Highlights:

- A new double layer-averaged two-phase flow model is proposed for barrier lake formation due to landslide impacting a river

- Grains play a key role in driving water movement during subaqueous landslide motion and a two-phase theory is warranted

- Grain size effects are revealed, i.e., coarse grains and grain-size uniformity favour barrier lake formation

- A new threshold for barrier lake formation is proposed, based on landslide-to-river momentum ratio and grain size

Abstract

A granular landslide impacting a river may lead to the formation of a landslide dam blocking the streamflow and subsequently a barrier lake. Should a barrier lake outburst, the flood may be destructive and spell disastrous consequences downstream. The last decade or so has witnessed a number of experimental and numerical investigations on barrier lake outburst flooding, whilst studies on barrier lake formation remain rare, especially a physically enhanced and practically viable mathematical model is still missing. Generally, barrier lake formation is characterized by multi-physics, interactive processes between water flow, multi-sized sediment transport and morphological evolution. Here, a new double layer-averaged two-phase flow model is proposed, featuring a step forward compared with existing continuum models that involve a single-phase flow assumption and presume a single sediment size and also discrete models that preclude fine grains and assume narrow grain size distributions. The proposed model is first validated by laboratory experiments of waves due to landslides impacting reservoirs and landslide dam formation over dry valleys. Then it is applied to explore the complicated mechanism and threshold for barrier lake formation. The water and grain velocities are shown to be disparate, characterizing the primary role of grains in driving water movement during subaqueous landslide motion and also the need for a two-phase flow approach. The grain size effects are revealed, i.e., coarse grains and grain-size uniformity favour barrier lake formation. A new threshold condition is proposed for barrier lake formation, integrating the landslide-to-river momentum ratio and grain size effects. The present work facilitates a promising modelling framework for solving barrier lake formation, thereby underpinning the assessment of flood hazards due to barrier lakes.

Keywords: barrier lake formation; granular landslide; waves; double layer-averaged model; two-phase flow model; grain size effect; threshold condition

1. Introduction

Barrier lake formation due to landslides impacting rivers represents a typical class of fluvial processes with rapid changes in time and space. When subaerial landslides impact narrow river valleys, they may propagate as underflows. Accordingly, a vertical double-layer flow structure is formed as characterized by a subaqueous water-sediment mixture flow layer immediately above the riverbed and an upper clear-water flow layer. In general, large water waves and active sediment transport can be generated by landslides impacting river valleys. Due to rapid deposition of a large amount of sediments, a landslide dam can be formed [1-2] as the riverbed aggrades rapidly and then emerges from the water. Moreover, water waves may trigger more landslides or collapses on the opposite riverbank, which entrain more sediments into river and facilitate landslide dam formation, as evidenced by the recent Baige barrier lake in China [3]. Resulting from sustained upstream inflow and significant water-level rise, the water impounded by landslide dam may create a barrier lake, which may inundate the lands and infrastructures upstream. Furthermore, due to the rather loose structure, landslide dam formed by granular landslide is easy to burst, leading to destructive downstream floods and debris flows, often with high casualties and severe infrastructural damages [4-6]. The most common failure scenario of barrier lakes concerns overtopping flow with subsequent dam breaching and erosion [1]. Typical historical examples include the Tortum landslide dam in Turkey [7] as well as the Tangjiasha barrier lake [8] and the recent Baige barrier lake [3] in China. In fact, the post-behaviour of a barrier lake is highly correlated with its formation process. Therefore, enhanced understanding of barrier lake formation due to granular landslide impacting a river is important to public safety and risk

72   management [9].

73   Over the past few decades, numerous efforts have been devoted to study barrier lake

74   failure and the resulting flood, including laboratory experiments [10-12] and numerical

75   modeling studies [13-18]. However, studies on barrier lake formation remain rare. Physically,

76   barrier lake formation involves complicated interactive processes between water flow,

77   multi-sized sediment transport, and morphological evolution. Field observation is certainly

78   the most straightforward approach to understanding this natural phenomenon. However, such

79   observations are difficult to conduct due to the rapid, short-lasting, unpredictable occurrence

80   and destructive power of landslides. Laboratory experiments in well-controlled conditions

81   have been conducted in flumes to investigate landslides impacting water bodies [19-21].

82   However, these experiments have mainly focused on landslide-generated-waves, while

83   sediment transport and morphological evolution are sparsely observed [22]. Consequently,

84   they are not able to fully reveal the complicated mechanism underlying barrier lake formation.

85   Comparatively, computational modelling is attractive, which has already become one of the

86   most   proactive   approaches   to   enhancing   the   understanding   of

87   hydro-sediment-morphodynamic processes in fluvial rivers, reservoirs, estuaries, and oceans

88   [23]. To date, however, there is a lack of a physically enhanced and practically viable

89   mathematical model for barrier lake formation due to granular landslide impacting a river. In

90   particular, sediment transport has not yet been sufficiently well resolved by existing models

91   based on either discrete mechanics or continuum assumption. Consequently, the modelling

92   framework for whole process flood risk management due to barrier lakes is still out of reach.

93   *1.1. Discrete models*

94   During the past decade, discrete models have been widely used for resolving the

95   mechanical behaviour of landslides, such as Discrete Element Method (DEM) [24],

96   Discontinuous Deformation Analysis (DDA) [25], Smoothed Particle Hydrodynamics (SPH)

97   [26] and Materials Point Method (MPM) two-phase models [27]. Regarding landslides

98   impacting water bodies, SPH models have been already applied for modelling landslide

99   motions and the generated waves [28]. Note that MPM two-phase models [27], which are

100   currently only used for landslide motions, can potentially be extended for barrier lake

101   formation by applying the governing equations of water phase for river flow modelling.

102   Moreover, discrete models for landslide motions can be coupled with the other models for

103   water flows. Typical examples include coupled DEM models and fluid flow such

104   computational fluid dynamics (CFD) models [29], SPH models [30] and Lattice-Boltzmann

105   Method (LBM) [31] as well as coupled DDA-SPH models [32-33]. However, constrained by

106   the excessive computational cost, a convention in discrete models is to introduce unjustified

107   assumptions in terms of sediment transport. First, most discrete models essentially exclude

108   fine grains. Specifically, DEM models [29-30] usually employ coarse grain models [35-36],

109   in which upscaled grains with a size larger than real cases are used. Besides, DDA models

110   [32-33] presume that landslides are composed of several large blocks. Such practices are

111   physically unjustified as coarse grains can settle faster than finer grains under a given flow

112   condition. Second, discrete models adopt much narrower grain size distributions (e.g.,

113   DEM-CFD models [29]) or even presume a single sediment size (e.g., MPM two-phase

114   models [27], SPH models [28] and DDA-SPH models [32-33]) due to restricted shape

115   functions used for fluid-solid interaction. However, the sediments in landslides may be highly

116 heterogeneous with widely distributed sizes, ranging from clay size (10^{-5} m) to boulder size

117 (10^1 m) [36]. Moreover, excess pore pressure is found to be influenced by grain size

118 distribution (GSD) [37], which plays a critical role in landslide behaviors. Therefore, grain

119 size data reveals the oversimplification of the models that presume narrow grain size

120 distributions or a single sediment size, and they also reinforce the notion that grain-size

121 heterogeneity may be critical to barrier lake formation due to granular landslides impacting

122 rivers [38]. Third, mass exchange with the bed has not been fully accounted for by discrete

123 models. Specifically, sediment erosion has not been modelled by these models except for a

124 few cases by a single DEM model [39], while the static sediment layer is regarded as

125 sediment deposit during the simulation [29].

126 *1.2 Continuum models*

127 As far as continuum models are concerned, double layer-averaged models hold great

128 promise for resolving barrier lake formation due to their ability to reflect the two-way

129 coupling between landslide motions and water flows [40] and the sensible balance between

130 their theoretical integrity and applicability [22]. Double layer-averaged models employ two

131 sets of governing equations to describe the lower water-sediment mixture flow (landslide)

132 layer and the upper clear-water flow layer. However, existing double layer-averaged models

133 have suffered from some major short-comings.

134 First, existing double layer-averaged models [22, 41-43] are based on a single-phase

135 flow premise, in which the water-sediment mixture in the lower flow layer are regarded as a

136 single-phase flow. Therefore, the velocities of the sediment phases in the lower flow layer are

137 assumed to be equal to the mixture velocity. Consequently, the relative motions and

138 interactions between water and sediment phases are not incorporated explicitly. Indeed, this

139 practice is only applicable for sediment-laden flow with sufficiently low sediment

140 concentrations, in which the water phase dominates and the interphase and inter-grain size

141 interactions are rather weak [23]. By contrast, landslides are primarily characterized by rather

142 high sediment concentrations, characterizing the dominant role of sediment phases and the

143 existence of strong interactions between water and sediment phases. Even intuitively,

144 sediment phases may drive the water movement during landslide motions. In this regard, a

145 two-phase flow theory is certainly the way forward [44] and a double layer-averaged

146 two-phase flow model is therefore warranted.

147 Second, existing double layer-averaged models [22, 41-43] are confined to single-sized

148 sediment transport (i.e., the sediment size is kept at a single value, normally the median or

149 mean sediment diameter, throughout the simulation). Clearly, the models that assume a single

150 sediment size do not reflect the nature of landslides, which are typically characterized by

151 broad grain size distributions.

152 Third, most double layer-averaged models [41, 43] ignore mass exchange with the bed.

153 Consequently, they cannot model the deposition process of landslide materials, which is vital

154 to barrier lake formation. Note that the double layer-averaged model by Liu and He [42]

155 incorporated the mass exchange with the bed. However, an additional term, which denotes a

156 real (rather than apparent) momentum exchange with the bed, was incorrectly added into the

157 momentum conservation equations. Physically, no real momentum exchange can be involved

158 into mass exchange with the bed, as highlighted by Cao et al. [23]. The consequence of this

159   extra term can be serious. For example, according to Liu and He [42], the riverbed is eroded

160   by subaqueous landslide instead of being deposited, which is questionable from physical

161   intuition. Arguably, this is why this model has not yet been validated by any observed data.

