**pH and Vascular Tone**

A thesis submitted to the  
University of Glasgow  
in Candidature for the degree of  
Doctor of Philosophy  
in the Faculty of Science

by

Ahbor Dolly Awani Ighoroje

from

The Institute of Physiology  
The University  
Glasgow

April, 1987

## **Acknowledgements**

I would like to thank Professors Sheila Jennett for letting me use available facilities in the department and I.A. Boyd for giving me the opportunity to come and study in this department.

My special thanks go to my supervisor Dr. Neil C. Spurway who not only guided me expertly throughout the course of this work but also together with his wife Mrs. Allison Spurway took an interest in my welfare during my stay in this country.

My gratitude also goes to Ann Ward whose technical and friendly assistance I shall always treasure and to Francis Burton Jnr. who helped me through with most of the computer programmes.

Thanks to everybody in the department who gave me tremendous support during my illness and indeed throughout my stay here.

My love and thanks to Richard and Itari for their support through very hard times and to my mama Flora Efebo who has been the main influence in my life. Thank you, Lizzie, Nengi and Uncle Gani, Thanks to God.

## SUMMARY

The mechanisms by which extracellular pH ( $\text{pH}_0$ ) and intracellular pH ( $\text{pH}_i$ ) affect vascular tone, and by which  $\text{pH}_i$  itself is regulated in the vascular smooth muscle cells, have been investigated.

The majority of experiments were carried out with isolated rabbit ears activated with  $10^{-6}\text{M}$  noradrenaline and perfused at constant flow. Other preparations studied were perfused whole femoral beds of rabbits and frog whole body. The perfusing solutions were phosphate, HEPES or  $\text{CO}_2 / \text{HCO}_3^-$  - buffered Ringer's having  $\text{Cl}^-$  as the bulk anion, and appropriately oxygenated.

$\text{pH}_i$  was modified at constant  $\text{pH}_0$  using two different procedures, one was the application and withdrawal of  $\text{CO}_2$  and the other was the " $\text{NH}_4^+$  pulse" technique, which involved the application and washout of  $\text{NH}_4^+$ .

The procedures which can be expected to lower  $\text{pH}_i$  at constant  $\text{pH}_0$  both raised tone while the reverse steps reduced it. With every fluid used  $\text{NH}_4^+$  application or lowering / withdrawal of  $\text{CO}_2$  dilated the vascular bed while  $\text{NH}_4^+$  withdrawal or elevation / application of  $\text{CO}_2$  constricted it. The time courses of the changes in tone were reminiscent of pH responses to the above procedures, shown by intracellular pH electrode

measurement in various cell types e.g. vas deferens (Aicken, 1984), squid giant axon (Thomas, 1974,'84) and  $\text{pH}_i$  estimations by N.M.R. techniques with mixed arterial preparations (Dawson, Spurway and Wray, 1985) - in all these cases extracellular  $\text{NH}_4^+$  transiently raises cytoplasmic pH while the subsequent washout carries it for a period below the control level. By contrast with the mammalian preparations  $\text{NH}_4^+$  application actually vasoconstricted while its withdrawal vasodilated.

The phenomena were investigated under varying ionic and external conditions and were compared under three  $\text{pH}_o$ 's: 6.7, 7.2, 7.7. There were no qualitative differences under all conditions though quantitatively there were variations. The results excluded all the explanations of the classical  $\text{pH}_o$  effect invoking direct  $\text{H}^+$  inhibition of intracellular events. Therefore displacement of  $\text{Ca}^{2+}$  by  $\text{H}^+$  from sequestering sites (S.R; mitochondria) other than the myofibrils themselves was proposed to account for these  $\text{pH}_i$  effects observed.

Some interventions, known to affect  $\text{pH}_i$  homeostasis in other cells, were employed to establish possible mechanisms of  $\text{pH}_i$  regulation. Replacement of all  $\text{Cl}_o^-$  with  $\text{PhSO}_3^-$ , or  $\text{H}_2\text{PO}_4^-$  with  $\text{HCO}_3^-$ , and the application of S.I.T.S. or amiloride all retarded the adaptation of tone from  $\text{NH}_4^+$  dilatation. Replacement of all  $\text{Na}_o^+$

with  $\text{Li}^+$ , choline, sucrose or  $\text{K}^+$ , replacement of  $\text{H}_2\text{PO}_4^-$  with  $\text{HCO}_3^-$  and applications of S.I.T.S., ouabain, amiloride and its derivatives all retarded to varying degrees the adaptation of tone from the washout constriction. Notably among the latter was the 10x greater potency of a claimed  $\text{Na}^+ - \text{H}^+$  exchange inhibitor than of a claimed  $2\text{Na}^+ - \text{Ca}^{2+}$  inhibitor. Quantitative considerations such as this lead to the conclusion that  $\text{Cl}^- - \text{HCO}_3^-$  exchange plays the major role in the elimination of alkaline load while excess  $\text{H}^+_{\text{i}}$  are eliminated mainly by a  $\text{Na}^+ - \text{H}^+$  exchange. Adaptation of tone from both dilatation and constriction is probably also influenced by changes of membrane potential and by the movements of other ions ( $\text{Cl}^-$ ,  $\text{Ca}^{2+}$ ,  $\text{K}^+$  and  $\text{NH}_4^+$ ) which must occur in parallel with the changing rates of antiportation.

It was incidentally noted that, while amiloride is vasodilatory, its derivatives may have either vasodilatory or vasoconstrictory effects on NA - activated vessels.

The significance of the work for normal physiology is considered to be:

(a) its refutation of proposals that dilatory effects of extracellular acidity are mediated by intracellular acidification.

(b) its indication that changes of body fluid pH brought about by  $\text{P}_{\text{CO}_2}$  variation are likely to produce tone responses smaller than - or even, at times, opposite to - the responses produced when  $\text{pH}_0$  is changed in identical amounts by variation of  $[\text{HCO}_3^-]_0$ .

## CHAPTER I

### INTRODUCTION

Since Gaskell (1880) observed relaxation with extracellular alkalinity, in both systemic resistance vessels and the heart itself, it has been widely accepted that the tone of these resistance vessels and heart was affected by the pH of the medium bathing them. Elliot and Jasper (1949) exposed the surface of the brain to an acidic (pH 6.2 ) medium and observed a dilatation of the pial vessels. Conversely, when Wahl et al (1970) microinjected  $\text{HCO}_3^-$  ions at constant  $\text{P}_{\text{CO}_2}$  into the cerebrospinal fluid of anaesthetized rats and cats, they were able to produce vasoconstriction in pial arterioles. Hutter and Hecht (1965) had also reported a decrease in excitability ( and conductance) of cardiac cell membranes with external acidity. In more recent investigations Allen and Orchard (1983) reported a reduction in cardiac contractility when they lowered the extracellular pH ( $\text{pH}_0$ ). The common feature of the above observations is, an indication of the importance of  $\text{pH}_0$  (besides neural and other chemical factors) in vasodilatation/constriction and therefore in the regulation of blood flow [Severinghaus 1968 ; Duling 1977 ; and Kontos 1981 ]

The mechanism just described sounds physiologically reasonable as there is adaptive advantage if vessels supplying acidotic tissues dilate - the acidifying agents in this context being  $\text{CO}_2$  and lactic acid.

Both  $\text{CO}_2$  and lactic acid however can pass through cell

membranes therefore they presumably affect intracellular pH ( $\text{pH}_i$ ) in the same sense as they do  $\text{pH}_o$ . Moreover, the contractile systems (myofibrils, actomyosin) of both skeletal and cardiac muscles (Fabiato and Fabiato, 1978) and smooth muscle (Schadler, 1967; Mrwa et al, 1974) are inhibited by acidity. It was therefore a reasonable postulate that the main site of pH action was intracellular, on the actomyosin (Peiper, et al, 1976; Duling, 1977).

Against this however, indications that  $\text{pH}_i$  affected vascular tone in opposite directions or at least in a more complex way than  $\text{pH}_o$  were obtained by McLellan et al (1974) and Pickard et al (1975, 1976). They investigated the vascular bed of the rabbit ear, perfused via its central artery and activated with noradrenaline, and also bovine middle cerebral artery strips variously activated. The behaviours of both preparations were compared in both phosphate and bicarbonate buffered solutions. Both preparations vasodilated markedly when  $\text{pH}_o$  was lowered in the phosphate-buffered medium. However, with  $\text{HCO}_3^-/\text{CO}_2$  adjusted 'physiologically' - i.e. when the external  $\text{HCO}_3^-$  concentration was kept constant and the  $\text{P}_{\text{CO}_2}$  was varied, so that  $\text{pH}_o$  and  $\text{pH}_i$  could be assumed to vary together - the effects on vascular tone were small inconsistent and often bidirectional. Varying external  $[\text{HCO}_3^-]$  while keeping  $\text{P}_{\text{CO}_2}$  constant, which should alter  $\text{pH}_o$  only, produced acid-dilatation about 2/3 that in  $\text{H}_2\text{PO}_4^-$ -buffered

medium.

The initial interpretations of their results were that  $\text{pH}_i$  might be acting oppositely to  $\text{pH}_o$ , at least over part of the pH range if not over all of it. They therefore varied  $[\text{HCO}_3^-]_o$  proportionately to  $P_{\text{CO}_2}$  so altering only  $\text{pH}_i$  and observed that  $P_{\text{CO}_2}$  elevation, which would acidify the cytoplasm, actually caused vasoconstriction.

However an alternative explanation to the concept of opposing actions by  $\text{pH}_i$  and  $\text{pH}_o$  for the last group of results was that the effects of  $\text{CO}_2$  might actually be direct molecular interactions at intracellular sites.

The aim of the present study is to investigate further the mechanism of pH effects on vascular tone. The procedure includes the modification of both  $\text{pH}_o$  and  $\text{pH}_i$  and observing their effects on vascular tone. I have however pursued principally the matter of  $\text{pH}_i$  modifications using for the first time on smooth muscles an alternative to the  $\text{HCO}_3^-/\text{CO}_2$  technique, namely that of the " $\text{NH}_4$  pulse".

### Intracellular pH Modifications

Intracellular acidification could theoretically be induced variously, for example:

- (a) Iontophoretically injecting a weak acid into the cell
- (b) Changing  $\text{pH}_o$  with permeant buffers

- (c) Applying  $\text{CO}_2$  (replacing a nominally  $\text{HCO}_3^-$ -free medium with  $\text{HCO}_3^-/\text{CO}_2$ ) which is known to cross the cell membrane very rapidly
- (d) Washing out of an  $\text{NH}_4$  salt solution after a brief application.

Both (c) and (d) above, which like (a) but unlike (b) do not involve changes of  $\text{pH}_0$ , have been employed in this study. The techniques are discussed in turn below.

### $\text{CO}_2$ -Induced Intracellular Acidification

The first proposal that  $\text{CO}_2$  produces a fall in  $\text{pH}_i$  was put forward by Overton in 1902. Years later, in 1920, Jacobs confirmed this. However Caldwell (1958) was the first, using pH-sensitive microelectrodes, to actually measure the  $\text{pH}_i$  transient induced by  $\text{CO}_2$ . He exposed crab muscle fibres and giant squid axons to a solution equilibrated with 100%  $\text{CO}_2$  and observed a pH drop of more than 0.5 units. Several other workers [Kosfyuk and Krishtal 1961, Paillard 1972, Thomas 1974, Aicken and Thomas 1975., Boron and DeWeer 1976., Jones 1977., Boron 1977; Boron and Boulpaep 1980 and Moody, 1981], using pH-sensitive microelectrodes, have also confirmed this with various muscle cells. Both Caldwell (1958) and Thomas (1974) also observed that non- $\text{CO}_2$  buffers are much less effective in lowering  $\text{pH}_i$  than  $\text{CO}_2$  though it is worth noting that most of them are not

entirely without intracellular effect.

### Basis for Intracellular Acidification induced by CO<sub>2</sub>

The intracellular acidification by CO<sub>2</sub> occurs as a result of the fact that CO<sub>2</sub> molecule rapidly diffuses across the cell membrane into the cell, hydrates and subsequently dissociates to form H<sup>+</sup> and HCO<sub>3</sub><sup>-</sup>

On removal or reduction of external P<sub>CO<sub>2</sub></sub> a loss of intracellular CO<sub>2</sub> occurs resulting in the association of H<sup>+</sup> and HCO<sub>3</sub><sup>-</sup> and therefore raising of pH<sub>i</sub>/alkalinization (Thomas 1974).

### NH<sub>4</sub><sup>+</sup> Induced Acidification and Alkalinization

Thomas (1974) pioneered the use of pH-sensitive micro-electrodes to monitor the pH<sub>i</sub> transients induced by ammonium salts. He exposed snail neurones to 5mM (NH<sub>4</sub>)<sub>2</sub> SO<sub>4</sub> and observed a rapid increase in pH<sub>i</sub> which was reversed on removal of the ammonium solution. Subsequently, this 'NH<sub>4</sub><sup>+</sup> pulse' technique has been applied on giant squid axon ( Boron and DeWeer 1976)., mouse soleus muscle fibres (Aicken and Thomas, 1977)., isolated perfused amphibian proximal renal tubules (Boron and Boulpaep

1980, 1983); crayfish neurones (Moody 1981) and guinea pig vas deferens cells (Aicken, Personal Communication 1984)

The " $\text{NH}_4^+$  pulse" technique entails the application of neutral ammonium salts to the extracellular medium. This drives the cytoplasm transiently alkaline. It then recovers slowly back towards control. Subsequent removal of the  $\text{NH}_4^+$  salt results in a rebound acidification as  $\text{pH}_i$  transiently falls below control: Fig1.

Dawson et al (1985), Spurway and Wray (1987) used  $^{31}\text{P}$  nuclear magnetic resonance (N.M.R) techniques on mixed arterial preparations to measure  $\text{pH}_i$  changes induced by  $\text{NH}_4^+$ .  $^{31}\text{P}$  N.M.R spectroscopy owes its usefulness for  $\text{pH}_i$  estimations to the pH sensitivity of the resonance peak of inorganic phosphate (Gadian, 1982). Dawson Spurway and Wray were able to show that arterial cytoplasmic pH turns transiently alkaline with the application of extracellular  $\text{NH}_4^+$  and transiently acid on its withdrawal. Thus the mass of small cells in a V.S.M behave very much the same way as the large cells, studied by intracellular pH electrodes, referred to above.

### Basis for the $\text{pH}_i$ Modifications by the ' $\text{NH}_4^+$ Pulse'

#### Technique

Boron and DeWeer (1976) proposed the following scheme to explain  $\text{pH}_i$  modifications by  $\text{NH}_4^+$  application on exposure to a short pulse of  $\text{NH}_4^+$  solution known to contain both  $\text{NH}_4^+$  and a

small fraction of  $\text{NH}_3$ .  $\text{NH}_3$  rapidly enters the cell along its concentration gradient and combines with  $\text{H}^+$  to form  $\text{NH}_4^+$  and therefore raise  $\text{pH}_i$ . But this alkalization is subsequently blunted by  $\text{NH}_4^+$  which also enters the cell more slowly along its electrochemical gradient dissociating within the cell to form  $\text{NH}_3 + \text{H}^+$ .

If the cell is now returned to  $\text{NH}_4^+$ -free solution,  $\text{NH}_3$  once again leaves the cell rapidly along its concentration gradient. Thus resulting in the dissociation of internal  $\text{NH}_4^+$  into  $\text{NH}_3 + \text{H}^+$  and therefore a fall in  $\text{pH}_i$ .  $\text{NH}_4^+$  also leaves the cell, though at a slower rate than when it was driven into the cell earlier on due to a smaller electrochemical driving force ( $E_m$  is negative). The excess  $\text{NH}_4^+$  retained yields the protons which are responsible for the intracellular acidification.

On a prolonged exposure to the  $\text{NH}_4^+$  solution, however,  $\text{NH}_3$  entry will eventually fall to zero as  $[\text{NH}_3]_i$  approaches that of the outside. Alkalinization would cease so that the subsequent course for  $\text{pH}_i$  is determined mainly by  $\text{NH}_4^+$  and  $\text{H}^+$  entry, and possibly also to a small extent in smooth muscle (though a larger extent in more metabolically-active cells) by intracellular  $\text{CO}_2$  production. When  $\text{NH}_3$  is at equilibrium and assuming  $\text{pK}_a$  of  $\text{NH}_4^+$  to be the same on both sides of the membrane, the equilibrium potential for both  $\text{NH}_4^+$  and  $\text{H}^+$  would be the same.

In Fig. 1 an alternative understanding of this ' $\text{NH}_4^+$  pulse' mechanism developed in our laboratory (Ighoroje and Spurway unpublished) is briefly illustrated. It differs from that of Boron and DeWeer above which is also quoted by Thomas (1984) in that the dissociation of  $\text{NH}_4^+$  to  $\text{NH}_3 + \text{H}^+$  is assumed to take place extracellularly and then  $\text{H}^+$  goes slowly into the cell along its electrochemical gradient. However there is as yet no evidence for a choice of where this occurs. It is possible that both effects occur and do contribute to the overall  $\text{pH}_i$  alterations.

#### Fundamental Finding :

##### The Effect of $\text{pH}_i$ Modifications on Arterial (vascular) Tone

In this study both the ' $\text{NH}_4^+$  pulse' and, on occasions the application of  $\text{CO}_2$  have been used to modify the  $\text{pH}_i$  of perfused vascular preparations from the rabbit.

My main finding is that, on application of  $\text{NH}_4^+$ , vascular tone was transiently reduced while  $\text{NH}_4^+$  withdrawal or the application of  $\text{CO}_2$  both transiently raised vascular tone. Thereafter in all cases tone gradually adjusted itself back towards control level. Since the only chemical consequence common to both  $\text{CO}_2$  application and  $\text{NH}_4^+$  withdrawal is intracellular acidification, the

"Ammonium pulse" technique

Fig. 1: Simplified theoretical basis for the procedure to modify pH<sub>i</sub> in the vascular preparation.

vasoconstriction and vasodilatation respectively induced by the above procedures could safely be attributed to intracellular acidification and alkalinization respectively.

Having established this fundamental phenomenon, I have investigated the effect upon it of a number of anion and cation substitutions, and of the applications of certain drugs. The background to these follow-up studies are discussed below.

#### Anionic Effects :

McLellan et al (1974), investigating the mechanisms of  $pH_0$  effects, set about investigating the effects of anions on  $pH_0$  sensitivity. A reduction of  $pH_0$  from 7.7 to 6.8 when benzene sulphonate ( $PhSO_3^-$ ), an effectively impermeant anion, replaced  $Cl^-$  resulted in a reduction of vascular tone only about 1/5th of that obtained in  $Cl^-$  Fig ( II ). Replacement of  $Cl^-$  by  $PhSO_3^-$  at a  $pH_0$  of 7.2 or less, raised the tone to about double its original value. - ie. to almost exactly the tone reached in the most alkaline  $Cl^-$  solution used.

