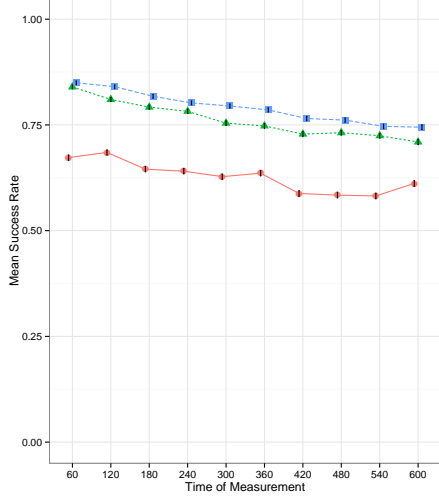

4.5 Availability by Time

The final aspect of the results that requires examination is the relationship between transfer success rates and the time at which the measurement was taken. Before proceeding with this, it is worthwhile to re-iterate how the system conducts its queries and measurements. The simulation starts querying for files sequentially after roughly 6 seconds of starting. Each node, with the exception of the sink (or master) node, generate files roughly once every two seconds. The master node attempts to query a known file and waits for a response. Assuming it does receive a response, it immediately begins an attempt to transfer the queried file. Upon completion of the file transfer, or if it exhausts retry attempts, it begins the next query. If the master node

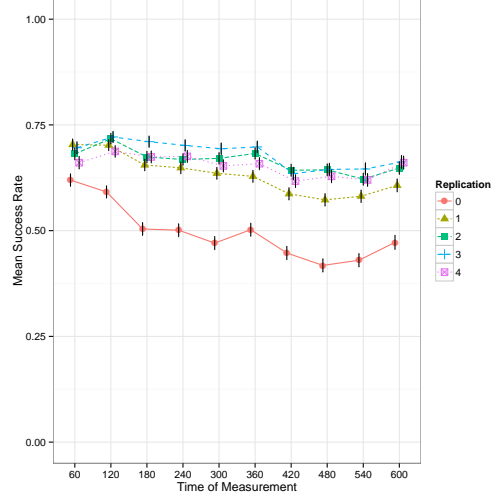

exhausts all known files (file names are a function of node number and simulation time, it is easy for the master to keep track of what files would have been generated), it sleeps for 3 seconds to allow nodes time to generate new files. If a node is disabled due to churn, any files that it would have normally generated are added to a taboo list that the master node checks before querying for a file. How the query process executes is vital to keep in mind as it leads to the concept that the older a file is, the higher its risk of being lost due to node churn.

4.5.1 Grouped by Nodes.

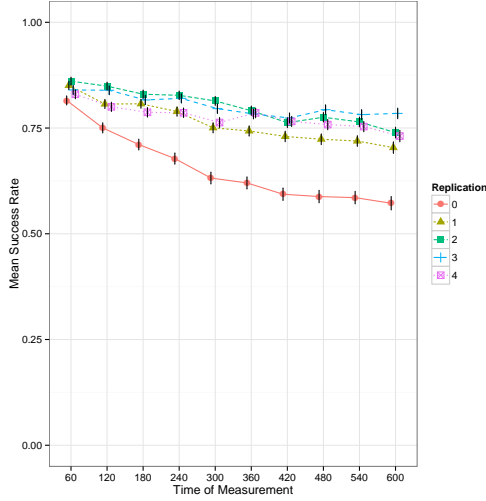

Transfer success rate based on time of measurement will be examined by first looking at these measurements with respect to swarm size. Figure 19 breaks this down by first showing mean values with replication count values being aggregated for each swarm size sample groups in Figure 19a. Trend lines indicate a steady gradual reduction in mean transfer success for the 45 node swarm, with a net loss of 13.01% over 540 seconds (a mean rate of 0.024% per second), and the 60 node swarm losing 10.5% at a mean rate of 0.19% per second. The 30 node swarm faces the same reduction in mean transfer success rate, although the impact of time is a bit more muted with the smallest swarm only losing 6.09% over the same time span. Figures 19b, 19c, and 19d show the breakdown of results by replication factor for each of the three swarm size samples (30, 45, and 60, respectively). The 30 node swarm shows more variation in mean rates, with increases in mean transfer success rates occurring near the 300 and 600 second time intervals. Further investigation would need to be conducted to examine this trend, although it is expected that this a result of the mobility of the small swarm, and not related to replication, due to the trend being present in varying degrees in all replication factors sample groups.

