Summary

In France, boars are classified by the National Program for Sow Herd Management, according to the size of the litters produced. All boars with an average of less than 8 live-born piglets, from at least 6 litters, are cytogenetically examined. Since 1979, three different reciprocal translocations have been identified by our laboratory in the hypoprolific group. A new fourth reciprocal translocation, not hitherto described, has just been found. The carrier *Landrace* boar had produced an average 7.2 ± 2.65 piglets in 24 litters, i.e. a 31.23 p. 100 reduction of prolificacy. This animal is carrying a new reciprocal translocation involving the small acrocentrics, nb. 16 and 17. The animal production and economic consequences of the chromosomal abnormalities are discussed.

Key words : Pig, hypoprolific, reciprocal translocation.

Résumé

Une nouvelle translocation réciproque chez un verrat hypoprolifique

En France, les verrats sont classés par le Programme National de Gestion Technique selon la taille des portées qu'ils produisent. Tous les verrats produisant en moyenne 8 porcelets par portée ou moins, sur un minimum de 6 portées, sont étudiés du point de vue cytogénétique. Ainsi, depuis 1979, trois translocations réciproques différentes ont été identifiées. Une nouvelle translocation, impliquant les chromosomes 16 et 17 est décrite chez un verrat *Landrace* qui produit 7.2 ± 2.65 porcelets en moyenne sur 24 portées. La réduction de la prolificité de cet animal est de 31,23 p. 100. Les conséquences des anomalies chromosomiques pour l'élevage sont discutées.

Mots clés : Porc, hypoprolifique, translocation réciproque.

⁽¹⁾ Presented at the 4th American Symposium on Cytogenetics of Domestic Animals, June 9-12, 1985. University of Illinois, Urbana, U.S.A.

I. Introduction

Chromosomal structural abnormalities in man and animals may cause reproductive disorders. The most frequent chromosomal abnormalities connected with reproductive failures in pigs are reciprocal translocations (FECHHEIMER, 1981 ; POPESCU, 1982 b). The consequences of heterozygosity for a reciprocal translocation are the formation of chromosomally unbalanced gametes by nondisjunction. Fertilization with unbalanced gametes results in embryos with unbalanced karyotypes, which are very often lethal. Thus, formation of chromosomally unbalanced embryos due to a reciprocal translocation will lead to reduced litter size.

II. Material and methods

In France, boars are classified according to litter size, within the National Program for Sow Herd Management. Almost 800.000 animals are checked each year. In cases where the boars are still alive when the listing is published every 3 months, all animals with an average of less than 8 live-born piglets from at least 6 litters are cytogenetically evaluated.

The last hypoprolific case was a *Landrace* boar which had produced an average 7.2 ± 2.65 piglets in 24 litters, i.e. a 31.23 p. 100 reduction of prolificacy (fig. 1). The cytogenetic study was made by classical staining as well as R, G and T - banding methods. The chromosomes were aligned according to the recommendations of the Reading Conference (FORD *et al.*, 1980).

III. Results and discussion

This animal was carrying a new reciprocal translocation, not hitherto described, involving chromosomes 16 and 17 (fig. 2). A very small distal segment of chromosome n° 17 was translocated to chromosome n° 16. Because of the small size of these chromosomes it was not possible to provide evidence for the reciprocal exchange.

Since 1979, three different reciprocal translocations have been identified in the hypoprolific group by our laboratory : 4/14 (POPESCU & LEGAULT, 1979), 3/7 (POPESCU *et al.*, 1983) and 5/14 (POPESCU *et al.*, 1984). The 16/17 translocation is the fourth one. For investigation of the consequences of these abnormalities on prolificacy, we produced some animals carrying both 4/14 and 3/7 translocation (BAHRI *et al.*, 1984).

Contrary to cattle, where the most frequent structural abnormality is Robertsonian translocation (POPESCU, 1982 a), reciprocal translocations seem to be the

most common ones in pigs. Including the latest abnormality described in France, the total number of different reciprocal translocations is now 19 (tabl. 1). The decrease in prolificacy varies between 26 and 100 p. 100. This variation might be explained by the different behaviour of each abnormal chromosome.