When Casteels (1971) had exposed smooth muscle cells (guinea-pig taenia coli) to potassium-free solution he had observed a smaller increase in  $K^+$  efflux in  $PhSO_3^-$  than in  $Cl^-$ . He therefore proposed that  $Cl^-$  ions might actually facilitate the passage of  $K^+$  ions through membrane. If this mechanism operates in V.S.M, it requires only a small auxiliary hypothesis to provide an explanation of the  $Cl^-$ -dependance of tone found by McLellan et al. The extra

Fig. II: Paired arteries - pH sequence:  $\text{H}_2\text{PO}_4^-$  buffer.

hypothesis is that increased  $[H^+]_O$  promotes greater entry of  $Cl^-$  ions into the membrane and consequently greater  $K^+$  flux. Greater  $K^+$  flux will hyperpolarize the cells and reduce their tone. No such effect could operate in  $PhSO_3^-$ , for these ions are more or less excluded from the membrane. It is encouraging that Siegel (1982) has observed both hyperpolarization and decreased  $K^+$  efflux in acidified  $Cl^-$  media. Equivalent observations in  $PhSO_3^-$  have not been attempted.

Because of these indications of the involvement of permeant anions in the  $pH_O$  effect, I have investigated their possible involvement also in the effect of  $pH_i$  on tone, in the work to be reported below. The possibility that  $Cl^-$  fluxes themselves might be pH-sensitive has been checked too, by the use of the radioisotope,  $^{36}Cl$ .

### Cationic Effects :

The hypothesis just outlined leads in turn to the suggestion that  $[K^+]_O$  is likely to affect the  $pH_O$  response. And indeed Pickard et al (1975) showed that the  $pH_O$  effects on contractions of bovine middle cerebral arterial strips varied considerably with extracellular potassium concentration. Effects of  $[K^+]_O$  variation on the  $pH_i$  response are accordingly described later in the text.

The cation most directly involved in vascular tone-generation is

however  $\text{Ca}^{2+}$ , whose entry into the cell facilitates triggering of the contractile proteins.  $\text{Ca}^{2+}$  is also associated with depolarization. A decrease of external  $\text{Ca}^{2+}$  depolarizes V.S.M. cells and increases membrane resistance while an increase has the opposite effects (Casteels et al 1977 a and b).

However  $\text{Ca}^{2+}$  is sequestered in intracellular sites e.g. sarcoplasmic reticulum (S.R), mitochondria and the inner surface of the plasma membrane (Somlyo and Somlyo 1971; Somlyo et al 1974., Debbas et al 1975., Somlyo et al 1979). Mobilization of these stores of  $\text{Ca}^{2+}$  is more important in certain forms of excitation-contraction coupling than  $\text{Ca}^{2+}_o$  entry (Gabella 1971., Devine et al, 1972, 1973., Popescu and Diculescu, 1975) thus implying that extracellular  $\text{Ca}^{2+}$  is not necessarily required to evoke contraction (Bohr 1963., Keatinge 1966., Van Breeman and Seigel, 1980., Casteels and Droogmans, 1981), though it is necessary for full maintained tone. In particular, the main physiological agonist, noradrenaline, evokes an initial response about 2/3 as strong in  $0\text{-Ca}^{2+}$  as in normal- $\text{Ca}^{2+}$  medium (Van Breeman et al 1973-rabbit aorta) though sustained responses to NA, and almost the total response to elevated  $[\text{K}]^+_o$ , depend on external  $\text{Ca}^{2+}$ .

In the light of this evidence, a number of experiments on the effect of  $\text{Ca}^{2+}$  upon the responses to  $\text{pH}_i$ -variation will be described below.  $^{45}\text{Ca}$  flux studies have also been attempted.

The involvement of  $\text{Na}^+$  was investigated with a number of

experiments in which  $[\text{Na}]_o^+$  was substituted with lithium, choline and sucrose (sucrose in addition inevitably substituted  $\text{Cl}_o^-$ )

### pH<sub>i</sub> Regulation

Because it was generally assumed, at the turn of the century, that ions were distributed across the plasma membrane according to the Donnan equilibrium, the pH<sub>i</sub> regulation was also assumed to involve merely the redistribution of the ions. In contrast, however Fenn and Cobb (1934) and Fenn and Maurer (1935), obtained results in frog sartorius muscle which indicated that pH<sub>i</sub> was much higher than that predicted from K<sup>+</sup> distributions. They argued that K<sup>+</sup> was still in equilibrium across the plasma membrane but pH<sub>i</sub> was regulated by "some independent mechanism within the muscle ..... with a continuous supply of energy ..... in spite of the demands of membrane equilibrium". These views were substantiated by the pioneering microelectrode studies of Caldwell (1958), Spyropoulos (1960) and Kostyuk and Sorokina (1961). The possibility of active ion transport had been put forward by Hill (1955), when he proposed an H<sup>+</sup>-extruding mechanism similar to the Na<sup>+</sup> pump.

The central problem of pH<sub>i</sub> regulation however is that the neutralization of intracellular acid is derived from various sources (Roos and Boron 1981). In the short term, several reversible and rapidly responding mechanisms help to buffer acid loads. Some examples of these mechanisms are physico-chemical buffering,

cellular consumption of non-volatile acids and transfer of 'acid' or 'alkali' between the cytosol and cellular organelles. Broadly speaking, all three processes can be described as buffering mechanisms since they reversibly consume  $H^+$ .

The long-term mechanisms involve the cell's ability to extrude  $H^+$  and/or accumulate  $HCO_3^-$  or  $OH^-$ . However, direct ATP-dependent outward pumping of  $H^+$  is no longer the favoured mechanism. The true acid-extrusion mechanisms were identified by their ability to return  $pH_i$  towards normal (control) after an acute acid loading. All the methods of intracellular acid loading used to investigate the ionic mechanisms of acid extrusion of various cells have indicated three main mechanisms. Firstly, an exchange of  $H^+$  (efflux) for  $Na^+$  (influx) in mouse soleus muscle (Aickin and Thomas, 1977), proximal tubule cells (Boron and Boulpaep, 1980) and crayfish neurons (Moody J 1981); secondly a coupling of  $Na^+/HCO_3^-$  influx to the efflux of  $Cl^-$  and/or  $H^+$  (Thomas 1977) in squid axons, snail neurons, and barnacle muscle; and thirdly an exchange of  $Na^+$  influx for  $H^+$  efflux that runs in parallel with and coupled to the  $Cl^-$  efflux which occurs in exchange for  $HCO_3^-$  influx (Aickin and Thomas 1977; mouse soleus muscle).

Historically so far, the mechanisms of recovery from alkaline load have been less fully investigated. However animal cells do recover from alkaline loads even though there has been no published evidence of the presence of a specialized transport

mechanism which accumulates acid during alkaline load. One mechanism proposed by Ighoroje and Spurway (1985) is the bailing out of excess alkali by a  $\text{Cl}^-$  (influx) -  $\text{HCO}_3^-$  (efflux) exchange system in V.S.M. There have also been various other suggestions however, of involvement of passive ion fluxes (Aicken and Thomas 1977) or of metabolically produced acid (Boron et al 1979).

Many of the experiments already mentioned, involving anion or cation substitutions, have yielded information on the  $\text{pH}_i$ -recovery mechanisms also. Each switch of  $[\text{NH}_4^+]_0$  invokes a rapid tone-change followed by a gradual tone-recovery. Basically the effects of substitutions upon the rapid changes have been interpreted as giving information about the mechanisms by which  $\text{pH}_i$  affects tone. By contrast, the effects of substitutions upon the gradual recoveries have been interpreted as giving information about the mechanisms of  $\text{pH}_i$  adaptation after a disturbance. Only one ion not previously mentioned has been varied for the latter but not the former purpose: This ion is  $\text{HCO}_3^-$ , used as a partial substitute for  $\text{Cl}^-$

In addition, the effects of certain drugs known to affect ionic pumping,  $\text{Na}^+$ - $\text{H}^+$  (or  $2\text{Na}^+$ - $\text{Ca}^{2+}$ ) exchange, or  $\text{Cl}^-$  movements, have been studied.

### Summary of Objectives

The main objective of this thesis was to document the effects of  $\text{pH}_i$  on vascular tone, and to identify the mechanisms involved. However the observations of the effect on vascular tone due to the procedures of  $\text{pH}_i$  modifications led further to the investigation of the mechanisms involved in the adjustment of  $\text{pH}_i$  induced changes in tone and therefore  $\text{pH}_i$  regulation.

## CHAPTER 2

### MATERIALS and METHODS

Most of the experiments were carried out on the vascular beds of isolated rabbit ears perfused via the central artery. Some others were on complete rabbit hindlimbs. A few further experiments were carried out on whole frog preparations.

#### Ear Preparations :

Large New Zealand white rabbits, usually aged about 3 months and weighing between 2 and 4 kgs. were killed by a blow to the back of the neck. (In preliminary experiments, preparations from animals killed by barbiturate overdose had proved unresponsive to noradrenaline (N.A.). All animals were cage-reared and normal at the time of sacrifice except for those that were chemically sympathectomised. These latter group of animals were about five months old at death and had been given six injections of 6-OH-dopamine hydrobromide (Sigma) over the preceding six weeks period. The first two doses given were 42mg/kg body weight, with subsequent doses of 75mg/kg body weight (Fronck, 1980).

The ears were removed from all animals immediately after death. The subsequent dissection of the ears involved the removal of the skin on the dorsal (vascular) surface as far as was possible - usually from about the proximal 2/3 of the length. The remaining skin was then opened over the central artery (to which it adheres much less strongly than it does to the underlying cartilage) and the

edges of the ears were trimmed just peripherally to the lateral veins. These last steps were taken to minimize oedematous build-up under the skin left in place. The proximal ends of the central arteries were then cannulated using flexible (Portex) cannulae. Usually cannulae of 1.4mm outer diameter (Pink cannulae) were used, cut obliquely with a sharp scalpel to about 100mm length. To aid both the identification and cannulation of the central arteries; the blood was left in them until dissection and cannulation were completed. Only then was it washed away with a syringe of Ringer's solution. This initial washing out with Ringer's solution provided a visual check that the main outflow was from the veins. Once a cannula had passed this test it was tied in place with two ligatures, one around the artery and one through the underlying cartilage. The ears (usually both members of a pair for one experiment) were then mounted one on each side of a twin perfusion system which will be described later in the text.

### The Hindlimb Preparation

While all the investigations of the mechanism of pH effects were carried out using the ear preparations just described, the generality of their occurrence (especially that of the responses to  $\text{pH}_i$  changes) was tested using complete rabbit hindlimbs perfused via the femoral arteries, and draining from the vena cava. As soon as possible after the animal's death a small incision was made to expose the femoral artery in the upper thigh. The artery was then cannulated using two ligatures to hold the cannula in place. The

cannula was then mounted on to the perfusion system. As the heart had in all cases been taken by another experimenter, a drainage route was already available.

### The Frog Preparation

A pithed frog preparation was used. The frog was placed in a supine position and tied firmly onto the dissecting board by strings attached to its limbs. An incision was made through the thoracic cage above the heart to expose it. Another small incision was then made through the ventricular wall close to the right atrium. The cannula was then inserted and directed into the aorta and held in place by two ligatures. Perfusion was therefore via aorta, through the complete vascular system, and out through the cut wall of the heart beside the inflow cannula.

### The Perfusion Apparatus

For both ear artery and whole hindlimb preparations there was a pair of matched but separate perfusion circuits which allowed independent but simultaneous perfusion of both ears/hindlimbs respectively.

The perfusion circuit as illustrated in Fig III consisted mainly of:

(1) A set of flasks containing physiological solutions and a multiway tap system from which the desired solutions could be drawn.

(2) A Watson Marlow 502 peristaltic 'constant flow' pump, adjusted to give the desired flow rate (see below) in each of two tubes placed in parallel, side by side within the pump. With the

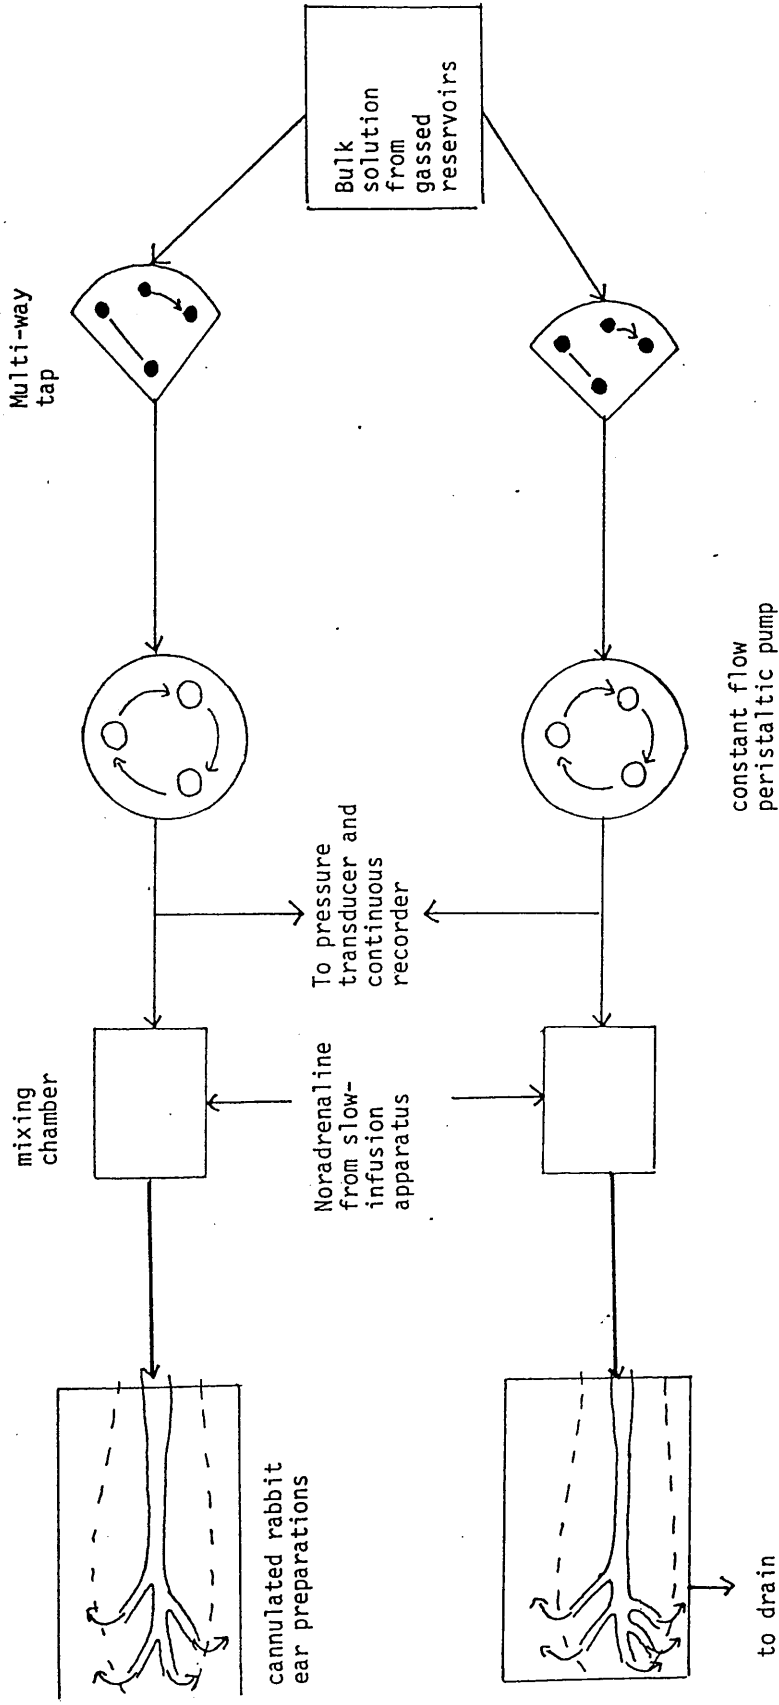

Fig. III: Perfusion circuit.  
 A pair of matched but separate perfusion circuits which allows independent but simultaneous perfusion of a pair of ears or hindlimbs.

range of tubings used, the desired flow-rate for rabbit preparations was always attained at pump r.p.m.s in the range 40-50% maximum.

(3) The cannulae were connected to the Watson- Marlow pump outflows via Elcomatic Em 751 pressure transducers.

(4) The two parallel outlets of a 'Palmer' slow infusion pump (through which NA was introduced) were attached in addition. The outlets from the slow infusion pump were immediately upstream from the cannulae to ensure that there was no time for significant oxidation of NA (even in alkaline media).

(5) Input (perfusion) pressures indicating changes in tone were continuously recorded on twin channel pen recorders (Devices, Linseis or Speedomax) via bridge amplifiers. The pen recorders were calibrated with a mercury manometer at the start or end of each experiment. A one minute time delay due to the tube system occurred between the selection of a new experimental solution and the beginning of biological response to it.

### The Flow Rates

After a few preliminary experiments, the flow rate of the bulk perfusate was chosen to give an initial pressure (i.e. before the introduction of NA approximately 30-45 mmHg above that caused by cannula resistance. The rate which produced this result in the majority of preparations was 7mls per minute. The flow rate of NA from the slow infusion pump was generally approximately 0.1ml/min. although this was adjusted frequently to give adequate vascular resistance - usually 2.5-4× initial vascular resistance, but

up to a peak of about twice this during determinations of dose-response patterns. A problem which commonly arose especially in very strongly activated preparations, and/or with the higher bulk flow rates, was that of sinusoidal pressure oscillations of periodicity 25-40 seconds. Usually this was tackled by turning NA perfusion-rate down again. The concentration of NA in the reservoir syringe of the slow infusion pump was calculated using the main flow rate, the anticipated infusion rate and the desired concentration value i.e.

$$\text{Syringe conc.} = \frac{\text{mainflow rate} \times \text{desired conc.}}{\text{syringe flow rate}}$$

#### Modifications to the Perfusion Circuit

Most of the perfusion experiments were carried out at room temperature (19-22°C) with the upper surfaces of the preparations exposed to the air and superfused by the perfusate flowing out from the cut ends of the veins.

However, there were some modifications in experiments carried out to investigate the effects of temperature and of CO<sub>2</sub> and O<sub>2</sub> tensions. The ears were trimmed laterally to about half their usual widths to fit into 30mls organ baths. Each cannulated ear was pinned onto the lower end of a specially trimmed cork mat attached to the outer rim of the organ bath. Each cannula was then connected to a pressure transducer firmly attached to the upper end of the cork mat, (Fig 1V). Bath temperature (37°C) was controlled by a water jacket, supplied from a bath thermostatically

- |       |   |                          |

Fig. IV: Modification to the perfusion circuit. 30ml organ bath with cork mats attached to the outer rim onto which the ears are pinned.

regulated to 39<sup>o</sup>c or a little higher to allow for loss of heat from the connecting tube system. The temperature of both organ and water baths were constantly monitored by means of attached thermometers. The perfusion solutions were contained in beakers placed in the water bath. The gases (100% O<sub>2</sub> and N<sub>2</sub>; 95% O<sub>2</sub>/5% CO<sub>2</sub>) were bubbled through sintered glass plugs at the base of the organ baths. For every change of perfusion solution, the organ baths were rinsed out and filled with the new perfusing solution, so that it bathed the blood vessels as well as flowing through their lumens.