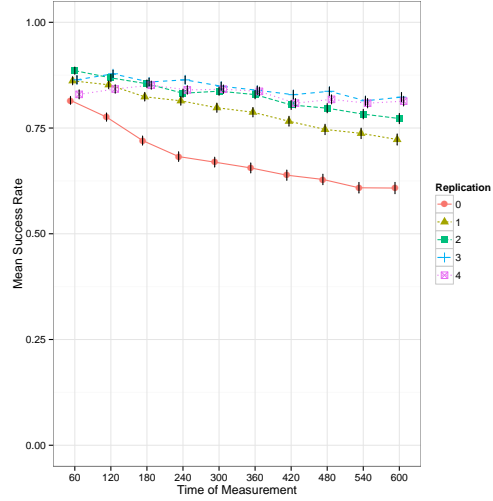

(a) By Node Count

(b) 30 Nodes

(c) 45 Nodes

(d) 60 Nodes

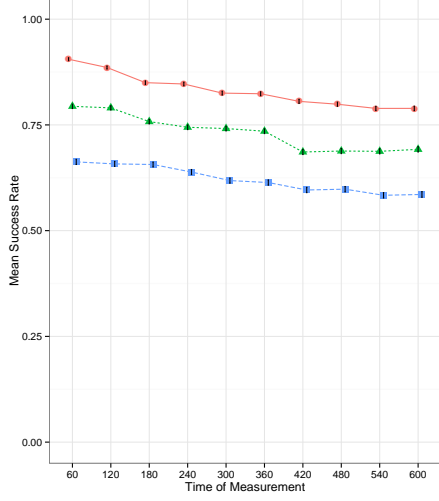

Figure 19. Mean Transfer Success Rate by Time, Replication, and Nodes - These charts demonstrate the impact of time of transfer on the mean transfer success rate. Figure 19a shows this effect with respect to swarm size, while Subfigures 19b - 19d break down each swarm size sample group further by replication count. With zero replication, mean transfer success rate decreases significantly over time, while this effect is attenuated to varying degrees by replication.

4.5.2 Grouped by Speed.

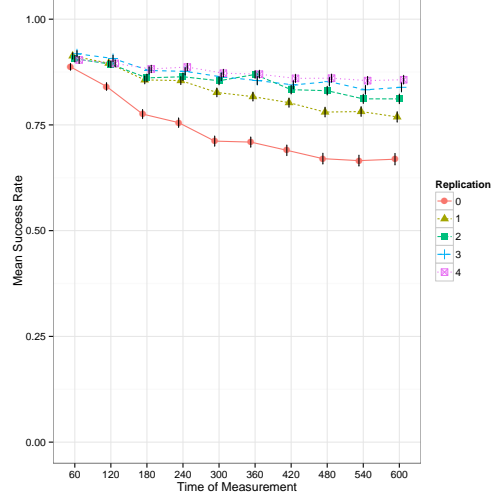

Just as was done for samples separated by node count, we can examine transfer success rate based on the time of measurement and node mobility as shown in Figure 20. From Figure 20a its clear that speed is an definitive factor. At 2 m/s, the mean transfer success rate drops by 11.62%. At 8 m/s, the mean transfer rate decreases by 10.17%, while at 15 m/s, the mean transfer success rate drops by 7.69%. Of course, the inverse relationship between speed and transfer success still stands. Aside from the baseline drop in transfer success rate based on increased speed, the time of the measurement appears to have the same impact. Figures 20b, 20c, and 20d show the results broken out by replication factor. One of the more interesting observations how replication affects transfer success rates at different speeds. At 8 m/s and 15 m/s we can see that setting the replication to a factor of 3 results in the highest levels of availability, however, at 15 m/s setting replication to a factor of 4 reduces its success rates to that below a replication factor of 2. This trend matches what is shown in top-right chart in Figure 15, and demonstrates that swarm size alone does not account for all increases in network traffic.