162   Furthermore, most double layer-averaged models [41-43] are based on the assumption of

163   a constant sediment concentration in the lower water-sediment mixture flow layer. However,

164   sediment concentration generally varies in time and space. Strictly, this assumption is far

165   from justified. In general, sediment concentration is an unknown variable that must be

166   resolved numerically, whereas in these double layer-averaged models [41-43], its value is

167   specified a priori, which inevitably introduces uncertainties. From a physical perspective, this

168   assumption leads to a violation of the fundamental mass conservation law for sediments.

169   Moreover, this assumption can lead to serious unphysical oscillations of numerical results

170   [45]. In addition, landslides impacting rivers usually take place over irregular and possibly

171   steeply sloping beds. The common assumption of low slopes in shallow water hydrodynamic

172   models is no longer valid, and the effects of steep slopes on sediment transport must not be

173   neglected. However, only a few double layer-averaged models [43] have ever considered the

174   effects of steep slopes on landslide motions but unjustifiably neglect their effects when

175   modelling water flows.

176   *1.3 Present work*

177   In this study, a double layer-averaged two-phase flow model is proposed for barrier lake

178   formation due to landslide impacting a river. Specifically, one set of layer-averaged

179   single-phase flow equations is introduced to describe the upper clear-water flow layer, while

180   another set of layer-averaged two-phase flow equations is deployed to describe the

181   subaqueous water-sediment mixture flow layer. The governing equations of the model are

182   established in a global Cartesian coordinate system with two axes within the horizontal plane

183   and one axis in the vertical direction. To account for the effects of steep slopes, the concept of

184   projected gravity proposed by Juez et al. [46] is incorporated. Compared to existing models

185   based on discrete mechanics or continuum assumption, the model features a step forward by

186   explicitly incorporating multi grain sizes, sediment mass conservation, mass exchange with

187   the bed and interphase and inter-grain size interactions. A new numerical algorithm is

188   proposed. Specifically, within the new model, the governing equations for each moving layer

189   are cast into a non-homogeneous hyperbolic system. The two hyperbolic systems of the

190   governing equations for the two layers are solved separately and synchronously. Each

191   hyperbolic system is solved by a quasi-well-balanced finite volume Slope Limiter Centred

192   (SLIC) scheme. The model is validated by laboratory experiments on waves due to granular

193   landslides impacting reservoirs [21] and landslide dam formation over dry valleys [47]. Then

194   it is applied to explore the underlying complicated mechanism and the threshold for barrier

195   lake formation due to granular landslide impacting a river.

196

197   **2. Mathematical model**

198   *2.1. Governing equations*

199   Consider shallow water-sediment flows over an erodible bed composed of non-cohesive

200   sediment with N size classes. Let d_k denote the diameter of the k th sediment size, where

201   subscript $k=1,2,.....,N$. The proposed model is developed by coupling the recent double

202   layer-averaged single-phase flow model [22] and the depth-averaged two-phase flow model

203   [48-50]. Here, "depth-averaged" or "layer-averaged" refers to the fact that the physical

204   quantities (velocity and volume fraction) are integrated and averaged along the depth of the

205   flow. Moreover, the shape factor, which arises from the depth-averaging procedure and

206   represents the effects of non-uniformity of vertical structure of velocity and sediment

207   concentration, are presumed to be unit. Indeed, it is a conventional practice in shallow

208   water-sediment models [53], which implies the effects of shape factors are neglected.

209   However, this practice does not mean that velocity and sediment concentration are assumed

210   to be constant along the flow depth. The model is established in a global Cartesian coordinate

211   system and uses the projected gravity concept [46] to account for the effect of steep slopes. In

212   general, interactions occur between the upper clear-water flow layer, the water and sediment

213   phases in the lower flow layer and the erodible bed, which are characterized by mass and

214   momentum exchanges. The coupled modelling approach is generally justified and thus

215   implemented [51]. The governing equations essentially comprise the mass and momentum

216   conservation equations for the clear-water flow layer, the water-sediment mixture, the water

217   and sediment phases in the lower water-sediment mixture flow layer, and the mass

218   conservation equations for the bed sediment.

219   For the upper clear-water flow layer:

220
$$\frac{\partial \rho_w h_w}{\partial t} + \frac{\partial \rho_w h_w u_w}{\partial x} + \frac{\partial \rho_w h_w v_w}{\partial y} = -\rho_w E_w \tag{1}$$

221
$$\frac{\partial \rho_w h_w u_w}{\partial t} + \frac{\partial}{\partial x}(\rho_w h_w u_w^2 + 0.5\rho_w g_{\psi_w} h_w^2) + \frac{\partial \rho_w h_w u_w v_w}{\partial y} = -\rho_w g_{\psi_w} h_w \frac{\partial \eta_s}{\partial x} - \rho_w E_w u_w - \tau_{wx} \quad (2)$$

222
$$\frac{\partial \rho_w h_w v_w}{\partial t} + \frac{\partial \rho_w h_w v_w u_w}{\partial x} + \frac{\partial}{\partial y}(\rho_w h_w v_w^2 + 0.5\rho_w g_{\psi_w} h_w^2) = -\rho_w g_{\psi_w} h_w \frac{\partial \eta_s}{\partial y} - \rho_w E_w v_w - \tau_{wy} \quad (3)$$

223   For the lower water-sediment mixture flow layer:

224
$$\frac{\partial \rho_m h_m}{\partial t} + \frac{\partial \rho_m h_m u_m}{\partial x} + \frac{\partial \rho_m h_m v_m}{\partial y} = \rho_w E_w - \rho_0 \frac{\partial z_b}{\partial t} \quad (4)$$

225
$$\frac{\partial \rho_m h_m u_m}{\partial t} + \frac{\partial}{\partial x}(\rho_m h_m u_m^2 + 0.5\rho_m g_{\psi_m} h_m^2) + \frac{\partial \rho_m h_m u_m v_m}{\partial y} = -\rho_m g_{\psi_m} h_m \frac{\partial z_b}{\partial x} - \rho_w g_{\psi_w} h_m \frac{\partial h_w}{\partial x} + \rho_w E_w u_w$$
$$+ \tau_{wx} - \tau_{bx} - \frac{\partial}{\partial x} h_m \sum [\rho_s c_k i_{s_k x}(i_{s_k x} - i_{fx})] \quad (5)$$
$$- \frac{\partial}{\partial y} h_m \sum [\rho_s c_k i_{s_k x}(i_{s_k y} - i_{fy})]$$

226
$$\frac{\partial \rho_m h_m v_m}{\partial t} + \frac{\partial \rho_m h_m u_m v_m}{\partial x} + \frac{\partial}{\partial y}(\rho_m h_m v_m^2 + 0.5\rho_m g_{\psi_m} h_m^2) = -\rho_m g_{\psi_m} h_m \frac{\partial z_b}{\partial y} - \rho_w g_{\psi_w} h_m \frac{\partial h_w}{\partial y} + \rho_w E_w v_w$$
$$+ \tau_{wy} - \tau_{by} - \frac{\partial}{\partial y} h_m \sum [\rho_s c_k i_{s_k y}(i_{s_k y} - i_{fy})] \quad (6)$$
$$- \frac{\partial}{\partial x} h_m \sum [\rho_s c_k i_{s_k y}(i_{s_k x} - i_{fx})]$$

227   For the size-specific sediment phase in the lower water-sediment mixture layer:

228
$$\frac{\partial \rho_s h_{sk}}{\partial t} + \frac{\partial \rho_s h_{sk} u_{sk}}{\partial x} + \frac{\partial \rho_s h_{sk} v_{sk}}{\partial y} = \rho_s F_k \quad (7)$$

229
$$\frac{\partial \rho_s h_{sk} u_{sk}}{\partial t} + \frac{\partial}{\partial x}(\rho_s h_{sk} u_{sk}^2 + \frac{1}{2} c_k \rho_m g_{\psi_m} h_m^2) + \frac{\partial}{\partial y}(\rho_s h_{sk} u_{sk} v_{sk}) = -\rho_m g_{\psi_m} h_{sk} \frac{\partial z_b}{\partial x} - \rho_w g_{\psi_w} h_{sk} \frac{\partial h_w}{\partial x}$$
$$- \tau_{s_k bx} + \tau_{wx} c_k + F_{s_k fx} + F_{s-s_k x} \quad (8)$$
$$+ \frac{1}{2} \rho_m g_{\psi_m} h_m^2 \frac{\partial c_k}{\partial x}$$

230
$$\frac{\partial \rho_s h_{sk} v_{sk}}{\partial t} + \frac{\partial}{\partial x}(\rho_s h_{sk} u_{sk} v_{sk}) + \frac{\partial}{\partial y}(\rho_s h_{sk} v_{sk}^2 + \frac{1}{2} c_k \rho_m g_{\psi_m} h_m^2) = -\rho_m g_{\psi_m} h_{sk} \frac{\partial z_b}{\partial y} - \rho_w g_{\psi_w} h_{sk} \frac{\partial h_w}{\partial y}$$
$$- \tau_{s_k by} + \tau_{wy} c_k + F_{s_k fy} + F_{s-s_k y} \quad (9)$$
$$+ \frac{1}{2} \rho_m g_{\psi_m} h_m^2 \frac{\partial c_k}{\partial y}$$