### Solutions

The control Ringer's solution contained 140mM Na Cl, 6mM KCl, 2.5mM Ca Cl<sub>2</sub> (except as below), 1mM Mg Cl<sub>2</sub> and 10mM glucose; It was buffered with 3mM phosphate to pH7.2 and gassed with 100% O<sub>2</sub>. For studies of the effects of pH<sub>o</sub> variations, the acid and alkaline pH<sub>o</sub>'s used were 6.7 and 7.7 respectively. In any series of experiments where the pH<sub>o</sub> variations would include the alkaline pH<sub>o</sub> the concentration of Ca Cl<sub>2</sub> was reduced to 1.5mM, to prevent the precipitation of calcium phosphate in the alkaline media. Alternatively in some series of experiments HEPES buffer was used (see below) to avoid the whole problem.

### P.V.P. [Polyvinylpyrrolidone, (Sigma)]

In the whole frog and rabbit hindlimb preparations, 20 and 40g/l of PVP respectively were added to all solutions to reduce oedema.

### NH<sub>4</sub><sup>+</sup> and CO<sub>2</sub> Solutions

For pH<sub>i</sub> modifications, the main solutions contained 30mM NH<sub>4</sub> Cl isosmotically replacing Na Cl. In pilot experiments carried out to investigate the maximal NH<sub>4</sub><sup>+</sup> effects 5,10,15,20 and 30mM of NH<sub>4</sub><sup>+</sup> had been used and 30mM was found to provide a just-supramaximal challenge. An alternative way in which pH<sub>i</sub> was modified in a short series of experiments was the use of HCO<sub>3</sub><sup>-</sup> (6.75,12.5 and 25mM) buffered mammalian krebs solution, gassed with CO<sub>2</sub> (1.75, 2.5 and 5%) in O<sub>2</sub>.

### Buffers

To investigate the effect of buffering power on pH<sub>i</sub> changes without necessarily changing or affecting calcium activity Hepes [0.5, 1.0, 3.0, 5 and 10mM] was used. Hepes was also used in some experiments designed to investigate the effects of varying calcium levels (0-10mM) on base tone, and on the changes in tone due to pH<sub>i</sub> modifications. Hepes was introduced as the Na<sup>+</sup> salt, except where it was used in Na<sup>+</sup> free Ringer's (see below): in that case it

was the acid (N-2-Hydroxyethylpiperazine-N<sup>1</sup>-2 ethanesulfonic acid) that was used (Sigma). Tris [Trizma base; (Sigma)] and  $\text{KH}_2\text{PO}_4$  were also used on a small numbers of occasions.

#### Anionic Substitutions :

The bulk anion  $\text{Cl}^-$  was replaced isosmotically with benzene sulph<sup>on</sup>ate ( $\text{PhSO}_3^-$ ) in all experiments designed to investigate the role of  $\text{Cl}^-$  in the modifications of vascular tone, whether by  $\text{pH}_0$  or by  $\text{pH}_1$  changes. The  $\text{NH}_4^+$ ,  $\text{Mg}^{2+}$  and  $\text{Ca}^{2+}$  salts of  $\text{PhSO}_3^-$  were not available, therefore  $(\text{NH}_4)_2 \text{SO}_4$  (15mM),  $\text{Mg AC}_2$  (1mM) and  $\text{Ca AC}_2$  (2.5mM) replaced  $\text{NH}_4 \text{Cl}$ ,  $\text{Mg Cl}_2$  and  $\text{Ca Cl}_2$  respectively. Control experiments to check the effect, if any, of  $\text{SO}_4^{+}$  were amongst the pilot experiments carried out. In these control experiments 15mM  $\text{Na}_2 \text{SO}_4$  instead of 15mM  $(\text{NH}_4)_2 \text{SO}_4$  replaced the osmotic equivalent of  $\text{NaPhSO}_3$ . Perfused blood vessels gave no detectable response to this change.

#### Cationic Substitutions :

In sodium substitution experiments  $\text{NaCl}$  was totally and isosmotically replaced by one of choline chloride, lithium chloride or sucrose and 3mM  $\text{KH}_2\text{PO}_4$  replaced  $\text{NaH}_2\text{PO}_4$  as buffer. For potassium-stimulated preparations  $\text{KCl}$  (50mM or 140mM) isosmotically replaced  $\text{NaCl}$  and NA was not infused. Lower

potassium concentrations (2,6,12,30mM) in addition to the above were employed with normal amounts of NA in the investigations of  $K^+$  effect on vascular tone and its  $pH_i$  responses.

$K^+$ -free solutions were prepared by the omission of KCl and equimolar replacement with NaCl.

$Ca^{2+}$ -free solutions were also prepared by the omission of  $CaCl_2$  and equimolar replacement with NaCl.

### Drug Solutions

All drug solutions were prepared by the addition to the experimental (Ringer's and  $NH_4^+$ ) solutions of the required volumes of the drugs, from stock solutions prepared as below.

#### Noradrenaline [NA, Arterenol bitartrate (Sigma)]

Stock solutions of  $10^{-3}M$  noradrenaline, with  $2 \cdot 10^{-5}M$  E.D.T.A to prevent oxidation, were prepared with distilled water and stored in a freezer. Dilutions were made with the Ringer's solution ( $Cl^-$  or  $PhSO_3^-$ ) appropriate to the respective experiments, to the appropriate syringe concentration to produce a final dilution in the perfusate usually between  $10^{-7}M$ - $10^{-6}M$ . The  $10^{-3}M$  stock solutions were prepared with distilled water and not Ringer's because of the several ionic variations required for different experiments.

#### S.I.TS [4-acetamido-4-isothiocyno stilbene-2,2<sup>1</sup>-Disulphonic Acid]

This anion-flux inhibitor was kept as molar stock [Sigma], which

was diluted to  $10^{-5}\text{M}$  in the physiological salines.

MeB ( $5 \cdot 10^{-4}\text{M}$ ); Hb ( $10^{-5}$ - $10^{-4}\text{M}$ ) and Ach ( $10^{-6}\text{M}$ )

The possible involvement of endothelium derived relaxing factor (E.D.R.F) on the vasodilatory effect of  $\text{NH}_4^+$  was investigated by the use of both methylene blue (MeB) and haemoglobin (Hb). Both MeB (G.T. Gurr) and Hb were diluted from prepared  $10^{-3}\text{M}$  stock solutions (in Ringer's) with both  $\text{NH}_4^+$  and Ringer solutions. As a third method of suppression of E.D.R.F release 20-40 seconds prepulses of distilled water were used to shock the endothelium. Acetylcholine [(Ach) Sigma] was also diluted from prepared  $10^{-3}\text{M}$  stock solutions with normal Ringer's and used to determine the degree of E.D.R.F inhibition achieved by each of the three interventions.

Oubain [Strophanthin: Sigma]

Ouabain ( $10^{-4}$ - $10^{-7}\text{M}$ ) was added to both the basic and  $\text{NH}_4^+$  solutions to investigate the involvement of the  $\text{Na}^+$  pump in  $\text{pH}_i$  homeostasis. Concentrations of  $10^{-3}$  to  $10^{-8}\text{M}$  in Ringer's were used to investigate the dose-dependence of its effects on mean-tone.

Amiloride and its Derivatives

Amiloride and seven of its derivatives were dissolved either by:

- (1) Dissolving a weighed sample in a small amount of water, warming and stirring.

or

(2) Suspending a weighed sample in a little amount of water and adding a slight excess of molar equivalent of isethionic acid and a little dimethyl sulphoxide (DMSO) warming and stirring.

Table A is a list of each drug and its mode of dissolution and accepted major category of ion transport inhibition. Final concentrations ( $10^{-3}\text{M}$ - $10^{-7}\text{M}$ ) were obtained by dissolution in the Ringer's solutions.

#### CN<sup>-</sup>/F<sup>-</sup>

Conveniently included in this subsection is the fact that 3mM NaCN and 1mM NaF were added to both the control and  $\text{NH}_4^+$  Ringer's in experiments to investigate the effects of metabolic inhibition on vascular tone and  $\text{pH}_i$ -responses. Both solutions were bubbled with 100%  $\text{N}_2$ .

#### Osmotic Equivalents :

Using published osmotic coefficients (Robinson G Stokes, 1957) together with a value of 0.96 for the osmotic coefficient of 0.1M  $\text{NaPhSO}_3$  obtained by freezing point depression measurements in this laboratory (Spurway unpublished), the osmotic equivalents of all the salts used to displace NaCl were estimated. Simple millimolar equivalent were not used e.g to introduce  $(\text{NH}_4)_2 \text{SO}_4$  its molarity was multiplied by 1.3 to get

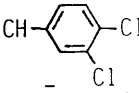

Symbol	Method of dissolution as above	Major ion transport inhibitor	X	Y	HQ
A	2	Na <sup>+</sup> - channel	F <sup>-</sup>	H <sub>2</sub> N-	3/2 H <sub>2</sub> O
B	2	Na <sup>+</sup> /H <sup>+</sup> antiport	Cl <sup>-</sup>	$\begin{array}{c} \text{C}_2\text{H}_5 \\ \diagdown \\ \text{N}^- \\ \diagup \\ (\text{CH}_3)_2\text{CH} \end{array}$	-
C	2	Na <sup>+</sup> /H <sup>+</sup> antiport and Na <sup>+</sup> /Ca <sup>2+</sup> exchange	Cl <sup>-</sup>	[CH <sub>3</sub> (CH <sub>2</sub> ) <sub>4</sub> ] <sub>2</sub> N <sup>-</sup>	-

equivalent NaCl molarity so that for 15mM  $(\text{NH}_4)_2 \text{SO}_4$  19.5mM NaCl was omitted.

### pH<sub>0</sub> Measurements

The pH<sub>0</sub>'s of all the solutions were checked with an 'Analytical measurements' pH meter which was itself calibrated prior to the start of each experiment with standard buffers. The pH<sub>0</sub>'s of the experimental solutions were adjusted using 5N-0.2N of NaOH, (KOH in Na<sup>+</sup>-free media), and HCl (acetic acid in Cl<sup>-</sup>-free media).

### Analysis of Traces

There are two ways of quantifying arterial- wall tone changes from pressure traces. These are:

(1) The ratio of amplitudes before and during experimental conditions.

This method is liable to distortions caused by bubbles and by "bounce" in the tubes.

(2) The ratio of mean displacement from base line (base line is the mean perfusion pressure with only a cannula being perfused).

This is a more reliable procedure and has been mainly applied in my measurements. Relative pressure values  $Q$  which are independent of the resistances of individual preparations, were calculated using the equation, (Fig 1V).

$$Q = \frac{D_e - D_c}{D_s - D_c}$$

$D_e$  = Mean experimental displacement from zero

$D_s$  = Mean control displacement from zero

$D_c$  = Mean displacement due to cannula from zero

$D_s$  for tone changes due to  $pH_i$  modifications was mean displacement during the 1-2 minutes immediately before  $NH_4^+/CO_2$  application.

$D_s$  for tone changes due to  $pH_o$  modification was the mean of displacement in the last  $pH-7.2$  period before and the first one after the test-period.

$Q$  values therefore are greater than one when experimental intervention produces an increase in tone and less than one when there was a decrease.

The  $Q$  values used for each of the parameters above were obtained using a computer programme which also converted the displacements to mmHg.

### $pH_i$

The parameters ( $D_s$  and at least five  $D_e$  values) measured, to characterize the response to each  $pH_i$  change, were mean displacements during:

- (a) The 1-2min pre- $NH_4^+$  period.
- (b) The maximum  $NH_4^+$  effect (usually occurring within 1-2mins of application).

- (c) The 1/2min just before  $\text{NH}_4^+$  withdrawal - this was 5mins after application in all experiments other than those specifically designed to investigate long-duration  $\text{NH}_4^+$  pulses.
- (d) The maximum effect due to  $\text{NH}_4^+$  withdrawal (usually occurring within 2-3mins of washout).
- (e) 5 and 10mins into washout in all experiments and 15,20mins also in a series of experiments to determine time dependent variations.

### pH<sub>0</sub>

The equivalent measurement for pH<sub>0</sub> changes were simply the maximum displacements got in 6.7 and 7.7. (Note that these solutions were never left perfusing for more than 5-10mins in experiments of this type).

### Mean / Base Tone

The tone changes directly due to the application of drugs were the maximum displacement obtained. On the other hand, effects of the drug on responses to pH<sub>i</sub>-change were characterized in the same way as those of all other pH<sub>i</sub>- changes, with the last 2 minutes in the drug-containing Ringer's taken as control.

### Calibration, Data

In all complete experiments the following parameters were also measured once.

- (1) The mean displacement due to cannula resistance (Dc) and  
(ii) A set of calibration values expressing the sensitivity of the recording pen in terms of mmHg.

### Graphical Representations :

Most of the results have been graphically represented, all showing the mean effects from many experiments pooled together with standard error bars. In all graphs pressure has been expressed relative to the mean standard value in the particular medium - the 'reference' value. Asterisks indicate tones significantly different from the reference value (paired t-test) or from control experiments (unpaired t-test) \*\* P<0.01; \* P<0.05; S P<0.10; NS not significant.

Recovery rates from both alkaline-induced relaxation and acid-induced constriction in the various drugs are expressed as percentage of the equivalent rates in control, (7.2 control Ringer's/NH<sub>4</sub><sup>+</sup>) situations. These percentages are calculated from

$$100 \times \left( \frac{t_{rb}}{t_{ra}} - 1 \right)$$

where  $t_{rb}$  and  $t_{ra}$  are projected recovery times (i.e. times for tone to return to unity) for experimental and control situations respectively.

Others represented in Table (E) were calculated from projected recovery times for individual experiments.

### Flux Experiments

In order to investigate the role of both  $\text{Cl}^-$  and  $\text{Ca}^{2+}$  in pH modifications of vascular tone, the following flux studies were carried out.

- (1)  $^{36}\text{Cl}$  efflux.
- (2)  $^{45}\text{Ca}$  efflux and uptake.

All the studies were done with mixed arterial preparations of the rabbit. They included, the ear, carotid, branchial and femoral arteries and aorta (both thoracic and abdominal). Both  $^{36}\text{Cl}$  (as NaCl solution) and  $^{45}\text{Ca}$  (as  $\text{CaCl}_2$  solution) were supplied by Amersham.

### The General Protocol

- (1) The arteries were dissected out from the rabbit and cleared carefully of all connective tissue which was not an integral part of the adventitia, in 7.2 Ringer's solution.
- (2) They were mounted on stainless steel holders and equilibrated in normal Ringer (7.2) for about 90mins.
- (3) They were then loaded in the required load solution (either  $^{36}\text{Cl}$  or  $^{45}\text{Ca}$ ) as specified below.

All experiments were carried out at room temperature. Some preparations were activated with NA ( $10^{-6}\text{M}$ ) or high  $\text{K}^+$  (140mM) whilst the rest (all for which no specific reference to activation is made below) were non-activated. For efflux studies activation was begun in the first wash solution and maintained throughout the efflux process while for uptake ( $^{45}\text{Ca}$ ) activation took place in the load solutions only.

### $^{36}\text{Cl}$ Efflux

The design of the experiments was to reveal variations in relative  $^{36}\text{Cl}$  efflux due to the pH changes. Loading was for 90mins after which tissues were washed out into test tubes (5ml) filled with equal volumes of the required unlabelled medium.

### $^{36}\text{Cl}$ Load Solution :

2.5mls of 7.2 Ringer's solution was labelled with 0.25ml of isotonic Na  $^{36}\text{Cl}$ .  $^{36}\text{Cl}$  was 9% of total  $\text{Cl}^-$  in load solution resulting in the activity of the load solution being  $2.5\mu\text{Ci/ml}$ .

### Unlabelled solutions :

For studies of  $\text{pH}_i$  effects 2.5ml aliquots of normal and of  $\text{NH}_4^+$  Ringer's were dispensed into 5ml test tubes arranged in appropriate order in test tube racks. After loading, tissues were placed for 1min in a tube of inactive Ringer's solution to rinse  $^{36}\text{Cl}$  from the tissue surfaces. They then began a progression through a series of tubes, spending 1min in each of the first 3 test tubes, 3mins in each of the next 4 while the ECS was being cleared and 1min in every tube thereafter for at least the next 45mins. This protocol ensured good time-resolution, while avoiding variations of sample-duration during the periods of physiological interest. (Preliminary experiments had revealed that, if durations were varied, disproportionally high count-rates were obtained from short-duration sample tubes; almost certainly isotope was squeezed out of the E.C.S. by meniscus and/or tube-edge effects, each time the tissues were moved from one tube to the next. In the

commonest design of experiments Table ( B ) 6 tubes of Ringer's were followed by 3 of 30mM  $\text{NH}_4^+\text{Cl}$  solution and those by 6 more of Ringer's; the  $\text{NH}_4^+$ /Ringer's cycle would then be repeated two or three times more. As an alternative to this series of short  $\text{NH}_4^+$  pulses, a single long  $\text{NH}_4^+$  pulse lasting 15mins would be studied; in these cases washout in  $\text{NH}_4^+$  Ringer was 15minutes followed by 25mins in normal Ringer's.

For studies both of  $\text{pH}_0$  and of  $\text{K}^+$  effects on  $^{36}\text{Cl}$  efflux, (which, on the basis of tone-changes, were thought unlikely to be as rapid as the  $\text{pH}_1$  effects) the duration of washout was 1min each in the first 3 test tubes and 3mins each in all subsequent ones. The total period in each experiment medium lasted 15mins (five test tubes). In control Ringer's before and after the test solution, the period was 20mins, (Table B).

After washout, in all the above experiments the tissue were left overnight in 2.5ml of normal HCl in order to release all radioactive  $^{36}\text{Cl}$  still present in the tissue. Aliquots of all the tubes except tube 1 were then put into vials preloaded with identical volumes of Ecoscint (an ecologically responsible scintillation solution) and counted in a Hewlett-Packard 'Tricarb' liquid scintillation counter. The aliquot in the last tube was neutralized with 5N-NaOH before being added to the Ecoscint.

#### Counting and Analysis

Each vial was counted 3 or 4 times, and counted with a back-

- (i)  $\text{NH}_4^+$  effects - washout was in  $\text{H}_2\text{PO}_4^-$  - buffered normal and  $\text{NH}_4^+$  Ringer's  $\text{pH}_0$  7.2  
(ii)  $\text{pH}_0$  or  $\text{K}^+$  effects - washout was in  $\text{H}_2\text{PO}_4^-$  - buffered normal Ringer's,  $\text{pH}_0$  7.2, 6.7 and 7.7 for  $\text{pH}_0$  effects and 6K<sup>+</sup>, 0K<sup>+</sup> and 140K<sup>+</sup> for  $\text{K}^+$  - effects.

ground count which had been determined by counting similar volumes of unlabelled Ringer or HCl. Then mean counts obtained were fed into the computer and a special programme calculated the efflux, content and rate quotients. These final results are illustrated graphically by efflux and content curves together with a plot of the rate quotients.