4.5.3 Grouped by Churn.

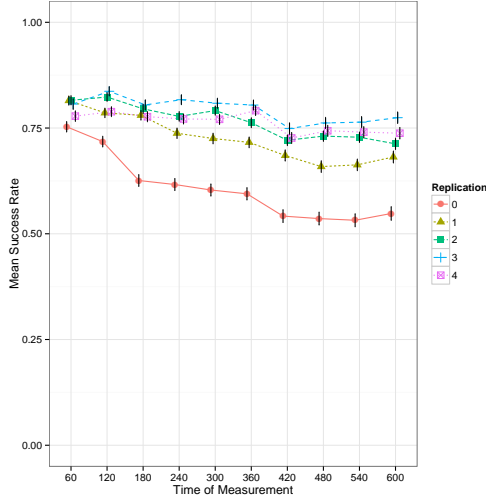

Figure 21 shows the measurements broken down by the added time component. Figure 21a shows mean success rates based on churn rates (with all other factor levels aggregated). Clearly churn rate has a detrimental impact on the ability to transfer a randomly selected file. 60 seconds into the simulation, all sample groups maintain a similar transfer success rate of roughly 80%. However, as simulation time progresses, the higher the churn rate, the greater the decrease in mean transfer success rate. This reduction is intuitively due to the fact that as churn rate increases, the higher the likelihood that all nodes that contain a copy of the file are eliminated from the

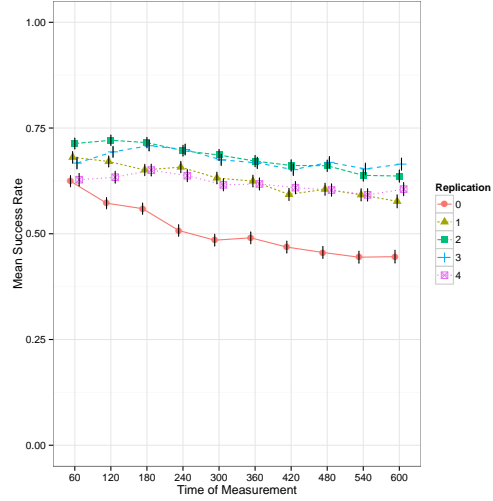

(a) By Speed

(b) 2 m/s

(c) 8 m/s

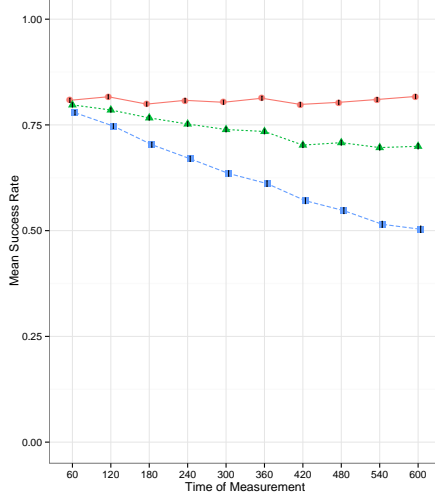

(d) 15 m/s

Figure 20. Mean Transfer Success Rate by Time, Replication, and Speed - Following the same format as Figure 19, these charts demonstrate the impact of time of transfer with respect to node mobility and replication. At lower speeds, higher levels of replication can be utilized to increase transfer success rate. No significant variance exists between sample groups with respect trends over time.

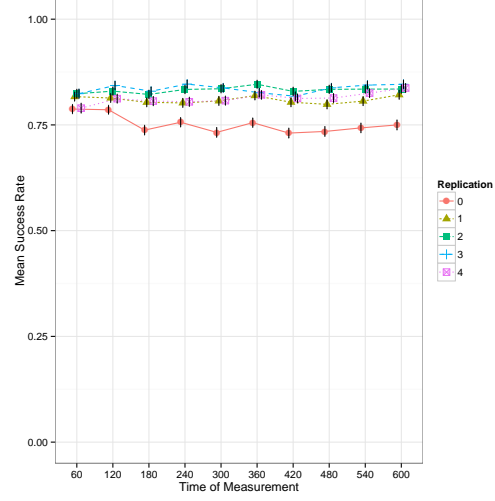

system as the system does not make an attempt to re-copy files after nodes have been eliminated. As expected, the success rate for the 0% churn sample group stays relatively constant throughout the full duration of the experiment. Figures 21b, 21c, and 21d go a step further and break down the individual churn rate factors based on replication rate. Looking only at samples where the churn rate factor is set to zero (Figure 21b), it is evident that replication improved availability, but as seen in data already presented, increasing replication beyond a factor of 2 proves to improve availability trivially.