231   For the water phase in the lower water-sediment mixture layer:

$$\frac{\partial \rho_w h_f}{\partial t} + \frac{\partial \rho_w h_f u_f}{\partial x} + \frac{\partial \rho_w h_f v_f}{\partial y} = \rho_w p \frac{F_T}{1-p} \tag{10}$$

$$\frac{\partial \rho_w h_f u_f}{\partial t} + \frac{\partial}{\partial x}(\rho_w h_f u_f^2 + \frac{1}{2}c_f \rho_m g_{\psi_m} h_m^2) + \frac{\partial}{\partial y}(\rho_w h_f u_f v_f) = -\rho_m g_{\psi_m} h_f \frac{\partial z_b}{\partial x} - \rho_w g_{\psi_w} h_f \frac{\partial h_w}{\partial x}$$
$$- \tau_{fbx} + \tau_{wx} c_f - \sum F_{s_k fx} \tag{11}$$
$$+ \frac{1}{2}\rho_m g_{\psi_m} h_m^2 \frac{\partial c_f}{\partial x}$$

$$\frac{\partial \rho_w h_f v_f}{\partial t} + \frac{\partial}{\partial x}(\rho_w h_f u_f v_f) + \frac{\partial}{\partial y}(\rho_w h_f v_f^2 + \frac{1}{2}c_f \rho_m g_{\psi_m} h_m^2) = -\rho_m g_{\psi_m} h_f \frac{\partial z_b}{\partial y} - \rho_w g_{\psi_w} h_f \frac{\partial h_w}{\partial y}$$
$$- \tau_{fby} + \tau_{wy} c_f - \sum F_{s_k fy} \tag{12}$$
$$+ \frac{1}{2}\rho_m g_{\psi_m} h_m^2 \frac{\partial c_f}{\partial y}$$

235   For the bed deformation:

$$\frac{\partial z_b}{\partial t} = -\frac{F_T}{1-p} \tag{13}$$

237   where t is time; x and y are the horizontal coordinates; η_s is the elevation of the

238   interface between the upper clear-water flow layer and the lower water-sediment mixture

239   flow layer; h_w is the thickness of the clear-water flow layer; u_w and v_w are the

240   layer-averaged velocity components of the clear-water flow layer in the $x-$ and

241    $y-$ directions; f, s and m denote the water phase, the sediment phase, and the

242   water-sediment mixture in the lower layer; h_m is the thickness of the lower water-sediment

243   mixture flow layer; $h_{sk} = h_m c_k$ is the size-specific thickness of the sediment phase in the

244   lower flow layer; z_b is the bed elevation; c_k is the layer-averaged size-specific volumetric

245   sediment concentration of the lower flow layer; $c_T = \sum c_k$ is the layer-averaged total

246   sediment concentration; $c_f = 1 - c_T$ is the layer-averaged volume fraction of the water phase

12

247 of the lower flow layer; ρ_w and ρ_s are the pure densities of the water and sediment phases

248 respectively, $\rho_m = \rho_s c_T + \rho_f (1 - c_T)$ is the density of the water-sediment mixture in the

249 lower flow layer; $\rho_0 = \rho_s (1 - p) + \rho_f p$ is the density of the bed; p is the bed sediment

250 porosity, and thus $1 - p$ is the volumetric sediment concentration of the stationary bed; u_{sk}

251 and v_{sk} are the size-specific layer-averaged velocity components of the sediment phase in

252 the lower flow layer; u_f and v_f are the layer-averaged velocity components of the water

253 phase in the lower flow layer; u_m and v_m are the layer-averaged velocity components of

254 the water-sediment mixture in the lower flow layer; u_m and v_m are defined as

255 $\rho_m u_m = \sum (\rho_s u_{s_k} c_k) + \rho_f u_f (1 - c_T)$ and $\rho_m v_m = \sum (\rho_s v_{sk} c_k) + \rho_f v_f (1 - c_T)$, according to

256 mass flux conservation; $i_{s_k x} = u_{sk} - u_m$ and $i_{fx} = u_f - u_m$ denote the differences among the

257 size-specific sediment velocity u_{sk}, the water velocity u_f and the water-sediment mixture

258 velocity u_m in the $x-$ direction, while $i_{s_k y} = v_{sk} - v_m$ and $i_{fy} = v_f - v_m$ denote their

259 counterparts in the $y-$ direction; τ_{wx} and τ_{wy} are the bottom shear stress components

260 for the clear-water flow layer; τ_{bx} and τ_{by} are the bottom shear stress components for the

261 lower water-sediment mixture flow layer; $\tau_{s_k bx}$ and $\tau_{s_k by}$ are the size-specific solid

262 resistance components in the lower flow layer; τ_{fbx} and τ_{fby} are the size-specific fluid

263 resistance components in the lower flow layer; $F_{s_k fx}$ and $F_{s_k fy}$ are the size-specific

264 layer-averaged interphase interaction force components; $F_{s-s_k x}$ and $F_{s-s_k y}$ are the

265 size-specific layer-averaged inter-grain size interaction force components, which are exerted

266 on sediment phase k by the other constituents of sediment phases and $\sum (F_{s-s_k x}) = 0$,

267 $\sum (F_{s-s_k y}) = 0$; E_w is the mass flux of the water entrainment across the interface between

268 two moving layers; F_k is the size-specific net flux of sediment exchange with the bed and

269 $F_T = \sum F_k$. $g_{\psi_w} = g \cos^2 \psi_w$ and $g_{\psi_m} = g \cos^2 \psi_m$ are the corrected gravitational accelerations

270 for the clear-water flow layer and the lower water-sediment mixture flow layer, where g is

271 the gravitational acceleration and ψ_w and ψ_m are the angles of the interface and the bed,

272 defined as $\cos \psi_w = 1 / \sqrt{1 + (\partial \eta_s / \partial x)^2 + (\partial \eta_s / \partial y)^2}$ and $\cos \psi_m = 1 / \sqrt{1 + (\partial z_b / \partial x)^2 + (\partial z_b / \partial y)^2}$,

273 according to Juez et al. [46].

274   For multi grain sizes, the concept of the active layer presented by Hirano [52], which has

275 been widely used in the context of fluvial hydraulics [53], is adopted to evaluate bed grain

276 size stratigraphic evolution. By analogy to fluvial hydraulics [52, 54-55], this concept is

277 based on a three-layer structure, composed of the water-sediment mixture flow layer, the

278 active layer, and the substrate layer. The active layer is located between the water-sediment

279 mixture flow layer and the substrate layer. Sediments within the active layer are assumed to

280 be well mixed in the vertical direction and can exchange freely with the upper and lower

281 layers. The substrate layer, known as the stratigraphy of the deposit, has a certain structure

282 and may vary over time. Physically, the active layer equation is based on the size-specific

283 mass conservation of the bed sediments. In general, three critical parameters are involved, i.e.,

284 the active layer thickness, the size-specific sediment exchange between the water-sediment

285 mixture layer and the bed, and the sediment fraction at the lower interface of the active layer.

286 Accordingly, the active layer equation is

287
$$\frac{\partial h_a f_{ak}}{\partial t} + f_{Ik} \frac{\partial \xi}{\partial t} = -\frac{F_k}{1-p} \tag{14}$$

288 where h_a is the thickness of the active layer; f_{ak} is the fraction of the k th size sediment

289 in the active layer such that $\sum f_{ak} = 1$; $\xi = z_b - h_a$ is the elevation of the bottom surface of

290   the active layer; and f_{Ik} is the fraction of the k th size sediment in the interface between the

291   active layer and the substrate layer, where $\sum f_{Ik} = 1$. In this study, the active layer thickness

292    $h_a = 2d_{84}$ is used following the convention in fluvial hydraulics [56], where $d_{84} =$ is the

293   grain size at which 84% of the sediments are finer. As shown in Eq. (14), the net flux of

294   sediment exchange [i.e., the right hand side (RHS) of Eq. (14)] accounts for the variation in

295   the fraction of the active layer [i.e., the first term on the left hand side (LHS) of Eq. (14)] and

296   the change in the sediment content due to movement of the interface between the active layer

297   and its substrate [i.e., the second term on the LHS of Eq. (14)]. Moreover, the bed

298   deformation equation, i.e., Eq. (13) can be readily obtained by integrating Eq. (14) over all

299   grain sizes, due to the fact that $\sum f_{ak} = 1$ and $\sum f_{Ik} = 1$.

300   To close the governing equations of the proposed double layer-averaged two-phase flow

301   model, a set of relationships must be introduced to determine the sediment exchange fluxes,

302   the shear stresses, the water entrainment, and the interaction forces, which are described in

303   detail in Text S1 (see Supplementary materials). Estimation of sediment exchange with the

304   bed is one of the key components of computational models of geophysical mass flows (e.g.,

305   landslides, debris flows, and avalanches). However, an understanding of the physical

306   processes underlying geophysical mass flows remains unclear [57-58]. Therefore, the widely

307   used closure model in fluvial hydraulics [53] is employed to estimate the mass exchange with

308   the bed. This closure model [53, 59-60] has been shown to perform well in modelling debris

309   flows [48] and landslides [22], and so is adopted in this study. In short, two distinct

310   mechanisms are generally involved in mass exchange with the bed: upward bed sediment

311   entrainment due to interphase and inter-grain size interactions and downward sediment

312   deposition as the result of primarily gravitational action. Following the conventional practice

313   in two-phase flow modelling, the total bed shear stresses for the water-sediment mixture in

314   the lower flow layer are divided into the bed shear stress components exerted respectively on

315   the water and sediment phases [61-63]. The solid resistance is determined by the Coulomb

316   friction law [64], which expresses the collinearity of shear stress and normal stress through a

317   friction coefficient. The fluid resistance is estimated using Manning's equation. Similarly, the

318   bottom shear stress for the clear-water flow layer is also estimated by Manning's equation

319   [43]. The mass flux of water entrainment E_w, which represents the mixing of the lower

320   water-sediment mixture flow layer with the upper clear-water flow layer across the interface

321   of the two moving layers, is determined by a slightly adapted version of the relationship

322   originally proposed for turbidity currents [65]. The interphase drag force is determined by

323   combining the Ergun equation for dense water-sediment mixtures and the power law for

324   dilute suspensions [66], while the inter-grain size interaction drag force includes a linear

325   velocity-dependent drag force, a inter-grain size surface interaction force and a remixing

326   force [67-68]. All the empirical relationships presented above to close the present model are

327   not new at all in the general field of shallow water hydro-sediment-morphodynamics. Indeed,

328   to date, there are no generally valid formulations available for representing sediment

329   exchange fluxes, shear stresses, water entrainment, and interaction forces. While uncertainly

330   is inevitably introduced, it can be carefully addressed by means of sensitivity computations

331   and analyses, a common practice in almost all computational models for shallow

332   water-sediment flows.