### $^{45}\text{Ca}$ Efflux

The protocol for  $^{45}\text{Ca}$  efflux was similar to that for  $^{36}\text{Cl}$  except that, due to the very high level of activity (2 $\mu\text{Ci/ml}$ ) obtained with  $^{45}\text{Ca}$  the arterial mass was greatly reduced. Individual experiments were carried out separately with aortic strips in addition to those with mixed arterial preparations. The final content (total radioactivity) was obtained by displacing  $^{45}\text{Ca}$  from the tissues using 5 parts of  $\text{HNO}_3$  (specific gravity 1.42) to 1 part of  $\text{HClO}_4$  (Sp. Gr. 1.54).

### $^{45}\text{Ca}$ Uptake During $\text{pH}_i$ Modifications of Tone

There were three  $^{45}\text{Ca}$ -labelled load solutions. These were, two normal Ringer's (specifically allocated to pre- and post- $\text{NH}_4^+$  uptakes, respectively) and one 30mM- $\text{NH}_4^+$ /Ringer's solution. A set of experiments was carried out after equilibration in O- $\text{Ca}^{2+}$  solution and another set after equilibration in normal Ringer's for 90 mins.

After the tissues were dissected and cleared free from all

connective tissues, they were mounted on stainless steel holders and grouped into 3 main categories. The first and second categories were equilibrated in inactive Ringer's and then  $^{45}\text{Ca}$  was loaded in the pre  $\text{NH}_4^+$  and  $\text{NH}_4^+$  load solutions. The third was equilibrated in unlabelled  $\text{NH}_4^+$  solution (sometimes for 5mins) and then  $^{45}\text{Ca}$  loaded in the post- $\text{NH}_4^+$  load solution. The duration of loading for the majority of experiments was 3mins in each case. In a few experiments duration of loading was 10mins (3mins was chosen as the commoner period because, in the majority of perfusion studies, peak  $\text{NH}_4^+$  dilatations or washout constrictions were obtained within 3mins of  $\text{NH}_4^+$  application or washout), (Table C).

The tissues were blotted lightly and left overnight to dry out. They were then weighed and digested with  $\text{HNO}_3/\text{HClO}_4$ . The digests were thereafter neutralized with 5-N NaOH, put in vials preloaded with identical volumes (10mls) of Ecoscint and counted in the Tricarb. The activities of the load solutions were also estimated: this was done by extracting 0.05ml sample volume from each load-tube, making up to 2.5mls with Ringer's and counting in 10mls of Ecoscint. Each vial was counted four times and the mean counts per minute (cpm) for each arterial mass was calculated.

The relative  $^{45}\text{Ca}$  uptake in pre- $\text{NH}_4^+$ ,  $\text{NH}_4^+$ , and post- $\text{NH}_4^+$  phase was obtained by dividing the specimen cpm by the product of the dry weight and the cpm of the individual load solutions.

Table C

Typical protocol employed for  $^{45}\text{Ca}$  uptake experiments;  $\text{NH}_4^+$  effects

	Pre- $\text{NH}_4^+$ Ringer's	$\text{NH}_4^+$ Ringer's	Post- $\text{NH}_4^+$ Ringer's
Unlabelled $\text{Ca}$ Equilibration medium Duration	Normal Ringer's 90 mins	$\text{NH}_4^+$ Ringer's	$\text{NH}_4^+$ Ringer's 5 mins
$^{45}\text{Ca}$ Load solution Duration	Normal Ringer's	$\text{NH}_4^+$ Ringer's	Normal Ringer's
	3 mins		

Thus

$$\text{Relative } ^{45}\text{Ca uptake (Q)} = \frac{\text{cpm in muscle}}{\text{dry weight} \times \text{cpm of load solution}}$$

## RESULTS

The results will be presented under three main parts. The first part will deal with the primary effects of  $\text{pH}_i$  change on vascular tone. The second part will deal with the regulation of  $\text{pH}_i$  by VSM including the influences of ions and drugs on this regulation. The third part concerns ion ( $\text{Ca}^{2+}$  and  $\text{Cl}^-$ ) fluxes.

### PART 1

#### Response to $\text{pH}_i$

The 'Basic'  $\text{NH}_4^+$  Effect in  $\text{H}_2\text{PO}_4^-$  - Buffered Chloride Ringer's.

pH 7.2

#### Noradrenaline Activation of Rabbit Ear Preparation

Noradrenaline 'biphasically' constricted the preparation. The first phase was transient usually lasting between 40-60 secs. while the second phase was slow and sustained usually peaking within 15mins, and levelling off thereafter. Fig (1A). Noradrenaline dose-dependently raised resting tone at a constant  $\text{pH}_0$  in normal phosphate-buffered ringer. Fig 1B is a log-conc/tone curve of maximum noradrenaline effect during the second phase in pH7.2, phosphate buffered  $\text{Cl}^-$  Ringer. All subsequent work with noradrenaline was done in the concentration range  $10^{-7}$  -  $10^{-6}\text{M}$  and most of it in  $3-6 \times 10^{-7}\text{M}$ .

#### $\text{NH}_4^+$ Effects on NA Activated Preparation

When  $\text{NH}_4\text{Cl}$ - containing solution perfused the N.A activated ear, tone started to fall very rapidly just a few seconds after  $\text{NH}_4^+$

Fig. 1A and B: NA activation of rabbit ear artery. A is a typical trace showing biphasic response to NA ( $\approx 10^{-6}$ M) in  $\text{Cl}^-/\text{H}_2\text{PO}_4^-$ ,  $\text{pH}_\text{O}$  6.7 medium - an initial transient phase lasting between 40-60 secs., and a more sustained contraction which followed (compare fig. 13B). B is a log-conc./tone curve of maximum NA effects during the sustained contraction phase in  $\text{Cl}^-/\text{H}_2\text{PO}_4^-$  medium  $\text{pH}_\text{O}$  7.2. Note the dose-dependent increase in tone. Here and in all subsequent illustrations, error bars indicate  $\pm$  S.E.M.

reached it. The maximum  $\text{NH}_4^+$  effect (i.e. maximum dilatation due to  $\text{NH}_4^+$  application) was usually attained within the first or second minute after which tone gradually recovered back towards control tone (Fig 2A). The magnitude of the  $\text{NH}_4^+$  dilatation was concentration - dependent over the range of 0-20mM  $\text{NH}_4\text{Cl}$ ., 25mM and 30mM gave virtually indistinguishable effects, only slightly greater than those of 20mM. These were taken as maximum dilator effects, and 30mM -  $\text{NH}_4\text{Cl}$  was chosen for all experiments subsequently described in this Thesis. Unless otherwise stated it was left perfusing for 5 minutes.

When  $\text{NH}_4^+$  was withdrawn from the perfusing solution, i.e. when normal Ringer's was reintroduced, tone immediately rose. This increase in tone, which was somewhat less rapid than the initial  $\text{NH}_4^+$  - induced decrease in tone, was followed by a recovery back towards control tone. Peak  $\text{NH}_4^+$  - withdrawal tone was usually attained within the first three minutes of withdrawing  $\text{NH}_4^+$  and was in this medium, always higher than control tone. From this peak, recovery or adaptation of tone back towards control level (from which it sometimes continued on to fall below it) took typically the next four to eight minutes; i.e. this adaptation of tone was considerably faster than recovery after  $\text{NH}_4^+$  -induced relaxation.

Provided the control, tone was not less than three times that in the unstimulated preparation, peak dilatation was consistently to

PROCEDURE TO RAISE  $pH_I$  DECREASES TONE

## AMMONIUM EFFECT ON ARTERIAL TONE (RABBIT)

Fig. 2A and B: Basic  $NH_4^+$  effect on arterial tone. A is a typical trace ( $Cl^-/H_2PO_4^-$   $pH_O$  7.2) showing a decrease in tone produced by 30mM  $NH_4Cl$  and an increase in tone on it's washout. B is the graphical representation of a series of 45 experiments on normally activated ears pooled together. The shaded portion represent the  $NH_4^+$  dilatation and the unshaded portions the pre- and post  $NH_4^+$  phases. The asterisks indicate the level of significance of any difference from the pre- $NH_4^+$  reference tone.

In all plots, differences from 1: \* $P < 0.005$  \*\* $P < 0.01$

between 40-60% of control tone while peak constriction was more variable but typically to about 150% of control. In lower noradrenaline concentrations the relative amplitude of the  $\text{NH}_4^+$  dilatation was less and that of the washout constriction greater.

Fig (2B) is a graphical representation of a series of 45 experiments on normally - activated ears pooled together, to illustrate the basic  $\text{NH}_4^+$  effect in phosphate buffered, pH 7.2 medium. The shaded portion indicates the period when  $\text{NH}_4^+$  perfused the preparation and the unshaded portions, the prior and subsequent Ringer - perfusion phases. Both  $\text{NH}_4^+$  - dilatation and washout constriction were very highly significant ( $P < 0.01$ ).

When  $\text{NH}_4^+$  was left perfusing for 20 mins. or more, tone recovered back towards control level and often overshoot.

### Results at 37°C

When  $\text{NH}_4^+$  was applied and washed out at 37°C the magnitude of the  $\text{NH}_4^+$  dilatation was not significantly different from that at room temperature. Tone however recovered quite rapidly and overshoot control tone even during the 5 mins. when  $\text{NH}_4^+$  was still present. On washout there was further constriction (larger than that at room temperature) followed by a rapid recovery towards control tone. This recovery did not overshoot reference tone even after 10 mins. of washout (cf Fig 18).

### K<sup>+</sup> - Activated Ear - Preparation

When the ears were perfused with 50mM or 140mM solutions, the 'basic' responses to NH<sub>4</sub><sup>+</sup> application and withdrawal were still obtained. When K<sup>+</sup> was being perfused in the continuing presence of NA, NH<sub>4</sub><sup>+</sup> dilatation was even greater than NA alone, but washout constriction was diminished (Fig 3). Reciprocally, when NA was withheld (so that K<sup>+</sup> elevation was providing the sole background tone) the NH<sub>4</sub><sup>+</sup> dilatation was reduced, recovery from the dilatation occurred very rapidly, and on subsequent washout a high peak constriction was obtained.

### The Non - Activated Ear Preparation

In unstimulated ears (i.e. no NA and normal K<sup>+</sup>), the NH<sub>4</sub><sup>+</sup> induced dilatation was greatly reduced in amplitude. It was followed by a rebound constriction even whilst NH<sub>4</sub><sup>+</sup> was still present. Further constriction on washout was only slight, though significant at the level P<0.05. After constriction, tone adapted back towards control tone in the normal way (Fig 4).

### Results in Other Buffers, pH 7.2 at Room Temperature.

When phosphate buffer was replaced by Hepes buffer in solutions perfusing NA - activated ears, the basic effects due to NH<sub>4</sub><sup>+</sup> application and washout were obtained as above, but there were secondary differences. The most marked difference statistically was that in normal (2.5mM) Ca<sup>2+</sup>, the NH<sub>4</sub><sup>+</sup> dilatation

Fig 3: Graphs of pooled results, showing basic NH<sub>4</sub><sup>+</sup> effects in 50-K<sup>+</sup> activated preparations, both in the presence and absence of 5 x 10<sup>-7</sup> M NA and in control (6-K<sup>+</sup>) NA activated preparations, (same data as Fig. 2) NH<sub>4</sub><sup>+</sup> dilatation was least when activation was by 50-K<sup>+</sup> only and most when 50-K<sup>+</sup> continuously perfused the preparation in the presence of NA. The washout constriction was biggest in 50-K<sup>+</sup> only and least in 50-K<sup>+</sup> + NA.

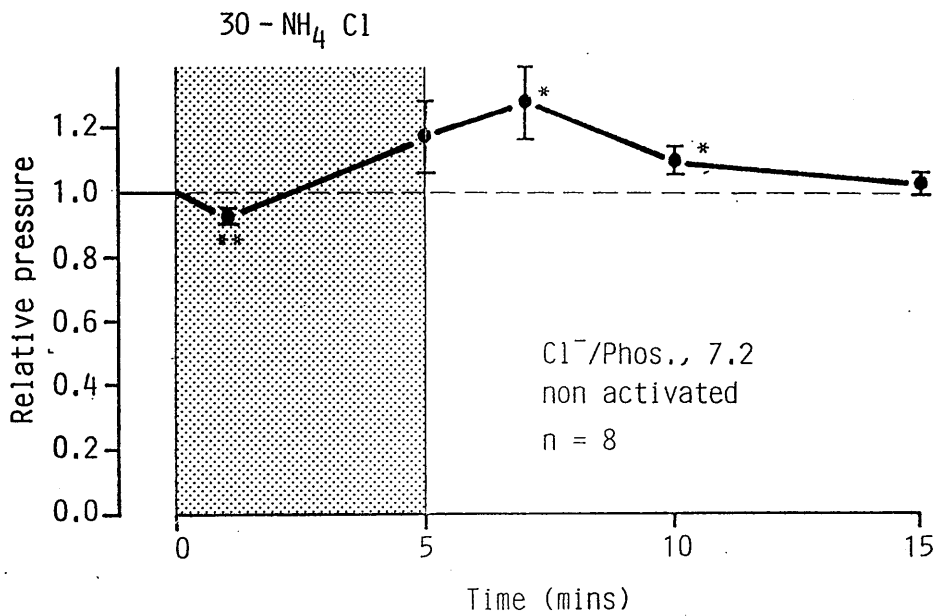

Fig. 4: Pooled results of basic NH<sub>4</sub><sup>+</sup> effect in H<sub>2</sub>PO<sub>4</sub><sup>-</sup> Ringer's pH<sub>o</sub>, 7.2 of unstimulated ears. NH<sub>4</sub><sup>+</sup> dilation was greatly reduced with rebound constriction during NH<sub>4</sub><sup>+</sup> pulse. Further constriction on washout. Asterisks indicate significant difference from pre<sup>+</sup>-NH<sub>4</sub><sup>+</sup> tone.

was transient and recovery from it overshoot reference tone (Fig 5A). However minimal activation (i.e. very low NA concentration) had been found necessary, to prevent instability in this series of experiments. Therefore this phenomenon may not necessarily be attributed to Hepes but to perhaps the batch of animals used. Particularly young rabbits (and also roughly dissected preparations!) tended to be unstable at the normal NA concentration; tone oscillations of many tens of mmHg amplitude and approximately 30 secs period set in. The low stabilized control tone obtained with lower NA levels may therefore be the reason for this overshoot. It was not seen in another series of experiments which also used Hepes but had higher (10mM)  $\text{Ca}^{2+}$  (see below) and normal NA concentration (Fig 5B). In any case, irrespective of the  $\text{Ca}^{2+}$  concentration the  $\text{NH}_4^+$  dilatation was always to approximately 50% of reference tone whilst the washout always produced further transient constriction, whatever the tone at which it began, before recovering back towards base tone.

The large similarities of these effects in  $\text{H}_2\text{PO}_4^-$  and Hepes buffers made it appropriate to capitalize on the superior  $\text{Ca}^{2+}$  - tolerance of Hepes. Thus another series of experiments were designed to investigate the effects of buffer concentration from 0 to 10mM. Fig 5C is a full time - course of the  $\text{NH}_4^+$  cycle summarizing the average results obtained with 0, 0.5 and 1.0mM Hepes. Fig 5D illustrates peak  $\text{NH}_4^+$  dilatations (E01) and washout constrictions (W02) of a wider Hepes concentration range. The asterisks in Fig 5C indicate significant differences from reference

Fig. 5A and B: Results in 3mM Hepes - buffered Ringer's, A with 2.5mM - Ca<sup>2+</sup> and B with 10mM - Ca<sup>2+</sup>. In A low stabilized control tone was achieved with low (typically  $2.5 \times 10^{-7}M$ ) NA concentrations (normal NA concentrations gave tone oscillations with about 30 secs period). Recovery from NH<sub>4</sub><sup>+</sup> dilation overshoot reference tone. No such overshoot obtained with new batch of experiments illustrated in B, which were performed under normal NA activation.

Fig. 5C: Pooled results of experiments to investigate effects of varying buffer concentration. Full time course of the  $\text{NH}_4^+$  cycles obtained in 0, 0.5 and 1.0mM Hepes. Asterisks indicate levels of significance of differences from reference tone.

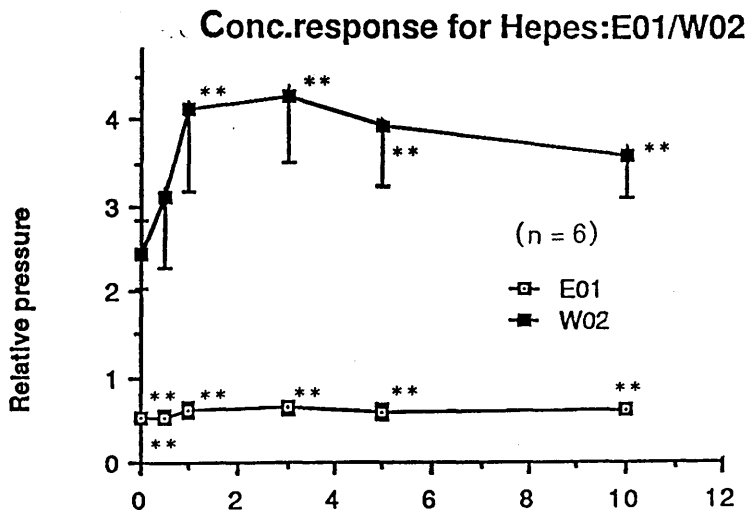

Fig. 5D: Peak  $\text{NH}_4^+$  dilatations (E01) and washout constrictions (W02) of a wider range of Hepes concentration (0, 0.5, 1.0, 3, 5 and 10mM). There is no significantly larger  $\text{NH}_4^+$  dilatation nor washout constriction with lower external buffering capacity; instead the latter increased with greater Hepes concentration to an optimum value at 3.0mM Hepes.

tone. It is of importance (see discussion) that neither the  $\text{NH}_4^+$  dilatation nor the washout constriction: were significantly bigger when external buffering capacity was lower; in fact the washout constriction increased with increasing buffer concentration up to an optimum value at 3.0mM Hepes.

### Tris Buffer

The basic responses to  $\text{NH}_4^+$  application and its withdrawal were obtained. There was a transient  $\text{NH}_4^+$  - dilatation which recovered slowly back towards control tone. The washout constriction was also transient, recovering back towards control tone more rapidly.

### Bicarbonate Buffer

$\text{CO}_2/\text{HCO}_3^-$  raised mean tone when it replaced  $\text{H}_2\text{PO}_4^-$ . This increase in tone was dependent on the external  $\text{HCO}_3^-$  concentration. Fig 6 is a bar plot illustrating the effect on mean tone of replacing a phosphate buffered Ringer with those containing 12.5mM and 25mM  $\text{HCO}_3^-$  respectively. There was about a 50% increase in 12.5mM and about 140% increase when the  $[\text{HCO}_3^-]_0$  was doubled.

In  $\text{CO}_2/\text{HCO}_3^-$  buffer both the  $\text{NH}_4^+$  dilatation and washout constrictions were obtained, and their magnitudes were not significantly different from those in phosphate buffered media. However their rates of recovery or adaption back towards control

**Fig. 6:** A bar plot of averaged results to illustrate effect on mean tone of the replacement of  $\text{H}_2\text{PO}_4^-$  buffered Ringer's with solutions buffered by 12.5mM<sup>-</sup> and 25mM  $\text{CO}_2/\text{HCO}_3^-$  respectively. Tone increased by about 50% in 12.5mM and 140% in 25mM  $\text{CO}_2/\text{HCO}_3^-$ .

tone were greatly reduced. The latter effects will be fully reported in a subsequent part of this chapter.