Increasing churn to 5% as illustrated in Figure 21c shows a definitive impact on mean transfer success rate. By increasing replication to a factor of 1, a mean gain of 14.34% in transfer success rate is achieved over no replication. Further increasing replication to a factor of 2 nets an addition increase of 4.26%.

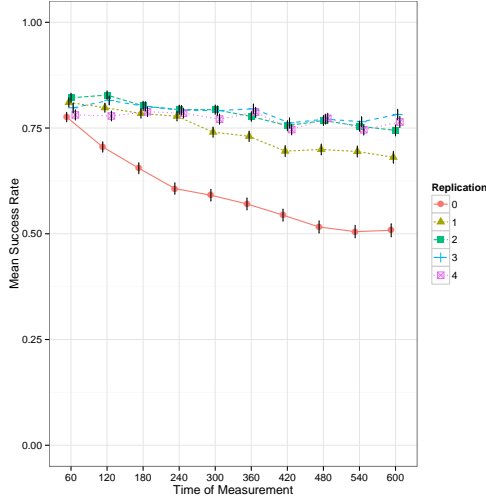

Figure 21d shows the results over time when churn rate is set to 10%. As expected the system experiences a significant drop off in transfer success rates when no replication is present. The trend line suggests that the system stabilizes at a minimum success rate of approximately 32%, although additional runs with a longer duration would be required to determine if this is in fact the case. The stabilization rate is a function of file generation speed, mean query/transfer speed (file size being a factor) and churn rate. Incrementing replication rate by 1 improves transfer success rate by 14.97% and setting replication to a factor of 2 further improves transfer success rate by 5.54%, and by 2.07% at a replication factor of 3. As a reminder, these percentages are reported as a mean value, averaged over the duration of the entire simulation run.

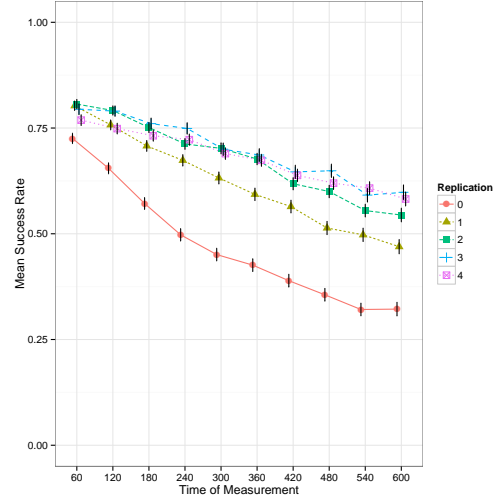

(a) By Churn Rate

(b) 0% Churn

(c) 5% Churn

(d) 10% Churn

Figure 21. Mean Transfer Success Rate by Time, Replication, and Churn - These charts show the impact of time of query with respect to churn rate and replication. When 0 churn is present in the system, time of transfer is not significant factor, while at 10% churn, time of transfer reduces the mean transfer success rate by up to 50%. This impact is attenuated by replication, but not eliminated.

4.6 Summary

The results shown in indicate that swarm size, mobility, churn rate, and most significantly, replication rate all contribute to the availability of data (as measured by query and transfer success rates). This chapter examined the collected data as an aggregate collection of samples and then looked at each factor for a higher level of granularity. The data showed that as replication level is increased, availability increases until the additional network traffic required to replicate the data exceeds the capacity of the system. The level at which this occurs depends primarily on the size of the UAV swarm over a fixed area, but node mobility and churn rate impact this as well. The data also showed that time plays a critical factor on availability and the longer a file resides in the system facing node attrition, the more likely it is to be unavailable for retrieval.

V. Conclusions and Recommendations for Future Work

If current trends hold, swarms of cheap, unmanned aerial vehicles (UAVs) will prove to be a useful tool in a variety of applications, especially military intelligence, surveillance, and reconnaissance (ISR) applications, but certainly not limited to ISR. It is expected that each UAV in these swarms will not be equipped with the specialized communication equipment required to make reliable long distance data transfers possible. It is also assumed that the data generated by the swarm would exceed the capacity of the long distance communication link. Instead of all the data being pushed to the remote destination, the data generated can reside in the UAV swarm until requested. Given this, it becomes a worthwhile task to examine the effect that replication has on availability. This chapter will present conclusions that can be drawn from the data presented in Chapter IV.

