6 Introduction

3

4 5

7 Continuous dynamic multi-segmental studies of lumbar motion have brought new depth to our understanding of the biomechanics of back pain and these are becoming more prevalent than static 8 9 radiographic studies in research. They are needed for the clinical validation of both laboratory and 10 FE modelling outputs that include motion (Jones and Wilcox 2008, Oxland 2016) and are necessary before *in vivo* studies of loading can be attempted during bending tasks. Our previous work showed 11 that it may be feasible to do this by adding finite element models from MRI to kinematic information 12 13 from fluoroscopy to estimate intervertebral loading during motion, thereby revealing the time points 14 when stresses are maximal (Zanjani-Pour 2018). However, we also now know that the motion shared between vertebral segments is more variable and less repeatable during loaded than passive 15 16 recumbent bending and also changes during motion (Breen, Hemming et al. 2019). This represents a 17 challenge to attempts to compare individuals or populations or to establish normative values. This 18 highlights the need to explore the nature of the interactions between motion segments during these 19 bending tasks.

20 Previous studies have suggested that passive recumbent lumbar flexion presents greater unevenness

21 of intervertebral motion sharing in patients with chronic, non-specific back pain (CNSLBP) than

22 asymptomatic controls, but did not find a difference during loaded flexion or explore interactions

23 between segments (Breen and Breen 2018, Breen, Mellor et al. 2018). Several studies have explored

24 how angular motion is shared between segments of the lumbar spine at points during weight

25 bearing flexion in both patients with back pain and healthy controls using either medical imaging or

surface markers (Teyhen, Flynn et al. 2007, Ahmadi, Maroufi et al. 2009, Aiyangar, Zheng et al. 2015,

27 Christe, Redhead et al. 2016, Gombatto, D'Arpa et al. 2017, Hemming, Sheeran et al. 2017, Papi, Bull

et al. 2019). These found greater flexion ranges in the upper than lower lumbar spine in patients

29 when compared to controls, however, no weight bearing studies have attempted to continuously

30 measure the proportions of the flexion and return motion that is accepted by individual levels, or to

31 describe the dynamic interactions between them during bending. This will be needed if we are to

32 model contemporaneous kinematics and loading to estimate relative intersegmental stresses during

33 bending motion.

- 34 The purpose of this study was to assess the motion contributions of adjacent lumbar levels during an
- 35 active weight bearing flexion and return protocol using quantitative fluoroscopy. Data were
- 36 collected using a guiding motion platform to minimise behavioural variation and allow the greatest
- effects to be obtained from the morphology and muscular activity during the motion.

38 Methods:

39 Participants

- 40 Eight patients with chronic non-specific low back pain (CNSLBP), yet without any obvious mechanical
- 41 disruption (for example surgery or spondylolisthesis) received fluoroscopic imaging during flexion
- 42 and return motion. These were matched for age and sex to 8 healthy controls who in turn were
- 43 extracted from a database of >100 asymptomatic individuals who had performed the same task.
- 44 Asymptomatic participants were included if they were between 21 and 80 years old, had a self-
- 45 reported body mass index of less than 30 kg.m⁻², were free of any back pain, had not experienced
- 46 back pain that limited their normal activity for more than 1 day in the previous year, had no history
- 47 of abdominal surgery or spondylolisthesis, had not received a medical radiation exposure of >8 mSv
- 48 in the previous 2 years, and were not currently pregnant. Ethical approval was provided by the
- 49 National Research Ethics Service (Bristol 10/H0106/65) and written Informed consent was obtained
- 50 from all participants.

51 Data collection

52 The Quantitative Fluoroscopy (QF) systems and procedures have been detailed extensively in the 53 literature (Breen and Breen 2017, Zanjani-Pour, Meakin et al. 2017, Breen, Mellor et al. 2018, du 54 Rose, Breen et al. 2018, Breen, Hemming et al. 2019). However, in brief, participants undertook a 55 standardised motion protocol during active weight-bearing flexion and return that reduces 56 behavioural aspects of participant bending, guiding the participants speed and range of motion 57 throughout their bend.

58 Participants were asked to fold their arms (left over right) out in front of them at chest height in a

- 59 comfortable position while standing upright in a neutral posture, the arm rest of a guided motion
- 60 control platform was then brought into position to meet the participants arms (See Figure 1). The
- 61 participants were guided by the motion control platform at 6°/s to perform trunk flexion from
- 62 upright standing to 60° flexion, directly followed by guided return to a neutral standing position.
- 63 During motion, the pelvis was constrained to reduce sacral translation but still allow some rotation
- 64 of the hips. This was performed using a belt secured around the participants' hips and a bracing pad
- 65 applied to the lower sacral segments (See Figure 1). Concurrently, fluoroscopic images were

- 66 acquired using a Siemens Arcadis Avantic digital C-arm fluoroscope (Siemens GMBH) with the centre
- of rotation of the motion platform aligned with participants' L3/L4 intervertebral disc. During the
- 68 bending protocol, fluoroscopic images were acquired at 15Hz frame rate. These were transferred to
- a dedicated workstation where the vertebral body positions (L2, L3, L4, L5 and S1) were identified
- for each by a semi-automated tracking process written in Matlab (V2013, The Mathworks Inc.). This
- 71 method has been previously validated and shown to have an accuracy in rotation measures of 0.52°
- 72 (Breen, Muggleton et al. 2006) and an inter- and intra-observer repeatability ranging from ICC 0.94–
- 73 0.96 (SEM 0.23°- 0.61°) (du Rose A. and Breen 2016).