333   *2.2. Numerical algorithm*

334   Eqs. (1-14) form a nonlinear system of fourteen partial differential equations, which is

335   currently too complicated to be solved numerically as a single system. Here a new numerical

336   algorithm is proposed. Following the numerical strategy proposed by Cao et al. [69], Eqs.

337   (1-12) can be divided into two reduced-order systems representing the clear-water flow layer

338   (Eqs. 1-3) and the lower water-sediment mixture flow layer (Eqs. 4-12), whereas the bed

339   deformation equation (Eq. 13) and the active layer equation (Eq. 14) are solved separately

340   from the remaining equations. Besides, regarding the mathematical model for the lower

341   water-sediment mixture flow layer, only two of the three governing equation systems for the

342   water-sediment mixture (Eqs. 4-6), the sediment phase (Eqs. 7-9) and the water phase (Eqs.

343   10-12) are independent and can in principle be used. As suggested by Li et al. [48-50], the

344   governing equation system for the lower water-sediment mixture flow layer is composed of

345   the equations for the water-sediment mixture (Eqs. 4-6) and the sediment phase (Eqs. 7-9)

346   because this system is hyperbolic and characterized by the straightforward derivation of the

347   real and distinct eigenvalues.

348   In summary, the proposed double layer-averaged two-phase flow model involves eleven

349   variables, including the thickness h_w and layer-averaged velocity components u_w and v_w

350   of the clear-water flow layer; the thickness h_m and layer-averaged velocity components u_m

351   and v_m of the lower water-sediment mixture flow layer; the size-specific thickness h_{sk} and

352   layer-averaged velocity components u_{sk} and v_{sk} of the sediment phase in the lower layer;

353   the bed elevation z_b; and the fraction of the k th size sediment in the active layer f_{ak}.

354   Correspondingly, the proposed model is composed of eleven governing equations, including

355   the complete mass and momentum conservation equations for the upper clear-water flow

356 layer (Eqs. 1-3) and the water-sediment mixture in the lower flow layer (Eqs. 4-6), the

357 size-specific mass and momentum conservation equations for the sediment phase in the lower

358 flow layer (Eqs. 7-9), the bed deformation equation (Eq. 13) and the active layer equation (Eq.

359 14). Within this model, the two systems representing the clear-water flow layer (Eqs. 1-3) and

360 the lower water-sediment mixture flow layer (Eqs. 4-9) can be proven to be hyperbolic [70].

361 Therefore, they can be solved separately and synchronously by a quasi-well-balanced finite

362 volume SLIC scheme, which is adapted from the numerical algorithm in Cao et al. [71] and is

363 described in Text S2 in the Supplementary materials. In general, two types of boundaries, i.e.

364 open and closed boundaries, are involved in this work. At an open boundary, such as the inlet

365 or outlet of a channel, the method of characteristics is used for subcritical flow conditions to

366 obtain the updated values of flow variables, which however should be directly prescribed at

367 the inlet and set to be zero gradients at the outlet for supercritical flows. The depth-averaged

368 sediment concentration c_k at an open boundary, however, needs to be specified. At a closed

369 boundary, such as the side walls of a channel, a free-slip and non-permeable condition is

370 employed [72].

371   The double layer-averaged two-phase flow model equations along with the model

372 closures and the numerical algorithm have been presented above. Essentially, the proposed

373 model has incorporated the leading-order physical factors in the mass and momentum

374 conservation equations, such as gravitation, resistance, inter-phase and inter-grain size

375 interactions. It is appreciated that more delicate and refined mechanisms may exist in

376 sediment-laden flows and modify the modelling results (e.g., viscous particle resuspension

377 [73] and shear-induced particle migration [74]). Yet these are presumably second- and

378 higher-order factors, and it is sensible to have these reserved for incorporation in the model in

379 the future.

2.3 Comparison with previous models

381 Table 1 compares the key physics and computational efficiency of the present and

382 previous models, which can be applied to barrier lake formation due to landslide impacting a

383 river. Physically, compared to existing models based on discrete mechanics [27-29, 32-33] or

384 continuum assumption [22], the present model features a physical step forward. Specifically,

385 compared to MPM two-phase models [27], SPH models [28], DEM-CFD models [29],

386 DDA-SPH models [32-33] that exclude fine grain, presume narrower grain size distributions

387 or a single sediment size, and incompletely consider mass exchange with the bed, the present

388 model is extended due to the incorporation of multi grain sizes and mass exchange with the

389 bed. In comparisons with the double layer-averaged single-phase flow model by Li et al. [22],

390 the present model is physically enhanced without evoking the presumption of equal solid and

391 fluid velocities embedded in a single-phase flow model for the sediment-laden layer,

392 explicitly incorporating multi grain sizes as well as interphase and inter-grain size

393 interactions.

394 Regarding computational efficiency, depth-averaged models within the framework of

395 shallow water hydrodynamics are the most efficient. Comparatively, discrete models such as

396 SPH models, DEM-CFD models and DDA-SPH models generally require excessively high

397 computational costs as they involve the calculation of the interactions of multiple discrete

398 bodies with continuously changing contacts. MPM two-phase models lie between

399   depth-averaged models and discrete models due to the hybrid Lagrangian and Eulerian

400   descriptions and the involved mesh-free techniques. If MPM two-phase model is to be

401   extended for barrier lake formation, higher dimensional shape functions are required for the

402   lower water-sediment mixture flow layer in landside-river interactions, which significantly

403   increase the computational time.

3. Computational case studies

The present double layer-averaged two-phase flow model is first validated by laboratory experiments on waves due to granular landslides impacting reservoirs [21] and landslide dam formation over dry valleys [47]. Then, based on numerical case studies, the model is applied to explore the complicated mechanism and the threshold for barrier lake formation due to landslides impacting rivers.

Here, a fixed uniform mesh is used for each case, with spatial steps sufficiently fine to ensure mesh independence of the solution, i.e. essentially equivalent solutions are obtained with an even finer mesh. The friction angle $\delta = 30°$. The empirical weighting parameter φ, which usually varies between 0.61 and 0.81 based on the sediment size [75], is calibrated to be 0.65 for the present computational cases. A unified and constant value of the modification coefficient ϕ (= 1) is used for all the cases. Unless otherwise specified, the values of the other common parameters are $\rho_f = 1000$ kg/m^3, $\rho_s = 2650$ kg/m^3, and $g = 9.8$ m^2/s, $p = 0.4$, $Cr = 0.5$. In this study, the transverse direction is along the center line of the sliding slope, while the longitudinal direction is along the center line of the river valley.

3.1. Waves due to granular landslides impacting reservoirs (Series 1)

In general, when granular landslide impacts a river, large waves and active sediment transport can be generated, both of which may affect barrier lake formation as evidenced by the recent Baige barrier lake in China [3]. First, a numerical simulation is undertaken of the waves driven by a granular landslide entering a reservoir, and the results are compared against laboratory data obtained by Bregoli et al. [21] whose experimental setup comprised a

431   landslide generator, a wave basin, and a measurement system (Fig. 1). Similar to previous

432   experiments [19, 20], Bregoli et al. [21] only measured the landslide-generated waves, but

433   ignored the associated sediment transport and morphological evolution. The landslide

434   generator consisted of a steep ramp with a slope angle varying from 0° to 27.8° and a

435   wheeled box containing granular material that slid on 6.2 m long rails fixed to the lateral

436   walls of the flume. And the rails had a very low degree of surface roughness and

437   deformability. On reaching the end of the ramp, the box was halted instantaneously by a

438   high-resistance shock absorber, and the landslide material released into a rectangular basin

439   4.10 m long and 2.45 m wide. The location $x = 0$ m corresponded to the point that the

440   landslide entered the water. Water level displacements were measured at eight locations ($x =$

441   1.7, 1.9, 2.1, 2.3, 2.5, 2.7, 2.9 and 3.1 m) along the central axis of the basin. This case relates

442   to a test where the angle of the ramp slope α was 27.8°, and the initial landslide was 1 m

443   long, 0.34 m wide, and 0.25 m deep. The landslide had an initial velocity of approximately

444   5.3 m/s at release. The landslide shape was assumed to remain unchanged during the

445   acceleration of the box. The basin's initial water depth h_{w0} was set to 0.20 m. The granular

446   materials comprised gravel of mean diameter $d = 16.9$ mm, grain density $\rho_s = 2820$ kg/m^3,

447   and bulk porosity $p = 0.4$. The Manning coefficients for bed roughness $n_b = 0.03$ s/m$^{1/3}$

448   and interface roughness $n_w = 0.005$ m$^{-1/3}$ s were calibrated to the measured wave level

449   displacement. The computational domain included the steep ramp and the basin. The spatial

450   steps Δx and Δy were both 0.02 m. A free-slip and non-permeable condition was

451   employed in the boundaries (i.e., side walls) [72]. Time $t = 0$ s coincides with the instant

452   that the landslide was released from the box. In this case, a double layer-averaged

453   single-phase flow model [22] is also used for comparisons. For simplicity, the double

454   layer-averaged two-phase flow model and the double layer-averaged single-phase flow model

455   are respectively labelled 'DLT' and 'DLS'. Note that all the modelling parameters in DLT and

456   DLS models are the same.

457   Fig. 2 shows the variations in time of the landslide velocity u_s and the thickness h_s at

458   the impact point computed by the DLT and DLS models, with the measured data from

459   Bregoli et al. [21] superimposed. Although appreciable discrepancies are observed, the

460   landslide motion predicted by the DLT model is fairly consistent with the measured data,

461   whereas the DLS results are characterized by a lower velocity and a smaller thickness. Fig. 3

462   displays the non-dimensional water level displacement time series at the eight gauges,

463   computed by the DLT and DLS models along with measured data obtained by Bregoli et al.