### Consequences of Ionic Modifications

A very substantial range of ionic substitutions or concentration changes was made, involving all the ions present in the basic Ringer's solution except  $Mg^{2+}$ . None of these changes had more than quantitative effects upon the fundamental  $NH_4^+$  phenomena, i.e. the rapid dilatation that occurs on  $NH_4^+$  application and the constriction (with nearly always an overshoot) that occurs on washout.

### Cationic Substitutions

#### Calcium:

$Ca^{2+}$  dose - dependently raised resting tone over the range 0-2.5mM; above this, tone plateaued. (Fig 7A).

Both  $NH_4^+$  - dilatation and washout constriction were present when  $[Ca^{2+}]_o$  was varied throughout the range from 0 to 10mM. The magnitude of the  $NH_4^+$  - dilatation decreased when  $[Ca^{2+}]_o$  was raised from 0 to a minimum at 1.5mM. That of the washout constriction decreased steadily with increasing  $[Ca^{2+}]_o$  above 0.5mM, Fig 7B. Afterwards there was adaptation of tone back towards reference tone in all instances.

In O- $Ca^{2+}$  with simultaneously O- $K^+$  the  $NH_4^+$  dilatation was

## Effect of Ca conc. on mean tone(7.2)

Fig. 7A: Mean tone effects of varying  $\text{Ca}^{2+}$  concentration (0, 0.5, 1.5, 2.5, 5 and 10mM) in  $\text{H}_2\text{PO}_4^-$  - Ringer's.  $\text{Ca}^{2+}$  dose-dependently raised resting tone over the range 0-25mM then plateaued above 25mM. The level of significance of differences from control

## Conc response for Ca(mM) E01/W02

Fig. 7B: A graph of averaged results illustrating peak  $\text{NH}_4^+$  dilatations (E01) and washout constrictions (W02) with varying concentrations of  $\text{Ca}^{2+}$  (0-10mM) in  $\text{H}_2\text{PO}_4^-$  Ringer's, pH<sub>O</sub> 7.2. E01 decreased with increasing  $[\text{Ca}^{2+}]_0$  to a minimum at 1.5mM. W02 decreased steadily with increasing  $[\text{Ca}^{2+}]_0$  above 0.5mM.

Fig. 8: Pooled results of 6 experiments showing full NH<sub>4</sub><sup>+</sup> cycle in simultaneously 0-K<sup>+</sup> and 0-Ca<sup>2+</sup> H<sub>2</sub>PO<sub>4</sub><sup>-</sup> Ringer's, pH<sub>O</sub> 7.2. NH<sub>4</sub><sup>+</sup> dilatation was abolished. Washout constriction was enhanced. Asterisks indicate significance of difference from reference tone.

abolished whilst the washout constriction was greatly enhanced. Fig 8.

### Potassium

All experiments described under this subheading are ones in which NA was present. O-K<sup>+</sup> in normal Ca<sup>2+</sup> raised resting tone to about twice that in normal K<sup>+</sup> (6mM). Reintroduction of K<sup>+</sup> subsequently lowered resting tone concentration - dependently up to a [K<sup>+</sup>]<sub>o</sub> of 12mM, after which tone rose instead (Fig 9A).

Fig 9B is an illustration of the full NH<sub>4</sub><sup>+</sup> cycle in 0, 2, and 12mM K<sup>+</sup>. In O-K<sup>+</sup>, NH<sub>4</sub><sup>+</sup> - induced dilatation was unaffected in magnitude but greatly enhanced in duration. Washout constriction was reduced in amplitude and little affected in duration. Washout constriction was enhanced in 12mM K<sup>+</sup>, where the control tone was minimal. At higher [K<sup>+</sup>]<sub>o</sub> [30, 50 and 140mM] both the NH<sub>4</sub><sup>+</sup> dilatations and the washout constrictions were smaller than in 12-K<sup>+</sup> (Fig. 9C). Fig. 9D is a bar plot with error bars of the basic NH<sub>4</sub><sup>+</sup> phenomena in different [K<sup>+</sup>]<sub>o</sub>, comparing them to that of control (6mM). 12K<sup>+</sup> showed highly significant differences during the whole NH<sub>4</sub><sup>+</sup> cycle. However apart from NH<sub>4</sub><sup>+</sup>-induced dilatation in 0mM and 30mM-K<sup>+</sup>, and the immediate constriction response to washout in 2mM-K, no other changes were of significantly different amplitude from those of control. Recovery or adaptation of tone back towards base tone occurred in all cases. The lower concentrations (e.g. 2mM) predominantly had slower

Fig. 9A: Mean tone effects of varying  $[K^+]_O$  (0-140mM)  $H_2PO_4^-$  Ringer's,  $pH_O$  7.2 in the presence of NA. A: pooled results of an average of 12 experiments.  $O-K^+$  raised resting tone to about twice that of control (6mM). Subsequent reintroduction of  $K^+$  dose-dependently lowered tone to a minimum at 12- $K^+$ , after which tone rose with further increasing  $[K^+]_O$ .

Fig. 9B: Pooled results of full  $NH_4^+$  cycles in 0, 2 and 12mM -  $K^+$   $H_2PO_4^-$  Ringer's  $pH_O$  7.2 with NA.  $NH_4^+$  dilatation was unaffected in amplitude, but lasted longer in  $O-K^+$ . Washout constriction was reduced in  $O-K^+$  but enhanced in 12- $K^+$ . Asterisks indicate significance of difference from reference tone.

Fig. 9C: Plot of EO1 and EO2 values obtained when varying  $[K^+]_O$  (0,2,6,12,30,50 and 140mM) in the presence of NA. Both  $NH_4$  dilatations and washout constriction were greatest when  $[K^+]_O$  was 12mM (cf Fig. 9B). Asterisks indicate significances of differences from reference tone.

Fig. 9D: Bar plot illustrating the basic  $NH_4^+$  phenomena with varying  $[K^+]_O$  (0-140mM) compared to control  $[K^+]_O$  -6mM. 12- $K^+$  showed highly significant differences (asterisks) during the whole  $NH_4^+$  cycle.  $NH_4^+$  dilatation in 0 and 30mM - $K^+$  and washout constriction in 2mM -  $K^+$  were also all significantly different in amplitude from those of control.

adaptations from the  $\text{NH}_4^+$ -induced dilatation while higher concentrations (e.g. 140mM) typically had predominantly slower adaptation from the washout constriction. In 0- $\text{K}^+$  both adaptations were slowed.

#### Sodium Substitution Other Than By $\text{K}^+$

When Lithium, sucrose or choline totally and isomotically substituted  $\text{Na}^+$  in normal  $\text{H}_2\text{PO}_4^-$  Ringer's, all three raised resting tone (Fig. 10). They also all permitted typical  $\text{NH}_4^+$  dilatations and washout constrictions. The only one of these whose magnitude differed significantly from that when  $\text{Na}^+$  was present was the washout constriction in sucrose: this was small.

In all these media there was adaptation of tone back towards reference level after both  $\text{NH}_4^+$  dilatation and washout constriction. Differences from control occurred in the rates of adaptation; but details of these will be discussed in part II of this chapter.

The results below describe the basic  $\text{NH}_4^+$  phenomena in preparations treated with drugs that affect cation transport.

#### Ouabain

Ouabain, the classical inhibitor of  $\text{Na}^+/\text{K}^+$  exchange pumps, is generally considered to have no other significant actions. Since most pumps are electrogenic (in the hyperpolarizing direction), inhibiting them produces a degree of depolarization, which has proved sufficient to activate some excitable tissues.

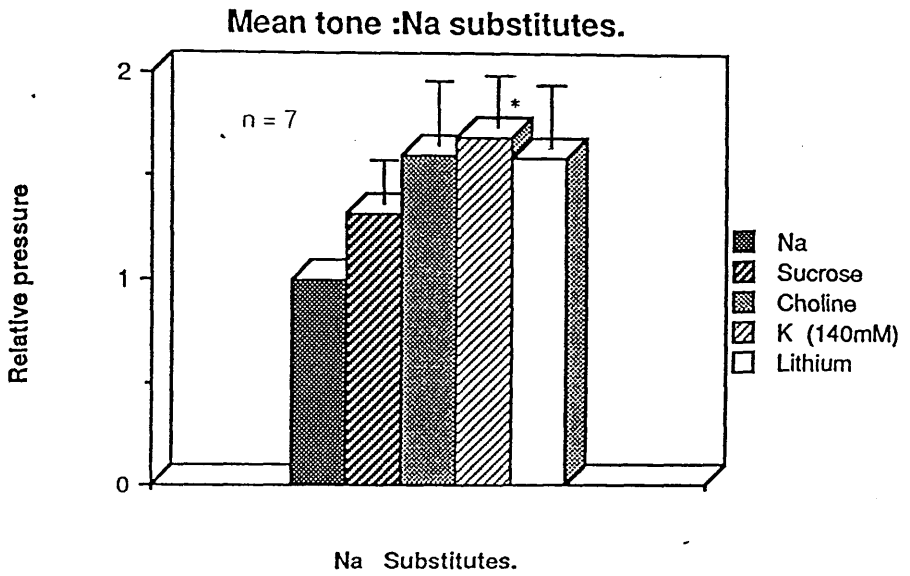

Fig. 10: Effect on resting tone of isosmotically substituting  $[Na^+]_0$  in normal  $H_2PO_4^-$  Ringer's with lithium, choline, sucrose and potassium: All four raised tone.

Despite reports of considerable tone-elevation in visceral smooth muscle e.g. (Daniel & El-Sharkawy, 1974) ouabain had a negligible effect on resting tone in the rabbit ear vascular bed (Fig. 11A). A just significant elevation at  $10^{-4}\text{M}$  was not repeated at  $10^{-3}\text{M}$ .

Both the  $\text{NH}_4^+$  dilatation and the washout constrictions were obtained at each of the different concentrations used ( $10^{-3}$  -  $10^{-8}\text{M}$ ). In all cases there was recovery of tone back towards reference level. The rates of these adaptations will be discussed in details in part II of this chapter.

Fig. 11B is a plot of the relative  $\text{NH}_4^+$  effects of ouabain compared to those in control solutions (i.e. with no drug). The differences looked considerable and were all in the same direction, but the number of experiments being naturally small with each ouabain concentration, unpaired t-tests within each individual ouabain concentration showed that, only  $10^{-4}\text{M}$  washout and  $10^{-3}\text{M}$   $\text{NH}_4^+$  application were statistically significant at an acceptable level. Pooling the results with all ouabain concentration together, since no concentration effect was apparent (at least for washout constriction) showed a significantly ( $p < 0.05$ ) enhanced washout effect.

At  $37^\circ\text{C}$ , the  $\text{NH}_4^+$  dilatation in the presence of  $10^{-5}\text{M}$  ouabain was significantly ( $p < 0.05$ ) less than that of control solution, while the washout constriction was greatly reduced. Recovery of tone from the dilatation overshoot reference level even while  $\text{NH}_4^+$  was

Fig. 11A: Effect on resting tone of different concentrations of ouabain ( $10^{-8}$ M -  $10^{-3}$ M). Pooled results of 4 experiments. Negligible effects at all concentrations except at  $10^{-4}$ M where ouabain raised tone slightly.

Fig. 11B: Plot of the  $\text{NH}_4^+$  effects in ouabain compared to those in control Ringer's (no drugs). Differences look considerable and are all in the same direction though only  $10^{-3}$ M  $\text{NH}_4^+$  dilatation and  $10^{-4}$ M washout constriction were significantly significant (at levels  $P < 0.05$  and  $P < 0.01$  respectively).

still present. That from the washout constriction was unaffected by ouabain.

### Amiloride

Amiloride, a cation-antiport inhibitor (see Discussion), dose dependently reduced mean tone when applied (cumulatively or non-cumulatively) and did so very highly significantly at the higher doses, (Fig. 12A).

It permitted both the  $\text{NH}_4^+$ - induced dilatation and the washout constriction, throughout the drug concentration range employed ( $10^{-7}\text{M}$  -  $10^{-3}\text{M}$ ). The magnitudes of the dilatations (expressed, as always, relative to pre- $\text{NH}_4^+$  tone) appeared somewhat enhanced in lower concentrations of Amiloride, where mean tone was minimally lowered (cf Fig. 12).

At higher concentrations ( $10^{-3}\text{M}$ ) where mean tone was greatly lowered, the  $\text{NH}_4^+$  dilatation and washout constriction (even when expressed as usual, relative to pre- $\text{NH}_4^+$  tone) were both substantially reduced (Fig. 12B).

$10^{-3}\text{M}$  Amiloride applied only during the  $\text{NH}_4^+$  phase greatly enhanced the  $\text{NH}_4^+$  dilatation; conversely, applied only during the washout period, it totally abolished the washout constriction. If this concentration of Amiloride was given as a 1-2 min. pulse during the washout period a rapid decrease in tone occurred, followed by an immediate recovery.

All of the amiloride derivatives also permitted the  $\text{NH}_4^+$  dilatation and washout constriction. However the points of interest

Fig. 12: Bottom original trace of representative experiment showing the effects of Amiloride ( $2 \times 10^{-4}$ M) on resting tone and the recovery rates from both  $\text{NH}_4^+$  dilation and washout constriction in that concentration of amiloride;  $\text{H}_2\text{PO}_4$  Ringer's  $\text{pH}_O$  7.2. Amiloride dilated the ear artery but retarded both recovery rates. Top: Control situation; same preparation, no drug present.

## A. Log conc./tone for Amil.

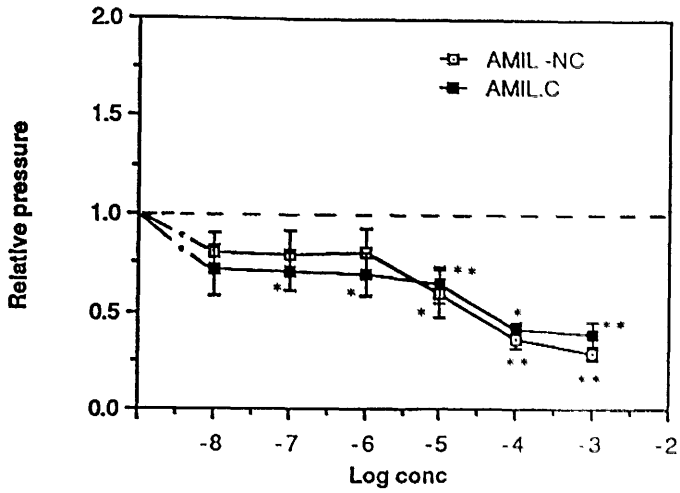

Fig. 12A: Cumulative (C) and non-cumulative (NC) log conc./tone plots for amiloride. For NC,  $n = 8$ ; for C,  $n = 6$ . Asterisks indicate significant reduction of tone as compared to control (drug-free  $H_2PO_4^-$  Ringer's,  $pH_O 7.2$ ).

## B. Log conc./response for E01/W02 in Amiloride

Fig. 12B: Plot of both  $NH_4^+$  dilatations (E01) and washout constrictions (W02) obtained in the presence of varying concentrations of amiloride ( $10^{-7}$  -  $10^{-3}M$ ). At  $10^{-3}M$  E01 was significantly reduced and W02 was also reduced ( $n = 4$ ).

as regards this group of drugs is their effect on the rate of recovery of tone after these  $\text{pH}_i$  induced changes: see part 2 of this chapter.

### Anionic Substitution

As previous workers (MacLellan et al 1974) found, the main anion substitute,  $\text{PhSO}_3^-$ , raised mean tone to about twice the value it had when  $\text{Cl}^-$  was the bulk anion (Fig. 13A). The initial NA effect, when the agonist was applied after the anion-substitution had been affected, was similar to but usually larger than that in  $\text{Cl}^-$  (Fig. 13B).

$\text{pH}_i$  modification with  $\text{NH}_4^+$  was investigated in  $\text{PhSO}_3^-$  media in the presence of different buffers -  $\text{H}_2\text{PO}_4^-$ , Hepes and  $\text{HCO}_3^-$ . Both the  $\text{NH}_4^+$  dilatation and the washout constrictions were obtained in all three buffers used. In all cases, the  $\text{NH}_4^+$  dilatations were greatly enhanced while the washout constrictions were greatly reduced and hardly overshoot reference tone: indeed in one buffer they did not even reach reference tone. (Fig. 13C).

When  $\text{pH}_i$  was lowered in  $\text{CO}_2/\text{HCO}_3^-$  buffered  $\text{PhSO}_3^-$  solution, by simultaneously changing both  $P_{\text{CO}_2}$  and  $[\text{HCO}_3^-]_0$ , there was an increase in tone.

This increase was however less than when  $\text{Cl}^-$  was the bulk anion (Fig. 13D).

### S.I.T.S.

The anion-flux inhibitor S.I.T.S. produced no quantitative differences in the amplitudes of either the  $\text{NH}_4^+$  dilatation or the

Fig. 13A: Effect on mean tone of totally replacing  $\text{Cl}^-$  with  $\text{PhSO}_3^-$  in  $\text{H}_2\text{PO}_4^-$  Ringer's.  $\text{PhSO}_3^-$  raised mean tone to about twice the value it had in  $\text{Cl}^-$  ( $n = 6$ ).

Fig. 13B: Original trace of NA activation in  $\text{H}_2\text{PO}_4^-$  - buffered  $\text{PhSO}_3^-$  Ringer's,  $\text{pH}_O$  6.7, showing biphasic response similar to but larger than those obtained in  $\text{Cl}^-$  (cf. Fig. 1A). At higher pH's the responses obtained in  $\text{Cl}^-$  were closer to that illustrated here.

Fig. 13C: Pooled results of full NH<sub>4</sub><sup>+</sup> cycles in H<sub>2</sub>PO<sub>4</sub><sup>-</sup> buffered PhSO<sub>3</sub><sup>-</sup> medium. The NH<sub>4</sub><sup>+</sup> dilatation was greatly enhanced while the washout constriction was greatly reduced and failed to reach reference tone.

Fig. 13D: Preparation perfused with 5% CO<sub>2</sub> and 25mM HCO<sub>3</sub><sup>-</sup> preceded and followed by periods in phosphate-buffered Ringer's; PhSO<sub>3</sub><sup>-</sup> the bulk anion throughout. CO<sub>2</sub>/HCO<sub>3</sub><sup>-</sup> raised tone which recovered slowly back on removal of the CO<sub>2</sub>/HCO<sub>3</sub><sup>-</sup>. This effect was much weaker in PhSO<sub>3</sub><sup>-</sup> than in Cl<sup>-</sup>.

washout constriction, whether in  $\text{H}_2\text{PO}_4^-$  - or in  $\text{HCO}_3^-$  - buffered media. S.I.T.S. however affected the recovery rates of both effects as will be discussed in the subsequent section.