5.1 Conclusions

Chapter IV presented the impact that replication has on data availability in several mobile ad hoc network (MANET) configurations, with consideration given to churn rate, swarm size, and node mobility.

As hypothesized, increasing replication clearly increases availability in the swarms of various sizes. The improvement in availability, as measured by mean query and transfer success rates of the sample groups only occurs until network traffic saturation is reached. Furthermore, the impact of the replication is modified by the other factors listed above.

The size of the swarm determines the baseline availability rates. Increasing node count over a given area reduces the possibility of network segmentation. Increases

to replication affect all swarm sizes similarly, with all swarms having nearly identical trend lines for mean query transfer success.

Adjusting node mobility shows very little significance in regards to query success rates, but dramatically impacts mean transfer success rates. Swarms moving at lower speeds make can make use of replication at higher factor levels. Faster moving swarms are hampered by this mobility and replication starts to have a detrimental effect at lower factor levels. Additionally, increasing replication to a factor of 1 significantly reduces the time to conduct a successful query, but does not dramatically impact total transfer time.

The rate at which churn occurs within the swarm plays a significant part in how replication affects availability. When no churn is present in the swarm, replication does not significantly impact query success, but does have a marginal impact on transfer success rates. In swarms where churn is present, replication increases transfer success by as much as 20 percent. It was also shown that the impact of the swarm's churn rate on availability (when selecting a random files) is greater the longer the file remains in the system.

5.2 Future Work

This research illustrates the complex interactions that exists in a mobile ad hoc network. There are number of potential areas that would benefit from deeper study.

First, as stated in Chapter III, the simulation uses an ideal model for wireless transmissions. Implementing a more realistic model would result in a more accurate data. Additionally, a number of research papers have looked at different routing protocols based on a number of node parameters such as battery level, neighbor count, etc. Implementing these protocols with a file transfer protocol could assist in optimizing replication.

Investigating different replication schemes with proactive protocols could also lead to optimizations in replication by reducing network transmissions. One example would be to include error correcting codes to the data and disperse file fragments to different nodes instead of flat file replication. Additionally, it might prove to be beneficial to modify the replication strategy to have each file periodically query for files to determine how many copies currently exist. This could greatly reduce the required replication factor by limiting the initial replication but ensuring that the copies remain in the swarm throughout the duration of swarm operation. This would entail additional control mechanisms to ensure that redundant nodes do not force additional replication.

There remains a large number of factors that could be modified to examine their impact with respect to replication and availability. This experiment did not alter the routing protocol used, file size or transmission speed. Modifying these factors would lead to greater granularity of data that could be leveraged to optimize replications schemes to improve data availability. Another modification to the experiment would be to replace the random selection of nodes during churn and replace with a cluster based scenario to what impact that would have on availability. This could help to simulate airborne collisions, or a cluster of UAVs flying over a particularly hostile area.

Finally, as mentioned by Klemm et al. [32], the ORION file transfer protocol could be merged into to an Ad hoc On-demand Distance Vector (AODV)-like routing protocol. This could greatly reduce the amount of control packets that are present in the system which may lead to further optimizations in transfer speeds and availability.

14. ABSTRACT A swarm of autonomous UAVs can provide a significant amount of ISR data where current UAV assets may not be feasible or practical. As such, the availability of the data the resides in the swarm is a topic that will benefit from further investigation. This thesis examines the impact of file replication and swarm characteristics such as node mobility, swarm size, and churn rate on data availability utilizing reactive protocols. This document examines the most prominent factors affecting the networking of nodes in a MANET. Factors include network routing protocols and peer-to-peer file protocols. It compares and contrasts several open source network simulator environments. Experiment implementation is documented, covering design considerations, assumptions, and software implementation, as well as detailing constant, response and variable factors. Collected data is presented and the results show that in swarms of sizes of 30, 45, and 60 nodes, file replication improves data availability until network saturation is reached, with the most significant benefit gained after only one copy is made. Mobility, churn rate, and swarm density all influence the replication impact.