464   [21]. Despite the distinguishable discrepancies, the results from the DLT model agree with

465   the observed data of landslide-generated waves more closely than the DLS model. Several

466   reasons might be responsible for the discrepancies between the experimental and numerical

467   results. First, the initial conditions are difficult to be set as the same as in the experiments,

468   especially the acceleration of box and the releasing process of landslide materials, which

469   however cannot be fully considered by the proposed model. Second, the empirical

470   relationships and parameters for model closures may also inevitably bring about some

471   discrepancies.

472   Figs. 4 and 5 show the sediment concentration distribution and bed deformation in the

473   basin (where measured data are unavailable), computed by the DLT and DLS models. The

474   landslide sustains a high sediment concentration (~ 0.6) after completely entering the water

475   and spreading over the flatbed (Figs. 4 a1-a2 and Figs. 4 b1-b2). No deposition occurs during

476   this stage, mainly because the landslide has attained a sufficiently high speed from the box

477   acceleration prior to release. The computed sediment concentrations determined by the two

478   models are nearly the same. After reaching the wall at $x = $ 3.34 m, the landslide decelerates

479   gradually, resulting in a decrease in sediment concentration (Figs. 4 a3-a4 and Figs. 4 b3-b4)

480   and bed aggradation due to deposition of the landslide material (Fig. 5). Sediment

481   concentrations determined by the DLS model decrease more rapidly than those determined by

482   the DLT model. Consequently, the DLS model is characterized by a more rapid sediment

483   deposition speed and a larger bed depositional area compared to the DLT model.

506   *3.2. Landslide dam formation over dry valleys (Series 2)*

507   Next, landslide slide formation over dry valleys due to a sudden release of granular

508   materials are considered, based on a series of flume experiments documented by Zhao et al.

509   [47]. In these experiments, to simplify the processes of landslide initiation and acceleration,

510   the landslide body was given a certain initial velocity to shorten the acceleration process and

511   the initial shape of the landslide was assumed to be regular block and the sliding path was

512   constrained in a sliding groove rather than a free slope surface. The geometry of the sliding

513   groove was 1 m × 1 m × 0.6 m with a slope angle of 30°. A valley was installed at the end of

514   the sliding groove (Fig. 6). The length of the valley was 3 m. The effects of three main

515   variables, including initial landslide velocity, valley shape (Fig. 7) and valley bed inclination,

516   on landslide dam morphology were investigated. The surface slope of landslide dam was

517   measured, which refers to the angle between the dam surface and the horizontal plane. φ_u

518   was defined as the angle in the upstream direction, while φ_d was defined as the angle in the

519   downstream direction. Table 2 summarizes the initial conditions of all the experimental cases.

520   The computational domain included the sliding groove and the dry valley. The spatial steps

521   Δx and Δy were both 0.02 m. Numerical modelling was performed within the time period

522   before the landslide reached the boundaries, where the boundary conditions can be simply set

523   at the initial static status. Time $t = 0$ s coincides with the instant that the landslide was

524   released from the groove. The Manning coefficients for bed roughness $n_b = 0.02$ s/m$^{1/3}$ and

525   interface roughness $n_w = 0.005$ m$^{-1/3}$ s were calibrated to the measured data.

526   To demonstrate the performance of the model, all the experimental cases listed in Table

527   2 were revisited. Table 2 also includes the computed upstream surface slope φ_u and its

29

528   downstream counterpart φ_d along with the measured data. The computed surface slope

529   determined by the proposed model is rather consistent with the measured data. As can be seen

530   from Table 2, dam morphology is indeed affected by initial landslide velocity, valley shape

531   and inclination of the valley bed. For instance, in rectangular valleys, the longitudinal

532   sections of a dam are trapezoidal (low or medium initial landslide velocity) or triangular

533   (high initial landslide velocity), and while in the forms of the other two valleys, the

534   longitudinal section is mainly trapezoidal. When the initial landslide velocity is fixed, with an

535   increase of valley bed inclination, the upstream surface slope decreases while the downstream

536   counterpart increases.
537

*3.3. Barrier lake formation due to sustained inflow of granular landslide (Series 3)*

This next case involves barrier lake formation due to sustained release of landslide materials, which were numerically designed by Zhao et al. [29] and computed by a coupled DEM-CFD model. The numerical setup comprised a grain container and an open fluid channel (Fig. 8). The grain container had a size of 5 m × 5 m × 1 m, and it was placed 2 m above the fluid channel. The dimension of the fluid channel was set as $L =$ 100 m, $W =$ 5 m, $H =$ 10 m. The computational domain included the grain container and the open fluid channel. The spatial steps Δx and Δy were both 0.05 m. The discharge of granular materials (q_s) into the fluid channel was kept constant. Therefore, the landslide velocity and thickness were determined by the method of characteristics, while the depth-averaged sediment concentration needed to be specified. Besides, a constant inflow discharge of clear water was maintained throughout the simulation by setting the flow velocity at the inlet boundary of the fluid channel as a constant value. At the outlet of the fluid channel, the method of characteristics was used for subcritical flow conditions to obtain the updated values of flow variables, which however should be set to be zero gradients for supercritical flows. Within the time period considered, the fluid channel was sufficiently long to ensure that the landslides did not reach the boundaries, where the boundary conditions for landslides can be simply set at the initial static status. The channel's initial water depth h_{w0} was set to 10 m. The granular materials comprised gravel of mean diameter $d =$ 200 mm. The Manning coefficients for bed roughness $n_b =$ 0.03 s/m$^{1/3}$ and interface roughness $n_w =$ 0.005 m$^{-1/3}$ s were calibrated to the predicted results by Zhao et al. [29]. Time $t =$ 0 s

565   coincides with the instant that the landslide was released from the grain container. The total

566   duration of the simulation (T_d) was 60 s.

567   According to grain size distribution by Zhao et al. [29], the mixture could be separated

568   into two size fractions: $d_1 = $ 150 mm (50%) and $d_2 = $ 250 mm (50%). First, three cases

569   with different initial flow velocities are revisited (i.e., Case 3-1, 3-2 and 3-3, see Table S1 in

570   Supplementary materials). Then, a total of 21 numerical cases are conducted to investigate

571   the roles of landslide inflow discharge, grain size and initial water depth (see Table S1).

572   Specifically, landslide inflow discharge ranges from 0.5 m^3/s to 4.5 m^3/s, medium grain size

573   varies from 10 mm to 400 mm and initial water depth increases from 5 m to 25 m. Note that

574   in Table S1, "Y" denotes the formation of barrier lake, whilst "N" means no barrier lake is

575   formed.

576
577
578   **Fig. 8.** Schematic view of the setup for Series 3 (modified from Zhao et al. [29]).

579

580   Figs. 9 and 10 show the computed sediment deposit lengths and heights under different

581   initial flow velocities along with the predictions from Zhao et al. [29]. Three dimensionless

582   number, the normalized time [T], deposit height $[\mathrm{H}]$, and length [L] are defined as

583    $[\mathrm{T}] = t / \sqrt{h_{w0}/g}$, $[\mathrm{H}] = h/h_{w0}$ and $[\mathrm{L}] = l/L$, respectively, where the initial water depth

584    $h_{w0} =$ 10 m and the fluid channel length $L =$ 100 m. Note that in Zhao et al. [29], the

585   sediment deposit length was normalized by h_{w0} although the length and height did not share

586   the same axis. Besides, the sediment deposit height is defined as the height of the static

587   sediment layer during the simulation in Zhao et al. [29], while in the present study, it is

588   defined as the bed aggradation depth. Due to the symmetric geometrical configuration, the

589   deposit length is defined as the backward (for grains moving towards the inlet direction) and

590   the forward (for grains moving towards the outlet direction) lengths of the deposit front to the

591   symmetric axis of the grain container. In terms of deposit heights and lengths, the present

592   model exhibits good agreement with the computed results by Zhao et al. [29]. According to

593   Fig. 9, it is noted that for water flows with non-zero initial velocities, the forward deposit

594   length is always larger than the backward deposit length. This is mainly because the initial

595   flow together with the movements induced by landslides impacting into the channel can

596   move the grains forwards along the channel. The difference between the forward and

597   backward deposit lengths is rather large for grains transported by flows at the initial velocity

598   of 5 m/s. For this case, the incoming grains are transported forwards by the rapid flows, such

599   that a large number of grains can move long distances away from the source region. Fig. 10

600   demonstrates that the evolutions of deposit heights follow almost the same trend for these

601   cases, and the constant height periods are evident to be observed.

602
603

Fig. 9. Evolution of sediment deposit lengths under different initial flow velocities.

605

606

Fig. 10. Evolution of sediment deposit heights under different initial flow velocities.

35

608

609   Fig. 11 shows barrier lake formation process as represented by the evolutions of

610   landslide thickness plus bed deformation $h_s + \Delta z_b$ and water thickness h_w, in relation to

611   Case 3-1. Obviously, landslide directly crashes into the river and forces the water running up

612   to the opposite side of the channel. Specifically, it can be observed that solid grains move as a

613   sequence of surges. The first surge starts to spread longitudinally once the grains reach the

614   channel wall (at [T] = 2, Fig. 11a1). As evidenced by a series of successive figures, grains in

615   the first surge move with the highest mobility (see Figs. 11a1-a2) In the meantime, the

616   incoming granular grains generates the second surge spreading just on the top of the first

617   surge. The spreading velocity of the second surge is much slower than that of the first surge

618   (comparing Fig. 11a3 to Fig. 11a2). After [T] = 15, a series of small surges have formed and

619   deposited on the surface of the landslide dam. The sediments would finally block the river

620   and lead to the formation of a barrier lake after [T] = 35, when a thick and stable landslide

621   dam is formed on the river floor.