### Results From Metabolically Inhibited Preparations

Application of  $\text{CN}^-/\text{F}^-$ , to inhibit metabolism, reduced mean tone by about 1/3 to 1/4 in the majority of preparations whilst in one there was complete loss of tone in the course of 70-90 mins. Both  $\text{NH}_4^+$  dilatation and washout constriction were present in these poisoned preparations, except where no tone remained. The fractional  $\text{NH}_4^+$  dilatation was slightly reduced while the washout constriction was enhanced (Fig 14).

### Results From Denervated Ears.

Chemically sympathectomised ears were about 10 times more sensitive to NA than those of untreated animals, and were rather unstable in their response to many ionic changes. Nevertheless,  $\text{NH}_4^+$  dilatations and washout constrictions were present in all preparations. There were moreover, no qualitative differences, nor even detectable quantitative ones, from those of control preparations.

### Consequences Of Endothelial Inhibition

Three methods, namely, the applications of haemoglobin (Hb), methylene blue (MeB), and distilled  $\text{H}_2\text{O}$ , which had been reported to inhibit endothelium - dependent relaxations in other

Fig. 14: Graph of pooled results showing basic  $\text{NH}_4^+$  effects when 3mM NaCN/1mM NaF replaced osmotic equivalents of NaCl in both  $\text{NH}_4^+$  and normal  $\text{H}_2\text{PO}_4^-$ -buffered Ringer's. The fractional  $\text{NH}_4^+$  dilatation was significantly reduced while the washout constriction appeared enhanced in these metabolically inhibited preparations.

vessels (Furchgott et al 1985, Martin et al 1986), were tried for their effects on the  $\text{NH}_4^+$  dilatation. Their effect was tested by perfusing Ach ( $10^{-6}\text{M}$ , after preliminary trials of a range of concentrations) for about 2-3 minutes prior to the application and washout of  $\text{NH}_4^+$ .

In control situations where there were no inhibitions by MeB, Hb or dist.  $\text{H}_2\text{O}$ , the dilatations produced by both  $\text{NH}_4^+$  and  $10^{-6}\text{M}$  Ach were of comparable magnitudes. They were not in the inhibited preparations. (Fig. 15B).

The Ach-dilatation was diminished sometimes to as little as 20-15% of the control value, though was not abolished by any of these agents even when they had been applied at higher concentrations (MeB and Hb) or for longer periods (dist.  $\text{H}_2\text{O}$ ) than reported necessary by Furchgott et al to produce 100% inhibition of Ach-dilatation in rabbit aorta. In the case of dist.  $\text{H}_2\text{O}$ , there was little inhibition of the Ach-dilatation but mean tone fell slightly.

Both MeB and Hb raised mean tone, (Fig. 15A), and in accord with this, enhanced the  $\text{NH}_4^+$  dilatation while inhibiting the washout constriction. Nevertheless, both treatments diminished the Ach-dilatations. In MeB (which was the more effective) the mean Ach-dilatation was about 38% of its control dilatory effect (Fig. 15B). When MeB and Hb were washed out, all the consequences of their application were only partially reversed during the lifespan of the preparation. Relative to mean tone, the

**Fig. 15:** Endothelial inhibition with MeB and Hb. A: Bar plot illustrating relative change in resting tone when MeB ( $5 \times 10^{-4}M$ ) and Hb C ( $\approx 10^{-5} - 10^{-4}M$ ) were applied in  $H_2PO_4^-$  Ringer's,  $pH_0$  7.2. Both MeB and Hb raised tone. Dist.  $H_2O$  reduced tone to about 0.96 of that of control. B: Bar plot illustrating Ach and  $NH_4^+$  dilatation and washout constrictions obtained in the presence of MeB, Hb and after 20-40 secs. prepulses of dist  $H_2O$  compared to their respective controls (i.e. untreated preparations). Ach dilatations diminished in all three, and to about 38% of control dilatatory effect in more effective MeB.  $NH_4^+$  dilatations were enhanced while the washout constrictions were diminished. Average number of experiments pooled together in all cases was 3.

**Endothelial effect on E01/W02 (Hb;Ach & Dist.H2O)**

$\text{NH}_4^+$  dilatation after distilled water, was also slightly enhanced and the washout constriction also slightly inhibited.

#### Hypoxic And Hyperoxic Effects

Hypoxic and hyperoxic conditions, induced by continuous application of 100%  $\text{N}_2$  and  $\text{O}_2$  respectively, did not alter the basic  $\text{NH}_4^+$  effects qualitatively, nor even to any material extent quantitatively.

#### Effects On Other Vascular Preparations

In order to establish whether the  $\text{NH}_4^+$  phenomenon is applicable more widely than to the rabbit ear artery, some experiments were carried out on whole femoral beds of the rabbit and some other preparations.

#### Whole Femoral Beds:

All experiments carried out with whole femoral preparations were done at  $37^\circ\text{C}$  and activation was with NA. This preparation was dilated by  $\text{NH}_4^+$  application and constricted by its washout. The  $\text{NH}_4^+$  dilatation was significantly less than that of the ear artery also at  $37^\circ\text{C}$ , while the washout constriction did not differ significantly. Fig. 16.

#### Frog Whole Body Preparation.

The  $\text{NH}_4^+$  effects in the frog (activated with adrenaline) were

Fig. 16: Graphs of pooled results showing basic  $\text{NH}_4^+$  effects in ear artery and whole femoral preparations at  $37^\circ\text{C}$ ,  $\text{NH}_4^+$  dilatation was significantly less while the washout constriction was unaffected in the femoral preparation.

the converse of those in the mammalian vascular preparations. On application of  $\text{NH}_4^+$ , there was a transient increase in tone which recovered very rapidly, undershooting reference value. On washout there was further dilatation followed by a recovery towards reference tone. Due to problems with edema when perfusion lasted for longer periods, a few short-cycle experiments were performed, the  $\text{NH}_4^+$  phase lasting just 2 mins. instead of 5 and the washout phase 3 mins. instead of 10. There were no qualitative differences in either effects. However, recovery from the  $\text{NH}_4^+$  - induced constriction was understandably less complete whilst  $\text{NH}_4^+$  remained for just 2 mins. and after this brief treatment recovery from the washout - dilatation was rapid, (Fig. 17).

#### Modification Of $\text{pH}_i$ by $\text{CO}_2$ Entry

There are several possible procedures by which  $\text{CO}_2$  could be made to enter cells in order to acidify them, without altering  $\text{pH}_o$ . The simplest of these procedures is the replacement of a nominally  $\text{CO}_2$  - free buffer such as phosphate by a  $\text{CO}_2/\text{HCO}_3^-$  system of similar pH. Fig. 18A illustrates results obtained when 5%  $\text{CO}_2/25\text{mM HCO}_3^-$  - buffered solution replaced a phosphate - buffered one. There was an increase in tone on introduction of  $\text{CO}_2$ . On washout it fell. The responses were slower than in  $\text{NH}_4^+$  experiments though their magnitudes were just as great.

**Fig. 17:** Pooled results of full NH<sub>4</sub><sup>+</sup> cycles of whole frog preparation (activated with adrenaline). Perfusion with 30mM NH<sub>4</sub>Cl lasted 2 mins and washout with normal Ringer's 3 mins. There was transient increase in tone with NH<sub>4</sub><sup>+</sup> application followed by a decrease on washout.

Fig. 18A and B: CO<sub>2</sub>/HCO<sub>3</sub><sup>-</sup> effect on tone. A: Original trace of ear artery perfused with 5% CO<sub>2</sub>/25mM HCO<sub>3</sub><sup>-</sup> Cl<sup>-</sup> Ringer's pH 7.2, preceded and followed by periods in H<sub>2</sub>PO<sub>4</sub><sup>-</sup> buffered Cl<sup>-</sup> Ringer's pH<sub>O</sub> 7.2. CO<sub>2</sub>/HCO<sub>3</sub><sup>-</sup> raised tone which recovered slowly back towards reference value on removal of the CO<sub>2</sub>/HCO<sub>3</sub><sup>-</sup>. This effect was stronger than that obtained when PhSO<sub>3</sub><sup>-</sup> was the bulk anion of Fig. 13D.

B: CO<sub>2</sub>/HCO<sub>3</sub><sup>-</sup> - induced constriction in Cl<sup>-</sup> and PhSO<sub>3</sub><sup>-</sup> media. Magnitude of constriction increased with increasing [HCO<sub>3</sub><sup>-</sup>]<sub>0</sub> in both anions, though less so in PhSO<sub>3</sub><sup>-</sup>.

Equivalent experiments using 1.25%/6.25mM  $\text{HCO}_3^-$  and 2.5%  $\text{CO}_2$ /12.5mM  $\text{HCO}_3^-$  showed that the magnitude of the  $\text{CO}_2$  - induced constriction increased with concentration, (Fig. 18B). All these effects were diminished but present when  $\text{PhSO}_3^-$  had been totally substituted for  $\text{Cl}^-$ .

#### Responses To $\text{pH}_0$ Alterations.

The general trend by which  $\text{pH}_0$  affected vascular tone was, an increase in tone with increasing  $\text{pH}_0$ , in accord with the observations of Gaskell (1880). If the pH of Ringer's perfusing the ear artery was decreased from 7.2 to 6.7 tone fell. Conversely an increase to 7.7 raised tone.

In phosphate - buffered media, this classical response to  $\text{pH}_0$  was obtained, when either  $\text{Cl}^-$  or  $\text{PhSO}_3^-$  was the bulk anion, (Fig. 19A & 19A<sup>I</sup>). Even when MeB was applied, the response to  $\text{pH}_0$  in  $\text{Cl}^-$  phosphate Ringer's was in the normal direction, (i.e. an increase in tone with increasing  $\text{pH}_0$ ). The same result was also obtained in HEPES buffered  $\text{Cl}^-$  Ringer's. However in HEPES - buffered  $\text{PhSO}_3^-$  Ringer's the reverse was the case. Changing from 7.2 to 6.7 in this medium raised tone while a change from 7.2 to 7.7 lowered tone (Fig. 19B and 19B<sup>I</sup>).

An increase in external  $\text{K}^+$  concentration from 2.5 to 50mM, or total replacement of  $\text{Na}_0^+$  with sucrose, did not alter the direction

B<sup>1</sup>: Plot of 10 experiments pooled together for each of the anions showing these  $\text{pH}_0$  effects. Asterisks indicate significant difference from control  $\text{pH}_0$  (7.2).

#### $\text{pH}_0$ effect in HEPES/10 Ca: $\text{Cl}^-/\text{PhSO}_3^-$

of vascular response to  $\text{pH}_0$ , but both manoeuvres raised the sensitivity to  $\text{pH}_0$ . An increase of temperature from room temperature to  $37^\circ\text{C}$  did not significantly alter the response to  $\text{pH}_0$  changes either quantitatively or qualitatively. Table D fully lists the relative pressures in response to  $\text{pH}_0$  changes in variously - modified Ringer's.

There was an increase in tone with increasing  $\text{pH}_0$  in varying concentration of  $\text{Ca}^{2+}_0$ . The  $\text{pH}_0$  sensitivity however initially increased with increasing  $[\text{Ca}^{2+}]_0$ , peaking when  $\text{Ca}^{2+}_0$  was 1.5mM and then declining with higher  $[\text{Ca}^{2+}]_0$ , (Fig. 19C). In O-  $[\text{Ca}^{2+}]_0$   $\text{pH}_0$  sensitivity was almost abolished but simultaneously removing  $\text{Ca}^{2+}_0$  and  $\text{K}^+_0$  from the external media restored  $\text{pH}_0$  sensitivity. The relative reference tone in O-  $\text{Ca}^{2+}$  was 0.62 while that in simultaneously O- $\text{Ca}^{2+}_0$  and O- $\text{K}^+_0$  was 0.51.

$\text{pH}_0$  Effect On  $\text{pH}_i$  Changes.  
 $\text{pH}_0$  Effect On  $\text{pH}_i$  Changes.

To establish  $\text{pH}_0$  influence on the  $\text{pH}_i$  modifications induced by  $\text{NH}_4^+$  application and its subsequent washout, a number of experiments were each performed at a constant acidic (6.7) or alkaline (7.7)  $\text{pH}_0$  in various buffers and ionic compositions.

Qualitatively, none of these variations affected the  $\text{NH}_4^+$  dilatation or its washout constriction. Figs. 20A, B, C and D are bar plots

showing values in both  $\text{pH}_o$  6.7 and  $\text{pH}_o$  7.7, in (A) varying  $[\text{K}^+]_o$ ; (B) varying  $[\text{Ca}^{2+}]_o$  and (C and D) varying buffer, anionic or cationic substitutions. The general trend in the majority of these results is an enhancement of the  $\text{NH}_4^+$  dilatation in alkaline media and of the washout constriction in acidic media. The few exceptions to this generalization were certain of those obtained with HEPES - buffered  $\text{Cl}^-$  with 10mM  $\text{Ca}^{2+}$  in which both  $\text{NH}_4^+$  dilatation and washout constrictions were enhanced; and those with  $\text{PhSO}_3^-$  irrespective of the buffer used in which the washout constriction was enhanced in  $\text{pH}_o$  7.7 and there was no significant difference of the  $\text{NH}_4^+$  dilatation in both  $\text{pH}_o$ 's.

Another common feature was that the recovery from the  $\text{NH}_4^+$  dilatation was slower in the alkaline medium and that from the washout constriction relatively faster. Fig. 20E is a full time course for the  $\text{NH}_4^+$  cycle, illustrating the typical  $\text{pH}_o$  effect on  $\text{pH}_i$  modifications.

Table D: A table of relative pressures, response to  $\text{pH}_0$  changes and  $\text{pH}_0$  sensitivities in variously modified Ringer's. Q: values are relative to tone in basic  $\text{H}_2\text{PO}_4^-$  buffered  $\text{Cl}^-$  Ringer's  $\text{pH}_0$  7.2

pHo effect on wash out constriction: varied conditions

Fig. 20E: Pooled results of full-time course of  $\text{NH}_4^+$  cycle illustrating typical  $\text{pH}_o$  effect on recovery rates from both  $\text{NH}_4^+$  - dilatation and washout constriction. Recovery rate from  $\text{NH}_4^+$  dilatation was slower in the alkaline  $\text{pH}_o$  while that from the washout constriction was slower in the acid  $\text{pH}_o$ .

## PART II

### On The Adaptation Rates

The rates of return towards reference tone from both  $\text{NH}_4^+$  - induced dilatation and washout - induced constriction may be taken as indicators of the rates at which the smooth muscle cells recover respectively from alkaline and acid loads. The results outlined in this section are on the effects of ionic substitutions and certain drugs upon these rates. It will be seen that anion substitutions all principally affected recovery from the  $\text{NH}_4^+$  - induced dilatation. Cation - substitutions principally retarded recovery from the washout - induced constriction. However, the anion - flux inhibitor S.I.T.S. and the cation - exchange inhibitor amiloride both retarded both recoveries.

Peak dilatations were achieved in most media within the first or second minute after  $\text{NH}_4^+$  application and peak constrictions in the second or third minute after withdrawal. However in the case of the withdrawal (acidification) phase, some substitutes produced departures from this generalization: in particular, peak was not reached till the 5<sup>th</sup> or 6<sup>th</sup> minute in S.I.T.S., amiloride or sucrose. The values reached at peak were also markedly different from one another in the different media. The trough tones reached in the preceding responses to  $\text{NH}_4^+$  were themselves to some extent medium - dependent. If tone is assumed, for argument's sake to vary linearly with  $\text{pHi}$  then the driving force for  $\text{HCO}_3^-$  or  $\text{H}^+$  extrusion is proportional to the relative amount by which the

trough or peak tone differs from the pre-NH<sub>4</sub><sup>+</sup> tone. On this basis I shall express the inhibition of recoveries from alkali - induced relaxation and acid - induced constriction in terms of % - age recovery from the extreme tone perturbation at the end of 4 mins. for alkali relaxation and 8 mins. for acid constriction Fig.21 .

### Recovery From Alkaline Load

The rate of recovery of tone from the alkaline - induced relaxation was halved by substituting PhSO<sub>3</sub><sup>-</sup> for all Cl<sup>-</sup> (Table E). Figs 21A and B show the effects of two interventions both of which should reduce any efflux of HCO<sub>3</sub><sup>-</sup> which occurs in exchange for Cl<sup>-</sup> influx. One was the use of a Cl<sup>-</sup> - medium buffered by 5% CO<sub>2</sub>/25mM HCO<sub>3</sub><sup>-</sup> instead of 3mM phosphate. In this buffer, whilst the extent of NH<sub>4</sub><sup>+</sup> - dilatation was relatively unaffected, the rate of recovery from this dilatation was reduced to about 1/4 of that of control. The other intervention was the application of S.I.T.S. in both HPO<sub>4</sub><sup>-</sup> - and CO<sub>2</sub>/HCO<sub>3</sub><sup>-</sup> - buffered Cl<sup>-</sup> media. Recovery was yet more powerfully inhibited to about 1/8 control rate in both media: Alternatively, the second of the two results may be expressed as a further halving, by S.I.T.S., of the rate obtained in S.I.T.S. - free CO<sub>2</sub>/HCO<sub>3</sub><sup>-</sup>. Amiloride also retarded recovery from the alkali - induced relaxation in both HPO<sub>4</sub><sup>-</sup> and CO<sub>2</sub>/HCO<sub>3</sub><sup>-</sup> - buffered media. Recovery was reduced to between 1/2 and 1/3 control rate in H<sub>2</sub>PO<sub>4</sub><sup>-</sup> while in CO<sub>2</sub>/HCO<sub>3</sub><sup>-</sup> no

Fig. 21: Diagrammatic representation of the estimation of recovery rates from extreme tone perturbation at the end of 4 mins. for alkali relaxation and 8 mins. for acid constriction: a and c maximum.  $\text{NH}_4^+$  dilatation and peak washout constriction respectively b, tone after 4 mins. of maximum  $\text{NH}_4^+$  dilatation and d, tone after 8 mins. of peak washout constriction.

Table E: o/o - age recovery rates from  $\text{NH}_4^+$ - dilatation and washout constriction of variously modified media.

### Recovery from Alkaline Load

$\text{PhSO}_3^-$	8	7

Fig. 21A and B: Pooled results of full  $\text{NH}_4^+$  cycles in  $5\% \text{CO}_2/25\text{mM HCO}_3^-$  - buffered medium with and without SITS ( $10^{-5}\text{M}$ ),  $\text{H}_2\text{PO}_4^-$  - buffered medium with and without SITS ( $10^{-5}\text{M}$ ) and amiloride ( $2 \times 10^{-4}\text{M}$ ). All these interventions slowed recovery rates from both  $\text{NH}_4^+$  dilatation and washout constriction.

recovery could be detected during the 5 min. period studied.

Of the cations,  $K^+$  enhanced recovery from alkaline load,  $Li^+$  and choline did not significantly affect it, but sucrose inhibited it.

The effect of  $pH_0$  on the recovery from alkali load was examined in several media. The common finding was an inhibition of recovery in an alkaline medium ( $pH_0$  7.7) and an enhancement in an acidic one ( $pH_0$  6.7) cf Fig. 20E.