74 Data analysis

- 75 In order to investigate population differences in intersegmental spinal motion sharing metrics and
- 76 intervertebral range of motion (IV-RoM) for each level, dynamic motion sharing of segments from
- 77 L2-S1 were calculated throughout the bend and return.
- 78 Vertebral positions were established for each vertebra from L2-S1 and tracked throughout the
- 79 bending sequence. To compare intervertebral motion sharing across and between populations,
- 80 segmental motion profiles were normalised to a motion cycle as a percentage that clearly
- discriminated the outward (0-50%) from the return phase (50-100%). (See Figure 2).
- Motion Sharing was calculated as the contribution of each motion pair as a percentage of the L2-S1 motion. Because segmental angular differences from the participants' starting positions are small at the beginning and end of participants' bending sequences, they are close to the precision limit of the QF Systems at these points (0.52 degrees). Therefore, contributions to motion sharing from points where the L2-S1 angle was less than 10% of the maximum L2-S1 RoM were truncated to remove the large relative contributions to errors (equivalent to data points at less than 5% and greater than 95% of the motion cycle) (Figure 3).
- 89 We calculated the average inequality of the motion share (Motion Sharing Inequality, MSI) and its
- 90 standard deviation (Motion Sharing Variability, MSV) throughout the bend from the differences
- 91 between maximum and minimum contributions throughout the flexion and return sequences. To do
- 92 this, the range was calculated for each data point on the x-axis. Then, MSI was calculated as the
- 93 mean of all the ranges in the sequence and MSV as their standard deviation (Breen and Breen 2018).
- 94 We also determined the average percentage contribution, for individual levels, across the motion
- 95 (Average Motion Share, AvMS) and the standard deviation of each level's contribution across the
- 96 motion (Motion Sharing per Level Variance, MS(L)V). Lastly, in order to compare against the
- 97 literature, the percentage contribution at maximum bend (MS@max) was also computed. These

98 were compared between groups and with a systematic review of spinal kinematics by Widmer et al.
99 2019 (Widmer, Fornaciari et al. 2019)

100 Statistical analysis

101 The normality of the data was calculated using the Shapiro Wilk test in SPSS (version 24, IBM Corp.).

102 Independent t-tests were performed to test for differences between group data from a normally

103 distributed dataset and Mann-Whitney U was used for data that were not. Significance was set at

104 95%.

105 Mean motion share contribution and 95% confidence interval (±CI95) values across all participants

were computed at each 1% increment of the Motion Cycle of the controlled bending task for both

107 the asymptomatic control and CNSLBP patient populations. Statistically significant differences

108 between each level's contribution to motion was detected by the extent of overlap between the

109 ±CI95 bands, i.e. the absence of ±CI95 band overlap indicated statistically significant differences.

110 **Results**:

111 Each participant group consisted of 5 males and 3 females matched for age and sex. Shapiro Wilk

test for normality revealed that age, height and weight were likely to have come from a normally

distributed data set, but BMI data were unlikely to be normally distributed. Furthermore, the

114 Shapiro Wilk test found that motion metrics (range of motion and motion sharing within and

115 between levels) were a mix of normal and non-normally distributed data depending on level.

116 Therefore, for consistency all motion metrics were treated as non-parametric data. There were no

significant differences between groups in terms of age, height, weight, or BMI (Table 1). However,

the asymptomatic controls consistently gained higher ranges of intervertebral motion at all

measured levels, although this was only significant at the L5-S1 level (p=0.012) (Figure 4 & Table 2).

120 The L2-S1 range of motion was also significantly less among the patient population (p=0.046) (Figure

121 5 & Table 2)

122 Motion sharing inequality and variability

123 Among controls, in initial flexion and the latter part of the return phase, there was a top down

sharing of motion. However, at maximal bend the lumbar levels shared the motion more equally,

125 with L5-S1 receiving the least (Figure 6). Among patients, similar contributions to motion can be

seen during flexion, however, during return there was less symmetry of sharing, with L3-L4

127 continuing to receive more of the motion (Figure 7).

- 128 Although different in appearance, the MSI and MSV values for patients and controls (Figures 6 and 7)
- were not significantly different. However, MS(L)V was significantly higher at L4-5 in the patients
- 130 (p=0.021). This lack of variation can be seen as a flatter curve, especially in the return phase of
- 131 bending. (Figure 7).