622
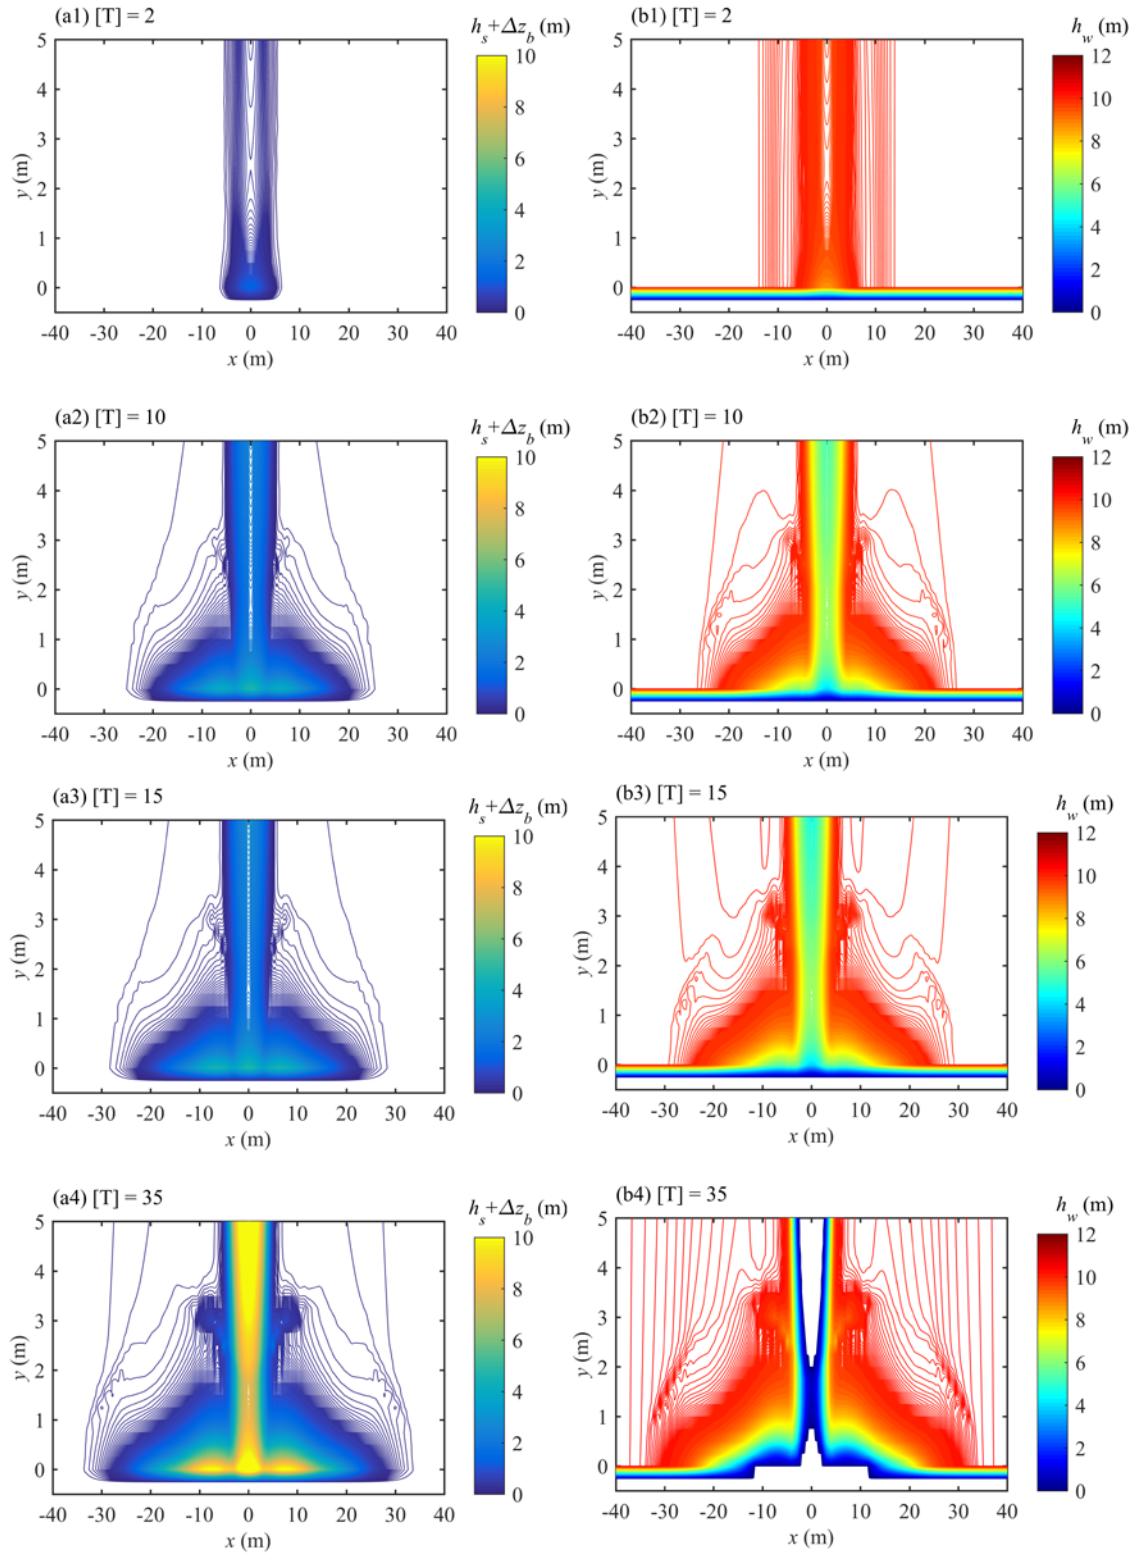

Fig. 11. Barrier lake formation: (a1-a4) landslide thickness plus bed deformation (b1-b4) water thickness, in relation to Case 3-1.

*3.4. Barrier lake formation due to sudden failure of granular landside (Series 4)*

To further demonstrate the model performance, a total of 29 numerical cases on barrier lake formation due to sudden failure of granular landslide (Fig. 12), which was designed based on experimental landslide dam formation over dry valleys [47], are evaluated. The length of the river valley was extended to 40 m, such that the landslide would not reach the upstream and downstream boundaries of the valley within the time of computation, where the boundary conditions for landslides can be simply set at the initial static status. Similar to Series 2, the computational domain included the sliding groove and the valley. The spatial steps Δx and Δy were set as 0.02 m. First, a constant inflow discharge was maintained at the upstream of the valley to form a steady river flow, and then subaerial granular materials were released from the sliding grove. At the inlet boundary of the valley, the flow velocity and thickness were determined by the method of characteristics, while at the outlet of the fluid channel, the method of characteristics was used for subcritical flow conditions to obtain the updated values of flow variables, which however should be set to be zero gradients for supercritical flows. The roles of river flow discharge, initial landslide volume and velocity, grain size, valley type and valley bed inclination angle were investigated. Specifically, three inflow discharges were used, including 0.3 m^3/s, 0.6 m^3/s and 1.2 m^3/s. Four initial landslide volumes, i.e., 0.1 m^3, 0.2 m^3, 0.4 m^3 and 0.6 m^3, were employed to represent small, medium and large landslide. Two landslide velocities with values of 1 and 3 m/s were respectively used to represent low and fast landslide movements. Following Zhao et al. [47], the valley shape was set to be rectangular, trapezoidal or V-shaped to investigate the influence of valley shape (see Fig. 2). Two values, i.e., 0° and 5°, were selected to represent the flat and sloping

649   valley bed. Table S2 in Supplementary materials summarizes the initial conditions of these

650   numerical cases and the results. Notably, it is impossible to form the landslide dam in case of

651   the river low with high velocity (i.e., the upstream river flow discharge is equal to 1.2 m^3/s).

652   In general, smaller river flow discharge, larger landslide volume and velocity, coarser grain

653   size, milder valley bed inclination angle, and rectangular valley shape are conducive to

654   barrier lake formation. Fig. 13, Fig. 14 and Video S1 in Supplementary materials collectively

655   show barrier lake formation due to sudden failure of the landslide, in relation to Case 4-1.

656   During the first stage, the landslide impacts into the channel and interacts with the river flow.

657   Due to the low velocity of the river flow, the front landslide can even climb to the other side

658   of the channel (Fig. 13a1 and Fig. 14a). Later, most of the landslide materials are deposited

659   on the channel bottom, forming the landslide dam (Fig. 13a2 and Fig. 14b). Soon after the

660   dam formation, the barrier lake is formed due to the blockage (Fig. 13b3 and Fig. 14c), and

661   the volume of the barrier lake gradually increases due to sustained upstream inflow, as shown

662   in Fig. 13b4 and Figs. 14d-f. With the increase of the lake volume, the water level exceeds

663   the dam height, overtopping begins (see Video S1, $t >$ 54 s).

673

674
675 **Fig. 14.** Typical instants of barrier lake formation in relation to Case 4-1.

676

677   Overall, the present double layer-averaged two-phase flow model has satisfactorily

42

678   resolved barrier lake formation due to landslide impacting a river (Sections 3.3 and 3.4).

679   Nevertheless, it may not necessarily mean the present model would be universally valid as

680   the numerical case studies were conducted in flumes with fixed bed slopes. In this connection,

681   more large-scale experiments on barrier lake formation with varied flume beds and more

682   observed data on natural barrier lake over irregular and steep slopes are warranted to further

683   support model development.

684

4. Discussion

4.1. Interphase interactions

687   It evaluates the interphase interactions by virtue of the relative velocities. Physically,

688   interphase interactions quantify the momentum and energy transfer between grains and fluids

689   [76], which essentially characterize waves and sediment transport due to granular landslides

690   impacting water bodies [77-78]. However, these processes have not yet been sufficiently

691   resolved as existing continuum models involve a single-phase flow assumption and presume

692   a single sediment size and discrete models cannot fully account for sediment transport. Here

693   V_{fs} and U_{fs} are defined as the velocity differences between the water phase of landslide

694   and the sediment phase of any size in the transverse ($y-$axis) and longitudinal ($x-$axis)

695   directions, respectively. Accordingly, $V_{fs}=v_f - v_{sk}$ and $U_{fs}=U_f - U_{sk}$, both of which are

696   normalized by $\sqrt{gh_{w0}}$. Therefore, $[V_{fs}]=V_{fs}/\sqrt{gh_{w0}}$ and $[U_{fs}]=U_{sf}/\sqrt{gh_{w0}}$. In relation to

697   Case 3-1, Fig. 15 displays the velocity differences between the water and size-specific

698   sediment phases of landslide in the transverse ($y-$axis) direction, while Fig. 16 shows the

699   counterparts in the longitudinal ($x-$axis) direction.