#### Recovery From Acid Load

All the  $Na^+$  substitutes retarded recovery from the washout - induced constriction except  $Li^+$ , in which recovery rate was actually enhanced. Sucrose produced the greatest retardation; recovery was much delayed in onset and, even when expressed as a fraction of the small overshoot attained, took place at 1/4 the control rate. Relative recovery in choline was 1/3 that of control, and in 140k about half of control. These results are tabulated in Table E in addition to those obtained when  $CO_2/HCO_3^-$  replaced  $H_2PO_4^-$  buffer and when S.I.T.S. and amiloride were applied in both buffers. Both S.I.T.S. ( $10^{-5}M$ ) and amiloride ( $2 \times 10^{-4}M$ ) inhibited recovery from the acid induced constriction in  $H_2PO_4^-$  - buffered medium. Relative recovery rate in S.I.T.S. was 1/8 control.

When  $CO_2/HCO_3^-$  replaced  $H_2PO_4^-$ , recovery was retarded to about half that in  $H_2PO_4^-$  - control. Application of S.I.T.S. in  $CO_2/HCO_3^-$  did not however retard this recovery further. On the

other hand application of amiloride in  $\text{CO}_2/\text{HCO}_3^-$  did retard recovery somewhat further. Figs. 22 A and B are graphical representations of the  $\text{NH}_4^+$  cycle in some of the experimental variations mentioned above.

Though  $\text{pH}_0$  effects on recovery from acid - induced constriction were not significant, the apparent trend was towards a retardation in an acid  $\text{pH}_0$  (6.7) cf Fig. 20E.

#### Amiloride :

#### Effects On Recoveries From Alkali - Induced Relaxation And Acid - induced constriction

$10^{-3}\text{M}$  amiloride applied at different stages of the  $\text{NH}_4^+$  cycle produced the following results.

##### (1) Throughout The $\text{NH}_4^+$ Cycle

When  $10^{-3}\text{M}$  amiloride was applied throughout the  $\text{NH}_4^+$  cycle, the recoveries from both the  $\text{NH}_4^+$  dilatation and acid induced constriction were completely inhibited Fig. 23A.

##### (2) During Alkaline Load [E01-E05]

Both recoveries, from the  $\text{NH}_4^+$  dilatation and from the washout constriction, were completely inhibited. The transient overshoot of tone on washout was also abolished.

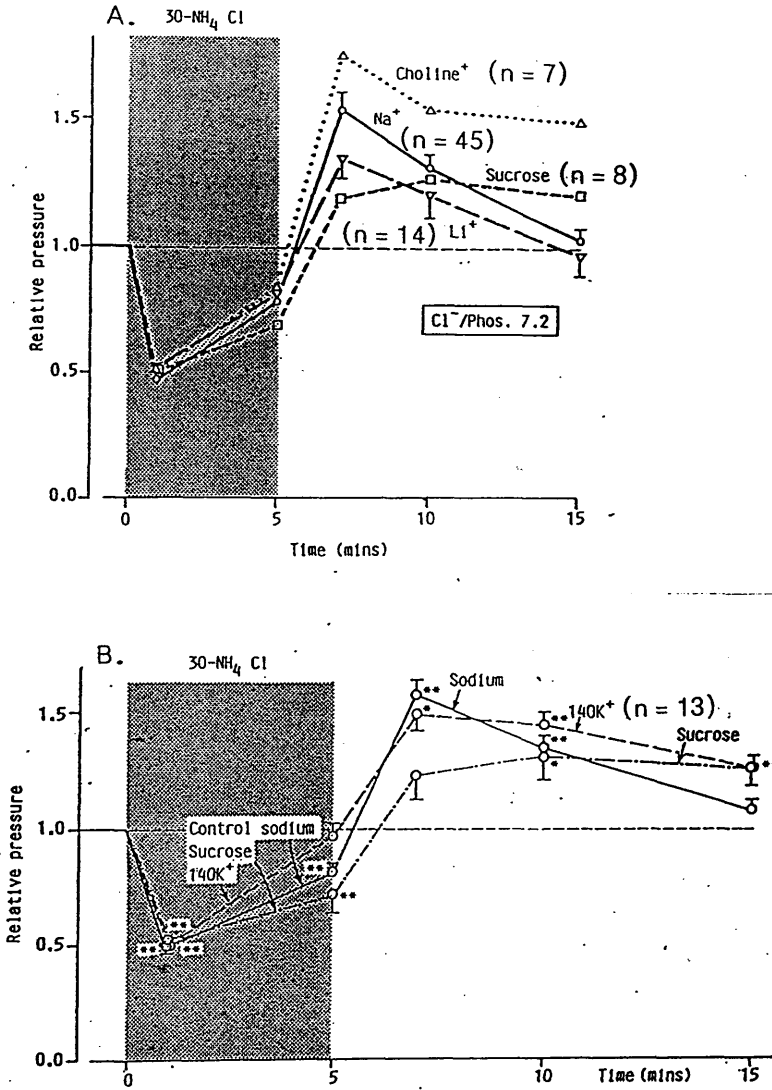

Fig. 22A and B: Pooled results of full NH<sub>4</sub><sup>+</sup> cycle in Na<sup>+</sup> substituted media: substitution with 140K<sup>+</sup>, Lithium, Sucrose and Choline. K<sup>+</sup> enhanced while sucrose inhibited recovery rate from NH<sub>4</sub><sup>+</sup> dilatation. All except Li<sup>+</sup> retarded recovery from washout constriction.

Fig. 23A and B: Pooled results of full  $\text{NH}_4^+$  cycles: A  $10^{-3}\text{M}$  amiloride applied throughout  $\text{NH}_4^+$  cycle. B: applied only within the first four minutes of washout phase. Recovery rates from both  $\text{NH}_4^+$  dilatation and acid constriction were infinitely inhibited in A. In B the transient increase in tone due to  $\text{NH}_4^+$  withdrawal was abolished.

### (3) During Acid Load:

- (i) Applied throughout the washout of  $\text{NH}_4^+$  it completely abolished the increase in tone normally observed. Fig. 23A.
- (ii) Applied within the first four minutes of washing, it abolished the transient acidification usually obtained within this period Fig. 23B.
- (iii) When a one - minute pulse was applied 5 mins. after  $\text{NH}_4^+$  withdrawal, there was a very rapid decrease in tone followed by a transient recovery.

### Dose - Dependent Effect Of Amiloride

When amiloride was applied throughout the  $\text{NH}_4^+$  cycle at concentrations between  $10^{-7}\text{M}$  to  $10^{-4}\text{M}$ , the recovery from  $\text{NH}_4^+$  - dilatation was inhibited dose - dependently. Except for  $10^{-5}\text{M}$ , there was considerable inhibition of the recovery from acid load although not strictly in a dose - dependent way Table F.

### Amiloride Analogues

Both  $\text{pH}_i$  and intracellular  $\text{Ca}^{2+}$  depend greatly on the transmembrane  $\text{Na}^+$  gradient (Vaughan-Jones et al 1983, Cardiac muscle), the dependence of either may perhaps, in some instances vary secondarily to changes in the other. Primarily however,  $\text{Na}^+$ - $\text{H}^+$  exchange which has been shown to be largely responsible for  $\text{pH}_i$  recovery from

acidosis in various cells maybe aided by other regulatory systems that control  $\text{pH}_i$  (e.g. an uptake of protons by mitochondria - Ellis and MacLeod 1985 on Purkinje fibres). Moreover, recovery of tone (which could directly respond to altered  $2\text{Na}-\text{Ca}^{2+}$  exchange) may depend on transmembrane  $\text{Ca}^{2+}$  transport. It was therefore necessary to investigate if the recovery of tone towards control after an acid - induced constriction is due to  $\text{Na}^+-\text{H}^+$  exchange or  $2\text{Na}+-\text{Ca}^{2+}$  exchange, since both would reduce tone. The slowed recovery of vascular tone after acid - induced constriction in amiloride ( $\sim 10^{-4}\text{M}$ ) may be due to inhibition of either of the cation exchange systems above, hence more specific amiloride analogues were employed to investigate tone - recovery in VSM.

Four categories of such analogues are

- (i)  $\text{Na}^+$  channel blockers.
- (ii)  $\text{Na}^+-\text{H}^+$  exchange inhibitors.
- (iii)  $2\text{Na}^+-\text{Ca}^{2+}$  exchange inhibitors.
- (iv) Non - specific  $\text{Na}-\text{H}^+$  and  $2\text{Na}^+-\text{Ca}^{2+}$  exchange inhibitor.

In Table A each of the drugs have been designated with a symbol (A-G) with the details of the specific chemical nomenclature and an indication of which mode of ion transport is considered to be chiefly inhibited.

I have in this part of my work investigated dose - dependent ( $10^{-7}$  -  $10^{-4}\text{M}$ ) effects not only on the adaptation of tone back to its initial value, after both intracellular alkalization and acidification, but also those on mean (reference) tone. The control medium in each case is  $7.2 \text{H}_2 \text{PO}_4^-$  - buffered  $\text{Cl}^-$  Ringer. The

degree of retardation has been estimated relative to that of the control experiment for each drug, which is itself designated as 100%. Note that this practice is different from that of the previous subsection and of Table E. The difference of presentation is due to the fact that the comparisons were made pairwise and each control itself adapted at a different rate from others.

#### "Na<sup>+</sup> Channel Blockers" A, E, F (cf Table A) On Mean Tone

Whilst amiloride dose - dependently reduced vascular tone (highly significantly at the higher concentrations) only one of the three Na - channel blockers (E, the 6 - Bromo derivative) behaved strictly comparably. F (6-iodo-) also decreased tone dose - dependently, but only after an initial increase with the introduction of the low doses of the drug. With A (6-Flouro-) all four concentrations raised mean tone. It was absolutely dose - independent over the range studied, (Fig. 24 A, B and C).

#### On The Recovery From Alkaline Load

Recovery from NH<sub>4</sub><sup>+</sup> dilatation was slower than that of control in all the concentrations of E, F and A employed. F appears to be most potent inhibitor and E the least (Table F).

#### Acid load.

Recovery was inhibited in the higher concentrations of F (10<sup>-5</sup> and 10<sup>-4</sup>M) and E, (10<sup>-4</sup>M). A showed the consistent effect.

Log conc/tone for Amil. deriv. : E

Log conc/tone for Amil. deriv. : F

C. Log conc./tone for Amil. deriv. : A

Fig. 24A, B and C: Log conc./tone of amiloride derivatives E, F and A: "Na<sup>+</sup> channel blockers". Asterisks indicate significant difference from control (no drug). E reduced tone dose-dependently, F only after an initial increase with introduction of the low doses. A, raised tone dose-dependently.

Table F: o/o - age recovery rates from  $\text{NH}_4^+$  dilatations and washout constrictions of amiloride and its derivatives. +ve means the adaptation takes (N-times) longer while -ve means it is faster than that of individual control (no drug) situations.

"Na<sup>+</sup> - H<sup>+</sup> Exchange Inhibitors" B & G on Mean Tone

Both B and G showed signs of raising tone at the lower concentrations. G, at higher concentrations caused tone to fall. Figs. 25 A and B.

On Recovery From: Alkaline Load.

Recovery from NH<sub>4</sub><sup>+</sup> dilatation was slower than that of control at the two higher concentrations (10<sup>-5</sup>, 10<sup>-4</sup>M) of both B and G. With G, but not with B the effect was strictly dose - dependent.

Acid Load

Both B and G completely inhibited recovery from the acid constriction in all concentration except (10<sup>-7</sup>M for B and (10<sup>-7</sup>, 10<sup>-6</sup>M) for G.

"2 Na<sup>2+</sup> - Ca<sup>2+</sup> Exchange Inhibitor" D on Mean Tone.

D dose - dependently caused tone to fall Fig. 26.

On The Recovery From: Alkaline Load

Recovery from NH<sub>4</sub><sup>+</sup> dilatation was retarded in an approximately dose - dependent way, retardation at 10<sup>-4</sup>M being very powerful.

Acid Load

At 10<sup>-4</sup>M inhibition was too powerful to analyse; At lower concentrations, the effects of D upon recovery from acid - induced constriction were inconsistent.

Fig. 25A and B: Log conc./tone of amiloride derivatives B and G: "Na<sup>+</sup> - H<sup>+</sup> exchange inhibitors". Both show signs of raising tone at the lower concentration. G reduced tone at the higher concentrations.

Fig. 26: Log conc./tone of amiloride derivative D: " $2\text{Na}^+ - \text{Ca}^{2+}$  exchange inhibitor". D reduced tone dose - dependently.

Fig. 27: Log conc./tone of amiloride derivative C: " $\text{Na}^+ - \text{H}^+$ ,  $2\text{Na}^+ - \text{Ca}^{2+}$  exchange inhibitor". C had no significant effect on tone.

"Na<sup>+</sup> - H<sup>+</sup>; 2Na<sup>+</sup> - Ca<sup>2+</sup> exchange inhibitor" C : On Mean Tone :

C had no significant effect on tone, (Fig. 27).

On The Recovery From : Alkali Load :

Recovery from the NH<sub>4</sub><sup>+</sup> dilatation was retarded dose - dependently, but not as powerfully at 10<sup>-4</sup>M as by G or D.

Acid Load :

There was inhibition of recovery rate at 10<sup>-5</sup> and 10<sup>-4</sup>M.

Effects of Amiloride on Mean Tone in Na<sup>+</sup> Substituted Media

(Li<sup>+</sup> and High K<sup>+</sup>)

10<sup>-4</sup>M amiloride reduced mean tone to about a third even when Na<sup>+</sup> was totally replaced with Li<sup>+</sup>, (Fig. 28).

Ouabain On

Recovery From : NH<sub>4</sub><sup>+</sup> - Dilatations.

Recovery from NH<sub>4</sub><sup>+</sup> dilatation was generally a little slower than control, but not dose - dependently, Table G.

Washout Constriction

Ouabain powerfully retarded recovery from the acid induced constriction at all the concentrations employed Table G. There was no change in the degree of retardation with 10<sup>-5</sup>M ouabain at 37°C (not tabulated).

Fig. 28: Amiloride: effect on tone in Na<sup>+</sup>, L<sub>1</sub><sup>+</sup> and K<sup>+</sup> (140mM). 10<sup>-4</sup>M amiloride introduced in Na<sup>+</sup> and Na<sup>+</sup> substituted (L<sub>1</sub><sup>+</sup> and K<sup>+</sup>) H<sub>2</sub>PO<sub>4</sub><sup>-</sup> Ringer's reduced tone to about a third even in total Na<sup>+</sup> substitution with L<sub>1</sub><sup>+</sup>. Asterisks indicate significant difference from control tone (normal Na<sup>+</sup> Ringer's).

### Retardation of Adaptation from Alkali/Acid Load in Ouabain

Dose (M)	% in alkaline load (4 mins)	% in acid load (8 mins)
10 <sup>-8</sup>	+16	+575
10 <sup>-7</sup>	-5	+682
10 <sup>-6</sup>	+53	+828
10 <sup>-5</sup>	+85	+672
10 <sup>-4</sup>	+67	+891
10 <sup>-3</sup>	-5	+925

Table G: o/o-age recovery rates from NH<sub>4</sub><sup>+</sup> dilatation and washout constriction of different ouabain concentrations (10<sup>-8</sup> - 10<sup>-3</sup>M). cf caption to table F.

### PART III

#### Ion Fluxes

Fig. 29A illustrates both efflux and content curves and the rate quotients of a typical experiment in which four 3 mins.  $\text{NH}_4^+$  pulses were applied to  $^{36}\text{Cl}$  - loaded arterial preparations.

There was no significant change in the rate of  $^{36}\text{Cl}$  efflux when the arterial preparations were immersed in 30mM -  $\text{NH}_4\text{Cl}$  medium nor when they were subsequently washed in Ringer (7.2). Thus neither intracellular alkalization due to  $\text{NH}_4^+$  application nor acidification due to washout, had any significant influence on the outward movement of  $\text{Cl}^-$ .

Fig. 29B illustrates the results obtained when  $\text{pH}_0$  was varied. After loading in  $^{36}\text{Cl}$  labelled  $\text{H}_2\text{PO}_4^-$  - Ringer (7.2), the arterial preparations were sequentially washed in  $\text{pH}_0$ 's 7.2, 6.7 and 7.7. There was no significant effect on  $^{36}\text{Cl}$  efflux when  $\text{pH}_0$  varied. Tissues in both 29A and B were non-activated.  $\text{NH}_4^+$  - pulses had no greater effects, however, in other  $^{36}\text{Cl}$  efflux experiments in which tissues were activated continuously, throughout the efflux with  $10^{-6}\text{M}$  NA.

Fig. 29C is a typical result obtained with varied  $[\text{K}^+]_0$ . After loading in the normal control Ringer's (6mM- $\text{K}^+$ ), the tissues were washed sequentially in inactive control, 0-K and in high -  $\text{K}^+$  Ringers. Yet again it will be seen that the ionic modifications were without significant effect on  $^{36}\text{Cl}$  efflux.

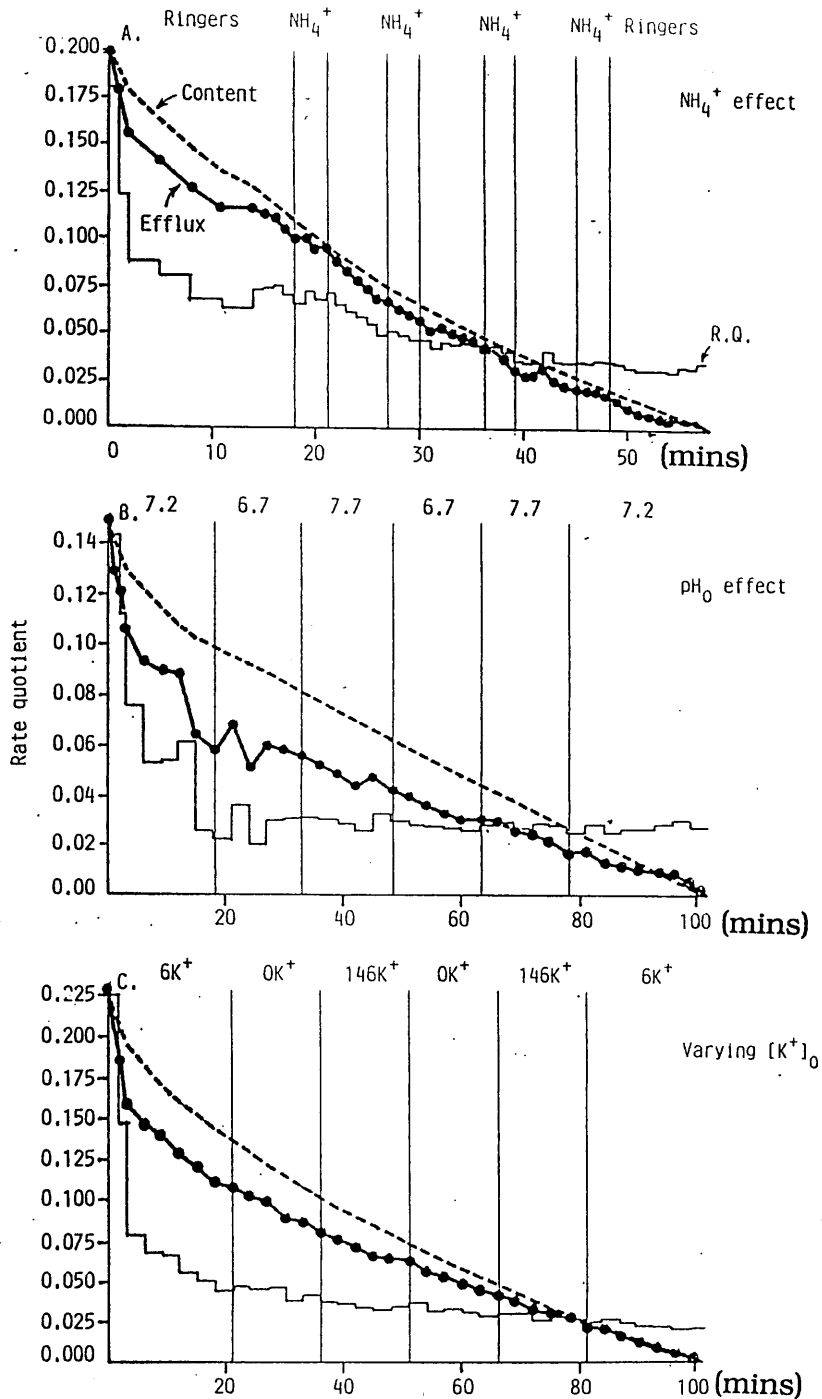

$^{36}\text{Cl}$  efflux (mixed arterial preparation)

Fig. 29A, B and C: Log (efflux), log (tissue content) and rate quotients (RQ) plots of typical  $^{36}\text{Cl}$  washout experiments performed on mixed arterial preparations. For clarity, in this and subsequent efflux curves ordinates are calibrated in terms of rate quotients (RQ) only, and only the lines linking count-points (not the points themselves) for the content curve are shown. S.E.'s of all counts were not greater than one line-width on the efflux plot. A:  $\text{NH}_4^+$  effects; B:  $\text{pH}_0$ ; C: effects of varying  $[\text{K}^+]_0$ . None of the three media modifications significantly affect Cl efflux.