132 Individual level sharing

Among controls, the average share of motion was highest at L2-L3 and lowest at L5-S1 and this

- tendency was greater with higher MSIs. Among patients, the average share of motion was highest at
- 135 L3-L4 and lowest at L5-S1, the L5-S1 contribution being significantly different from the other levels
- throughout most of the bending protocol (as defined by the lack in of overlap of the 95% CI bands
- about the L5-S1 level with any other level in Figure 7)

138 Comparison with the literature

139 Few studies have examined intervertebral motion sharing during dynamic flexion and return tasks 140 and none that can be compared directly. However, Widmer et al (2019) (Widmer, Fornaciari et al. 141 2019) recently presented a review of studies of lumbar kinematics and reported the segmental 142 contributions to flexion from multiple studies. On the whole, two different types of segmental 143 contribution profiles (spinal rhythms) were established. Type 1: A cranio-caudally decreasing 144 contribution pattern, in protocols where total lumbar RoM was limited either by restricting the 145 attempt or by starting the motion in a sitting position. Type 2: A cranio-caudally increasing 146 contribution pattern with a slight drop at the L5–S1 segment, in protocols where lumbar RoM was 147 unconstrained. Figure 8 and Figure 9, respectively, display these, with the control and patient data

- 148 from the present study included for each level.
- 149 When calculating the average motion sharing during flexion and return (AvMS), it was noticed that
- 150 the distribution of sharing was similar to Widmer's graph of limited flexion studies (Widmer,
- 151 Fornaciari et al. 2019). That is, decreasing contributions per level between L2-L3 and L5-S1, with the
- exception of L3-L4 whose average contribution (AvMS) was greater in patients (p=0.046) (Figure 8 &
- 153 Table 2). This is consistent with L3-L4 and L4-L5 remaining in a relatively flexed position as
- demonstrated by the high contribution to L2-S1 angle during the return phase in Figure 7. This
- 155 seems to characterise the difference in motion pattern between patients and controls.
- 156 In Figure 9, segmental contribution at maximum flexion for all studies, including the present one,
- 157 shows a cranio-caudally increasing contribution, with a drop at the L5–S1 segment. This suggests
- that when participant range is standardised to 60° of trunk bend, the lumbar segments (L2-S1) are
- 159 flexed near to their maximal range. In the present study, which includes both patients and controls,

the L5-S1 contribution at maximum was significantly lower in patients (Table 2) and significantly lessthan all other levels (Figure 7).

162 **Discussion**:

There were consistent but non-significant differences between patient and control motion sharing patterns. This lack of significance may be due to the range of L2-S1 motion of patients' spines being significantly less, particularly at the lower levels. The results also illustrate the effects of loading and muscle activity on the differences between lumbar flexion and return motion in controls and patients with CNSLBP. Widmer et al (2019) considered that contributions to flexion motion may be RoM dependent and this is consistent with our findings, where patients had lower L2-S1 RoM (p=0.046) and a lower contribution at maximum bend at L5-S1 (p=0.046).

170 Our previous studies of passive recumbent proportional motion did not dis-aggregate intervertebral

171 levels, but unlike this study, did find MSI to be significantly higher in patients (Breen and Breen 2018,

172 Breen, Mellor et al. 2018). These differences may be due to any combination of contributions from

behavioural influence on bending strategy, involuntary muscle activity and changes in passive tissue

174 restraint. For example, the increased variability of motion sharing in patients (MS(L)V at L4-5,

p=0.021) may be consistent with the work of Du Rose et al (du Rose, Breen et al. 2018), who

176 measured local and global lumbar sEMG activity during bending in controls and found that it

177 correlated negatively with MSV. Considered in relation to patients, this may suggest a guarding

178 effect. This present study did not include muscle oxygenation or electrical activity, which could shed

179 considerable light on these issues.

180 A further finding was that whether in patients or controls, contributions to motion change

181 continuously during bending. Although fairly consistent in groups, this makes static measurement of

182 IV-RoM of limited use as it is dependent on the phase of flexion as well as the restraint of the

183 segment.

184 Our finding that motion contributions change dramatically throughout the bend and seem to be

185 RoM dependent are consistent with the findings of the review by Widmer et al (2019). Therefore,

186 the significant reduction in patients' lumbar range of motion may be contributing to the significant

187 differences between population motion sharing characteristics. It may also be true that motion

188 sharing is dependent on the global position at which the participant starts their motion. This was not

investigated but highlights the need to standardise data collection protocols and only include those

190 which adhere to them in comparing studies.

191 The dynamic interactions between lumbar intervertebral motion segments during weight bearing 192 flexion and return were found to be different in patients with CNSLBP compared to healthy controls. 193 However, although global motion of participants in both groups were 60°, L2-S1 maximum range 194 was lower in patients, while individual level contributions changed during the motion and seem to 195 be RoM dependent. Therefore, it is unsurprising that only L5-S1 was significantly different between 196 groups in terms of motion sharing metrics. However, there also appears to be less variability in the 197 motion contributions of different levels in patients, although these were not significant in these 198 small populations. This lower variance in patients, particularly during return from full flexion, may be 199 related to increased muscle contraction. Therefore, muscle workload needs to be verified and/or 200 explained by further studies, with larger populations. These could include muscle electrical activity 201 and oxygenation alongside kinematics and loading as well as comparisons with passive recumbent

202 protocols within which muscle activity and loading are likely minimal.