700   As seen in Figs. 15, before reaching the channel wall at $y=$ 0 m, the grains generally

701   have higher speeds than the water phase in the transverse direction ($y-$axis), while the

702   coarse grains move faster than the fine grains by approximately 20% - 30%. After hitting the

703   wall, the landslide spread longitudinally and its velocity decreases. Compared to the water

704   phase, the grains decelerate more rapidly and move slower at the area around the wall,

705   although they still sustain a higher speed than the water on the edge of this area. Note that the

706   coarse grains settle faster than the fine grains as a larger grain size corresponds to a larger

707   absolute velocity difference in the transverse direction. Later, it is shown in Figs. 15(a3-a4)

708   and Figs. 15(b3-b4) that the velocity differences between the water and sediment phases

709   gradually shrink. This occurs because the barrier lake gradually forms (as shown in Fig. 11),

710   which greatly impedes the subsequent impact of landslide into the river.

711   Regarding the normalized velocity differences in the longitudinal direction ($x-$axis),

712    $U_{fs} >$ 0 in the downstream direction and $U_{fs} <$ 0 in the upstream direction indicate a

713   higher water speed than the sediment phases, and vice versa. As shown in Fig. 16, it is

714   observed that $U_{fs} >$ 0 where $x >$ 0, while $U_{fs} <$ 0 where $x <$ 0. Therefore, the grains

715   generally exhibit lower speeds than the water, though only a marginal velocity difference can

716   be distinguished. In contrast to the observations in the transverse direction, the coarse grains

717   move slightly slower than the fine grains. As time is going on (see Figs. 16 a3-a4 and Figs. 16

718   b3-b4), the presence of the barrier lake tends to dampen the velocity differences between the

719   water and sediment phases in the longitudinal direction, similar to those observed in the

720   transverse direction (Figs. 15 a3-a4 and Figs. 15 b3-b4).

721   Figs. 15 and 16 collectively show that water and grain velocities are disparate, which

722   characterize the primary role of grains in driving water movement in subaqueous landslide

723   motion. Consequently, grains play a major role in barrier lake formation due to granular

724   landslide impacting a river. Overall, these results clearly imply that a double layer-averaged

725   two-phase flow model is warranted, physically characterizing a step forward for barrier lake

726   formation as compared with a double layer-averaged single-phase flow model [22], in which

727   sediment velocity is assumed to be equal to that of the fluid phase.

728
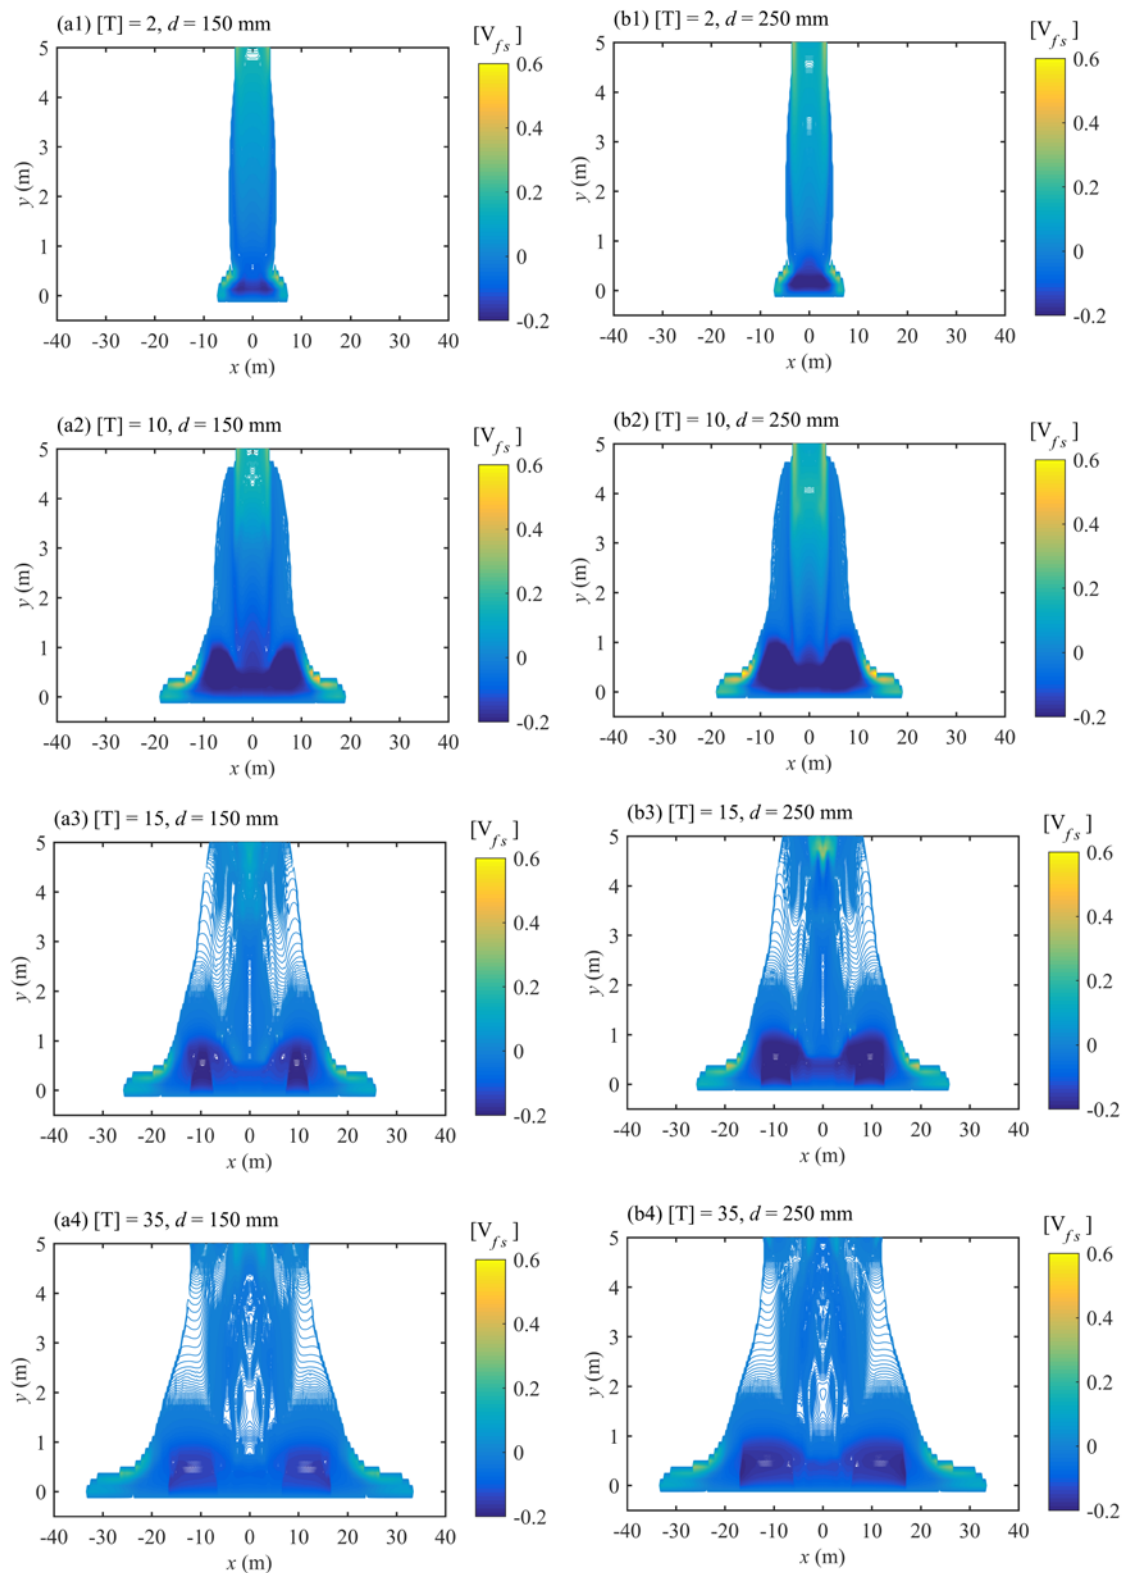

Fig. 15. Velocity differences between the water and sediment phases of landslide in transverse (y – axis) direction, in relation to Case 3-1, a1-a4 with $d = $ 150 mm, and b1-b4 with $d = $ 250 mm.

Fig. 16. Velocity differences between the water and sediment phases of landslide in longitudinal (x – axis) direction, in relation to Case 3-1,a1-a4 with $d =$ 150 mm, b1-b4 with $d =$ 250 mm.

737

4.2. Grain size effects

In section 3, the proposed model has demonstrated its capability of reproducing barrier

lake formation due to landslide impacting a river, in addition to resolving the effects of

critical factors, including initial landslide velocity, river flow condition, valley type, and bed

inclination angle. However, to date, there is a lack of studies available for investigating grain

size effects on barrier lake formation process, although grain sizes and grain-size

heterogeneity have been known as two of the most important factors controlling the

characteristics of landslide dams [37]. This is mainly because sediment transport has not been

fully accounted for by previous models.

747

4.2.1. Coarse vs Fine grain size

As stated above, discrete models [29-30, 32-33] generally exclude fine grains to improve

computational efficiency. Such practices are certainly far from justified as coarse grains can

be deposited faster than finer grains under a given flow condition. Here, in relation to Cases

3-8, 3-9 and 3-10, three different sediment mixtures with smaller mean diameters, i.e., $d_m =$

100 mm, 50 mm and 10 mm, are used for analysis. Evolutions of sediment deposit heights

under different mean diameters are presented in Fig. 17. Obviously, the computed results are

rather sensitive to the grain size. The larger the grain size, the faster the barrier lake can be

formed. Notably, when the grain size is rather small (i.e., $d_m < $ 50 mm), the barrier lake

cannot be formed within the considered computational time.