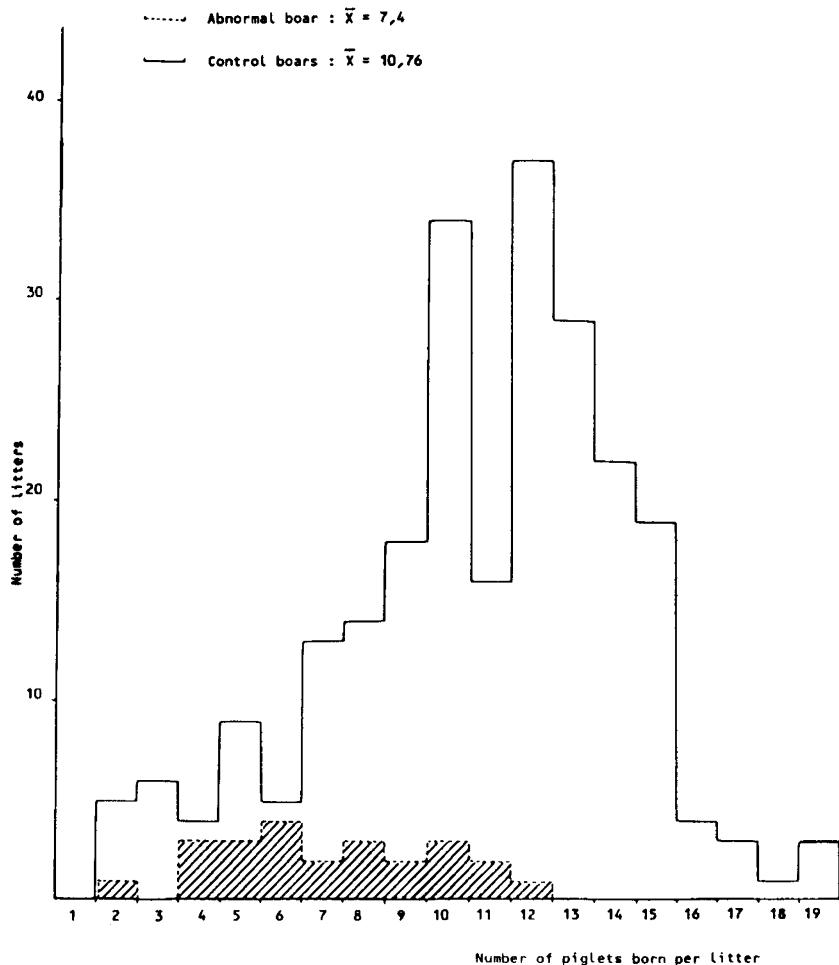

FIG. 1

Histogram of the litters sired by the boar carrying the 16/17 translocation (hatched) and by control boars from the same farm (full line).

— Control boars : $\bar{X} = 10,76$.
- - - Abnormal boar : $\bar{X} = 7,4$.

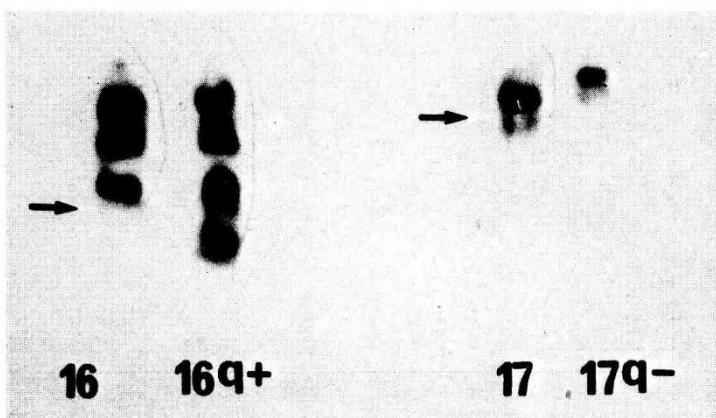

FIG. 2 c

R-banded (a) and T-banded (b) karyotypes carrying the 16/17 translocation. The G-banded (c) chromosomes no. 16 and 17 carrying the 16/17 translocation.

The frequency and different types of unbalanced gametes produced by each abnormal chromosome depend on the chromosome involved, the size of the translocated segment, and on the presence of chiasmata within the translocated segment. In 3 different cases of reciprocal translocations in pig, cytogenetic studies of embryos before and after implantation showed that reduction of litter size was due to formation of embryos with unbalanced karyotypes. Thus, ÅKESSON & HENRICSON (1972) found 5 different types of unbalanced karyotypes in pre-implantation embryos sired by a boar carrier of 11/15 translocation, KING *et al.* (1981), seven different types from a boar with a 13/14 translocation and POPESCU & BOSCHER (1982) six different types from a boar with a 4/14 translocation.

It should be pointed out that in these 3 studies the authors never found an unbalanced karyotype in newborn piglets sired by a heterozygous parent. This shows the lethal character of chromosomal unbalance and accounts for the embryonic mortality rise in carrier animals.

Use of a boar heterozygous for a reciprocal translocation in a natural mating herd may lead to a loss of a 100 piglets even before the farmer has discovered the low prolificacy of the animal. However, it seems that the translocation is maintained in a population over several generations, especially through the females. Indeed, because of the very low repeatability of litter size, it is difficult to detect the abnormality in females and the latter are generally culled after having produced 3-5 litters. The abnormality can therefore easily be maintained in the population (LEGAULT & POPESCU, 1981). For example, the 3/7 translocation, identified for the first time in 1980, is still present in several farms, in 1985 (POPESCU, not published).

On a sample of 6467 boars who had sired a minimum 6 litters, 10 of them were detected as hypoprolific (i.e. 1.5 p. 1000). Unfortunately cytogenetic examination is possible only on a small proportion of these suspected animals, primarily because they are dead at time of collection. Indeed, since 1979, we have studied only 24 hypoprolific boars. Among them 10 were carrying a translocation, which represents about 0.6 p. 1000.

In a recent paper, we estimated the financial consequences of a hypothetical chromosomal abnormality, using the simulation model PORSIM (POPESCU & TIXIER, 1984). So, in a herd of 42 sows, a translocation carrying boar was used for 9 months along with a normal boar. Comparison of the income of this farmer with a control farmer showed a 48 to 57 p. 100 reduction, depending on the type of production : i.e. 4000 to 6000 \$.

The frequency of chromosome abnormalities in the pig and their deleterious consequences for pig production clearly indicate the practical aspect of cytogenetic evaluation of breeding animals, in particular those intended for artificial insemination.