758

759
Fig. 17. Evolution of sediment deposit heights under different mean diameters.

761

4.2.2. Broad vs Narrow grain size distribution

Another shortcoming in existing models is that multi grain sizes are not sufficiently incorporated. Specifically, DEM-CFD models [29] usually assume much narrower grain size distributions than the real cases to reduce computational costs, while the double layer-averaged single-phase flow model [22], MPM two-phase models [27], SPH models [28] and DDA-SPH models [32-33] presume a single sediment size. Clearly, these practices cannot reflect the nature of sediment compositions in landslides, fundamentally featured by the broadly distributed grain sizes, ranging from clay size ($\approx 10^{-5}$ m) to boulder size ($\approx 10^{1}$ m) [36]. To address the effect of the grain size distribution (GSD), the grain-size heterogeneity is

771 adjusted by increasing the standard deviation of sediment composition (i.e., σ was

772 increased from 1.29 to 2.88), while retaining the same mean sediment diameter ($d_m =$ 200

773 mm) (Table 3). Fig. 18 illustrates the evolutions of sediment deposit heights under two GSDs,

774 in relation to Case 3-1. The sediment deposit height under a broader GSD increases much

775 slower than its counterpart with a much narrower GSD. And within the considered

776 computational time, the river is not blocked by the landslide and no barrier lake is formed

777 (Fig. 19). By comparing Fig. 19 to Fig. 11, it is found that the landslide with a higher

778 grain-size heterogeneity spreads faster and further after entering into the flume, echoing the

779 previous finding that grain-size heterogeneity can enhance landslide mobility [79].

780 Overall, the analysis above (Sections 4.2.1 and 4.2.2) clearly demonstrate that coarse

781 grains and grain-size uniformity favour barrier lake formation. Furthermore, it is implied that

782 existing discrete models [27-29, 32-33] exclude fine grains and presume narrower grain size

783 distributions or a single sediment size and the double layer-averaged single-phase flow model

784 [22] that assumes a single sediment size are inadequate for barrier lake formation due to

785 granular landslide impacting a river.

786

787

798   *4.3. Threshold for barrier lake formation*

799   The possibility that a barrier lake can be formed depends on many geomorphic factors

800   that concurrently involve both landslide and river dynamics [80]. Accordingly, the critical

801   index for barrier lake formation can be formulated by incorporating geomorphic variables of

802   both river and landslide. Existing critical indexes mainly include Annual Constriction Ratio

803   (ACR, Swanson et al. [81]), Dimensionless Flow Index (DFI, Ermini and Casagli [4]),

804   Dimensionless Constriction Index (DCI, Ermini and Casagli [4]), Dimensionless

805   Morpho-Invasion Index (DMI, Dal Sasso et al. [80]) and Morphological Obstruction Index

806   (MOI, Stefanelli et al. [82]). Specifically, ACR is defined as the ratio of the river channel

807   width to the landslide velocity. DFI is correlated with the landslide mass and the river

808   discharge, while DCI accounts for the grain size of landslide material based on DFI. MOI is

809   defined as the ratio of the landslide mass to the river channel width. Comparatively, DMI is

810   determined by the landslide-to-river momentum ratio. As compared to other indexes, DMI is

811   physically enhanced by incorporating the geometric, kinematic and dynamic characteristics

812   of landslide and river systems simultaneously [80]. However, DMI neglects the effect of

813   grain size, the role of which on barrier lake formation is demonstrated to be significant (see

814   Section 4.2).

815   In this study, a new non-dimensional critical index is proposed, which is defined as

816   follows,

817   $$I_{MP} = R_V R_u R_\rho / \theta \tag{15}$$

818   where R_V is the volume ratio of the landslide to the river and defined as $R_V = V_s / b h_{w0}^2$;

53

819      $R_u = U_s/U_w$ is the velocity ratio of the landslide to the river flow; $R_\rho = \rho_m/\rho_w$ is the

820   density ratio of the landslide to the river flow; θ is the Shields number. For the cases due to

821   sustained inflow of landslide material (i.e., Series 3), $V_s = q_s T_d$, while for the cases due to

822   sudden failure of landslide (i.e., Series 4), V_s is the initial landslide volume. Moreover, U_s

823   is the initial landslide velocity and U_w is equal to the initial river flow velocity. ρ_m is

824   equivalent to the initial landslide density. Physically, $R_m = R_V R_u R_\rho$ represents the

825   momentum ratio of the landslide to the river flow. Shields number θ characterizes the

826   mobility of sediment, which generally increases along with the decrease of grain size under a

827   given condition. Therefore, the proposed critical index I_{MP} accounts for both

828   landslide-to-river momentum ratio and grain size effect.

829   Table S3 in Supplementary materials summarizes the computed critical index I_{MP} for

830   Series 3 and 4. Fig. 20 presents the computed $R_V R_\rho/\theta$ against the velocity ratio R_u along

831   with solid circle and open square symbols respectively indicating barrier lake is formed and

832   not-formed. Importantly, the formation of a barrier lake occurs when $I_{MP} > 0.836$;

833   otherwise, barrier lake cannot be formed. In general, barrier lake formation is more likely to

834   occur with the increase of both landslide-to-river momentum ratio and grain size.

835
Fig.20. Threshold for barrier lake formation as presented by computed $R_V R_\rho / \theta$ against the velocity ratio R_u along with solid circle and open square symbols respectively showing barrier lake is formed and not-formed.

5. Conclusions

A new double layer-averaged two-phase flow model is presented and applied to solve barrier lake formation due to landslide impacting a river. Physically, it represents a step forward compared with existing models based on discrete or continuum assumption, which cannot fully resolve sediment transport (Table 1). The main conclusions are as follows:

1. The proposed model is validated by the benchmark laboratory experiments of waves due to landslides impacting reservoirs and landslide dam formation over dry valleys. It reasonably resolves barrier lake formation for extended numerical case studies, as per the

effects of key factors, including initial landslide volume and velocity, grain size, river flow condition, valley type, and valley bed inclination angle.

2. It is shown that grains essentially drive the water movement in subaqueous landslide motion and thus significantly affect barrier lake formation afterwards. Equally importantly, coarse grains and grain-size uniformity favour barrier lake formation. These results underpin that numerical continuum models, which involve a single-phase flow assumption and presume a single-sized sediment, and discrete models, which preclude fine grains and assume narrow grain size distributions or a single sediment size, are inadequate for barrier lake formation.

3. A new non-dimensional threshold for barrier lake formation is proposed, based on landslide-to-river momentum ratio and grain size. It is implied that a barrier lake is more likely to form with the increase of both landslide-to-river momentum ratio and grain size. This approach can serve as a useful tool in decision-making associated with prediction of barrier lake formation and management of emergencies induced by these events.

The present work facilitates a promising modelling framework for barrier lake formation due to granular landslide impacting a river, and therefore enhances whole-process flood risk management due to barrier lakes when coupled with the recent models for barrier lake failure and the resulting floods. Inevitably, uncertainties of the proposed model arise from the estimations of mass exchange between the landslide and the bed, interface and bed resistances, which require systematic fundamental investigations into the associated mechanisms.

Fig. 1. Experimental setup for Series 1 (adapted from Bregoli et al. [21])

Fig. 2. Granular landslide into a reservoir: DLT and DTS predictions and Bregoli et al.'s [21] measurements of temporal variations of (a) landslide velocity and (b) landslide thickness at impact with water in a basin.

Fig. 3. Granular landslide into a reservoir: DLT and DTS model predictions and Bregoli et al.'s [21] measurements of non-dimensional water level displacements with non-dimensional time water in a basin.

Fig. 4. Granular landslide into a reservoir: (a1-a4) DLT and (b1-b4) DLS model predictions of sediment concentration distributions in the basin.

Fig. 5. Granular landslide into a reservoir: (a1-a4) DLT and (b1-b4) DLS model predictions of bed deformation in the basin.

Fig. 6. Experimental setup for Series 2 (adapted from Zhao et al. [47])

Fig. 7. Valley types and geometry (adapted from Zhao et al. [47]).

Fig. 8. Schematic view of the setup for Series 3 (modified from Zhao et al. [29]).

Fig. 9. Evolution of sediment deposit lengths under different initial flow velocities.

Fig. 10. Evolution of sediment deposit heights under different initial flow velocities.

Fig. 11. Barrier lake formation: (a1-a4) landslide thickness plus bed deformation (b1-b4) water thickness, in relation to Case 3-1.

Fig. 12. Numerical setup for Series 4 (modified from Zhao et al. [47]).

Fig. 13. Barrier lake formation in relation to Case 4-1: (a1-a4) landslide thickness plus bed deformation (b1-b4) water thickness.

Fig. 14. Typical instants of the barrier lake formation in relation to Case 4-1.

Fig. 15. Velocity differences between the water and sediment phases of landslide in transverse ($y-$axis) direction, in relation to Case 3-1, a1-a4 with $d = $ 150 mm, and b1-b4 with $d = $ 250 mm.

Fig. 16. Velocity differences between the water and sediment phases of landslide in longitudinal ($x-$axis) direction, in relation to Case 3-1, a1-a4 with $d = $ 150 mm, b1-b4 with $d = $ 250 mm.

Fig. 17. Evolution of sediment deposit heights under different mean diameters.

Fig. 18. Evolutions of sediment deposit heights under different grain size distributions, in relation to Case 3-1.

Fig. 19. Landslide movements and waves under a broad grain size distribution, in relation to Case 3-1: (a1-a4) landslide thickness plus bed deformation (b1-b4) water thickness.

Fig.20. Threshold for barrier lake formation as presented by computed $R_V R_\rho / \theta$ against the velocity ratio R_u along with solid circle and open square symbols respectively showing barrier lake is formed and not-formed.