### $^{45}\text{Ca}$ Efflux

Figs. 30 A & B show two typical sets of  $^{45}\text{Ca}$  efflux, content and rate quotient curves when  $\text{pH}_i$ 's of mixed arterial preparations were modified using the  $\text{NH}_4^+$  pulses. Experiment A consisted of four 3 min.  $\text{NH}_4^+$  pulses applied to non-activated tissues while B consisted of a long (15 mins.)  $\text{NH}_4^+$  pulse applied to a preparation which was NA ( $\sim 10^{-6}\text{M}$ ) - activated throughout the efflux. In both instances there was no significant influence on  $^{45}\text{Ca}$  efflux by either intracellular alkalization or acidification.  $\text{NH}_4^+$  - pulse experiments done on preparations continuously stimulated with high  $\text{K}^+$  produced similar results to those illustrated for a preparation activated by NA.

$\text{pH}_o$  variations also produced no significant results, (Figs. 30C and D). 'C' illustrates a typical result obtained with a mixed arterial preparation while D illustrates one obtained with aortic strips (used separately to reduce the mass of individual experiments because of very high activity of the  $^{45}\text{Ca}$  load solution). In each case the tissues after loading in  $^{45}\text{Ca}$  - labelled  $\text{H}_2\text{PO}_4^-$  - Ringer's were washed in 7.2, 6.7 and 7.7  $\text{H}_2\text{PO}_4^-$  - inactive Ringer's. Both 'C' and 'D' show similar final rate quotients. In D it took a longer time for the RQ to settle down, probably due to the lower ratio of smooth muscle mass to connective tissue in the aorta. Yet again, the experimental interactions (here  $\text{pH}_o$  changes) were without reproducible effect.

Fig. 30A, B, C and D: Log (efflux), log (tissue content) and RQ plots of typical  $^{45}\text{Ca}$  washout experiments performed on mixed arterial preparation A and B  $\text{NH}_4^-$  effects.

A: four 3 mins  $\text{NH}_4^-$  pulses; B: one 15 mins  $\text{NH}_4^+$ ; C:  $\text{pH}_0$  effect and D:  $\text{pH}_0$  effect on aortic strips. There was no significant  $\text{Ca}^{2+}$  efflux in any of these variations.

$pH_0$ :  $^{45}\text{Ca}$  efflux (mixed arterial preparation)

### $^{45}\text{Ca}$ Uptake

Figs. 31 A, B and C are bar plots showing the pooled results of  $n=11, 19$  and  $13$   $^{45}\text{Ca}$  experiments respectively. In A pre-loading equilibration was in  $\text{O-Ca}^{2+}$  Ringer and in B equilibration was in normal Ringer's both non-activated. In A there was no significant difference in  $^{45}\text{Ca}$  uptake during the  $\text{NH}_4^+$  - or post- $\text{NH}_4^+$  phases, relative to that in the pre- $\text{NH}_4^+$  phase. By contrast in B there was significantly ( $P<0.05$ ) less isotope uptake in the post- $\text{NH}_4^+$  phase.

Uptake was clearly more in all phases of the  $\text{NH}_4^+$  cycle when the tissues had been equilibrated in  $\text{O-Ca}^{2+}$  Ringer's instead of normal Ringer's.

Activation with NA significantly reduced  $^{45}\text{Ca}$  uptake in both the  $\text{NH}_4^+$ - ( $P<0.01$ ) and post- $\text{NH}_4^+$  ( $P<0.05$ ) phases, relative to that in the pre- $\text{NH}_4^+$  phase, (Fig. 32C). The reduction during  $\text{NH}_4^+$  was to a value only just greater than  $1/2$  of that during post- $\text{NH}_4^+$  phase. Note, however, that part of the contrast between this result and that in non-activated Ringer's - equilibrated tissue arises because the 'pre- $\text{NH}_4^+$ ' uptake by the activated tissue is greater.

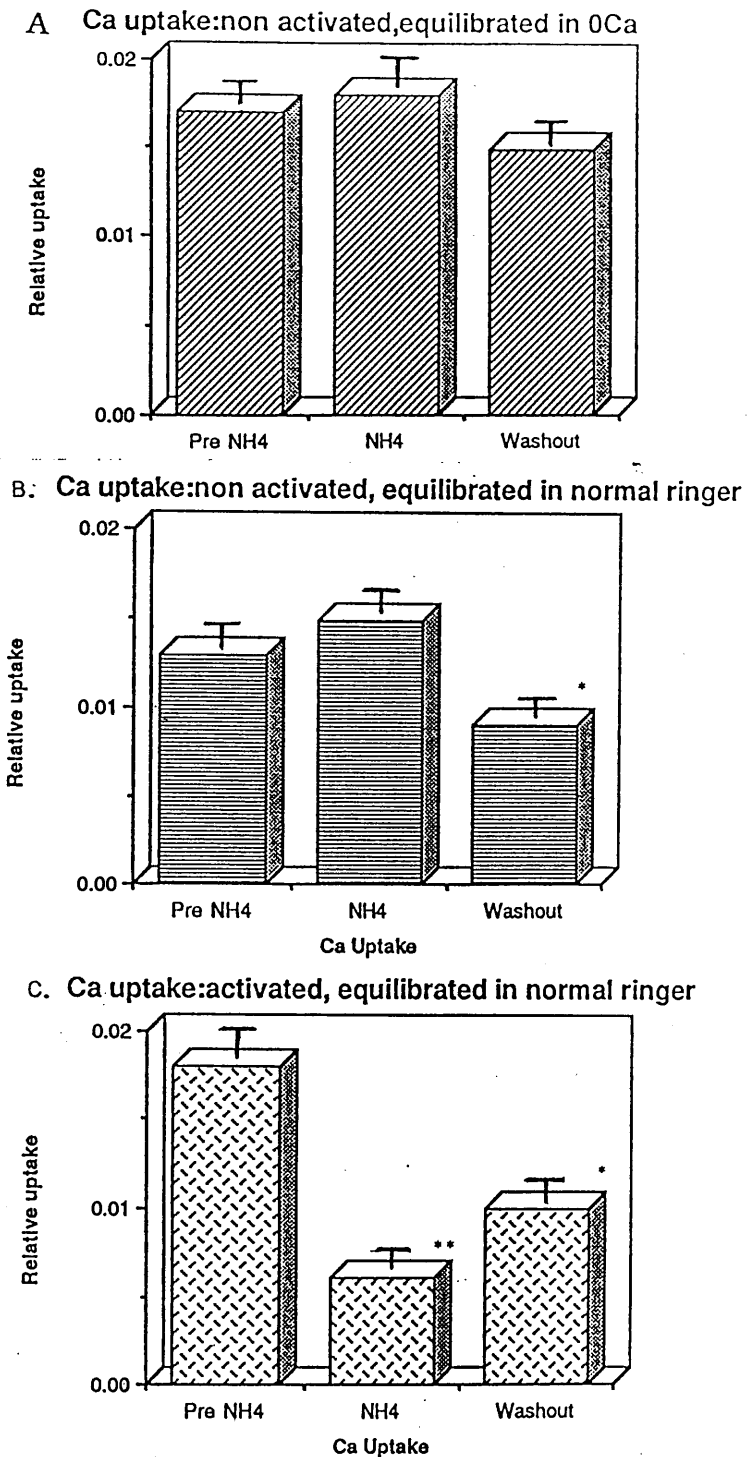

Fig. 31A, B and C: Pooled plots of relative  $^{45}\text{Ca}$  uptake of mixed arterial preparations. A: 11 experiments in which tissues were pre-equilibrated in  $0\text{-Ca}^{2+}$ , not activated before  $^{45}\text{Ca}$  loading. B: 19 experiments, non-activated and equilibrated in normal Ringer's and C: 13 experiments, NA ( $10^{-6}\text{M}$ ) activated equilibrated in normal Ringer's. Asterisks indicate significant uptake relative to pre- $\text{NH}_4^+$  phase. No significant difference in  $\text{Ca}^{2+}$  uptake during or post- $\text{NH}_4^+$  phases in A. In B, there was significantly less uptake in post- $\text{NH}_4^+$  phase. In C,  $\text{Ca}^{2+}$  uptake was

## CHAPTER IV

### DISCUSSION

#### Dependence Of Tone On pH.

##### pH<sub>o</sub>

During extracellular acidification vascular tone decreased and during extracellular alkalinization it increased; The only exception will be discussed at the end of this subsection. The physiological advantages of the normal result were seen already by Gaskell (1880). They are that blood vessels will dilate to increase perfusion locally, during regional acidosis caused by production of metabolites such as lactic acid or CO<sub>2</sub>; And they will also dilate more generally to maintain flow as the heart is weakened by systemic acidosis.

The mechanisms, however, of pH<sub>o</sub> effects are still unclear, one proposed mechanism is that H<sup>+</sup> ions enter the cell and displace Ca<sup>2+</sup> from sites at which it activates contraction (Peiper et al 1976; Duling, 1977). This Ca<sup>2+</sup> - displacement mechanism is best demonstrated in skeletal and cardiac muscles [Fabiato and Fabiato, 1978 b], in which the site of the Ca<sup>2+</sup> ion's activation is, of course, troponin. In smooth muscle, according to current views, the principal site of activation is calmodulin (Grand et al, 1979). Nevertheless, some evidence for a pH effect on the smooth muscle contractile proteins, parallel to that seen in striated muscle, has been put forward (Peiper et al 1976, Duling 1977, Mrwa et al 1974). In the light of this evidence, it is relevant to draw early attention to the fundamental finding of this Thesis:

That the overall effect of  $\text{pH}_i$ -change in VSM is in the opposite direction to that, reported by the above authors, on the isolated contractile proteins. A possible mechanism by which  $\text{pH}_i$  actually operates will be discussed later. Meanwhile, the finding itself excludes the proposal that the normal vasodilatory effect of extracellular acidity is mediated by protons which have entered the smooth muscle cells. The argument is developed below.

In this connection, it is interesting that several observations appear to exclude the involvement of just one mechanism, even for the striated - muscle instances; for example when  $\text{pH}_0$  was altered by changes in external  $\text{CO}_2$  in mammalian cardiac cells (Ellis & Thomas, 1976a) and mouse soleus muscle (Aicken & Thomas, 1977), the resulting  $\text{pH}_i$  changes were monophasic yet the changes in tension they generated were biphasic (Fry & Poole-Wilson, 1981); And even though intact skeletal muscle is less sensitive than cardiac muscle to  $\text{pH}_0$  changes (Pannier, Weyne & Lensen; 1970) the  $\text{Ca}^{2+}$  sensitivity of the contractile proteins was highly affected by pH (Fabiato and Fabiato, 1978 a and b).

In my own, vascular experiments,  $\text{pH}_0$  sensitivity increased with increasing  $[\text{Ca}^{2+}]_0$  up to  $1.5\text{mM-Ca}^{2+}$  and then fell with further increasing  $[\text{Ca}^{2+}]_0$  (Fig. 19C); So the mechanism of  $\text{pH}_0$  action appears to depend on  $[\text{Ca}^{2+}]_0$ . The effect of  $\text{Ca}^{2+}_0$  itself on tone is illustrated in Fig. 7A. Tone increased with increasing  $[\text{Ca}^{2+}]_0$ .

The results illustrated in Fig. 29B and 30C and D provided no evidence that either  $\text{Cl}^-$  or  $\text{Ca}^{2+}$  efflux is responsible for the fundamental  $\text{pH}_0$  effects. It would have been interesting to study the effects of  $\text{pH}_0$  on  $^{45}\text{Ca}$  uptake, but time did not allow this.

The results obtained in Hepes - buffered  $\text{PhSO}_3^-$  Ringer's indicates an anion - dependence not merely of the magnitude of the  $\text{pH}_0$  effect (McLellan et al, 1974) but of it's direction. Hepes probably penetrates or seeps slowly into the cell in both  $\text{Cl}^-$  and  $\text{PhSO}_3^-$ . But since in  $\text{Cl}^-$  solutions the extracellular pH (acid dilatation) dominates, there is little indication of the buffer entry. In  $\text{PhSO}_3^-$ , however, the residual  $\text{pH}_0$  mechanism is too weak to counteract, the consequences of  $\text{pH}_i$  change. These consequences have been extensively documented in the main part of this Thesis. Meanwhile it is necessary to point out that the opposing buffer - dependent effects of  $\text{pH}_0$  - change in  $\text{PhSO}_3^-$  are explicable in the above terms only if  $\text{H}_2\text{PO}_4^-$  buffer penetrates VSM cells less than Hepes. The latter molecule is much larger but might have lipid solubility, or carrier affinity. So the suggestion, though speculative, does not seem impossible.

### $\text{pH}_i$

The effect of replacing a nominally bicarbonate - free medium with one containing  $\text{CO}_2/\text{HCO}_3^-$  is intracellular acidosis. Now the tone - responses obtained when  $\text{CO}_2/\text{HCO}_3^-$  replaced phosphate

buffer were similar to those obtained in  $\text{PhSO}_3^-$ /Hepes media i.e. increase in tone with lowered pH. They were also similar to those of Pickard and colleagues (e.g. 1976), when, starting with a low - molarity  $\text{CO}_2/\text{HCO}_3^-$  buffer they raised both  $[\text{HCO}_3^-]$  and  $\text{P}_{\text{CO}_2}$  together, and so lowered  $\text{pH}_i$  without altering  $\text{pH}_o$ . However, as the earlier authors pointed out, in  $\text{CO}_2/\text{HCO}_3^-$  - based experiments, the possibility cannot be excluded that direct molecular interactions of  $\text{CO}_2$  at intracellular sites account for the increase in tone observed when  $\text{P}_{\text{CO}_2}$  is elevated.

The other method of  $\text{pH}_i$  modification is that of the " $\text{NH}_4^+$  pulse" technique. The fundamental  $\text{NH}_4^+$  pulse result is a decrease in tone when the inside of the cell is driven alkaline by  $\text{NH}_4^+$  application and an increase when it is driven acid by the subsequent removal. Intracellular acidification therefore produces similar results to those when  $\text{CO}_2/\text{HCO}_3^-$  replaced  $\text{H}_2\text{PO}_4^-$ . However they were opposite to those produced in cardiac muscle in response to  $\text{pH}_i$  changes or those produced by  $\text{pH}_o$  modifications in both cardiac and (with the single exception discussed above) vascular smooth muscle. The fact that the changes in  $\text{pH}_i$  produced by the  $\text{NH}_4^+$  - method are in the direction implied above was confirmed by Spurway and Wray (1987) using the N.M.R. technique.

Even given that the  $\text{pH}_i$  behaviour is what had been assumed,

the changes in tone due to the application and withdrawal of  $\text{NH}_4^+$  are not fact total proofs of an intracellularly mediated mechanism. It can be argued that these results may actually be mediated through  $\text{pH}_0$  effects, for when  $\text{NH}_3$  enters the cell it must briefly leave the extracellular medium acid and when  $\text{NH}_3$  leaves it must drive the external medium briefly alkaline. The time courses of the changes in tone however argue against this mechanism, as they are similar to those of  $\text{pH}_i$  in VSM itself (Spurway & Wray, 1987) and also in squid giant axons (Boron & De Weer 1976a), mouse soleus muscle (Aicken & Thomas 1977) and in snail neurons (Thomas 1984).  $\text{pH}_0$  would vary in the opposite direction to these but not on the same time - course. The difference arises because the extracellular space was not a confined volume but was being constantly renewed. Therefore the  $\text{pH}_0$  displacement would have been greatest when  $\text{NH}_3$  was leaving or entering the ECS fastest, and would have declined to zero again when  $\text{pH}_i$  levelled off at its maximum or minimum: i.e. the  $\text{pH}_0$  change would have been effectively the differential of the  $\text{pH}_i$  change and so several times more rapid than the tone - responses observed.

My experiments on the effects of identical  $\text{NH}_4^+$  pulses in different molarities of external buffer point to the same conclusion. Hepes was used, in case the molarity had to be raised sufficiently for interactions with  $\text{Ca}^{2+}$  to become a problem in  $\text{H}_2\text{PO}_4^-$ . The

principle underlying the experiments was that the  $pH_0$  changes would be bigger, and last longer in low capacity buffers. In fact the responses were slower and a decrease in external buffer concentration decreased the magnitude of the response to  $NH_4^+$  washout. Thus the possibility that the changes in tone due to  $NH_4^+$  application and its withdrawal might be mediated by changes in  $pH_0$  is eliminated.

At this point it is appropriate to take stock and say that if the apparent intracellular pH actions are not due to antiphase  $pH_0$  changes, then they really are intracellular, and really are pH actions opposite in direction to those of extracellular pH. These are the grounds upon which the assumption previously made by some authors (cf pp 5 and 121 above) that the site of action of  $pH_0$  is intracellular, brought about by the follow-up drift of  $pH_i$  occurring in most buffers, must be considered incorrect.

In fact other experiments described in this Thesis suggest that any interaction between  $pH_0$  and  $pH_i$  is very modest. Typically in an externally alkaline media the dilatations induced by intracellular alkalinisation were larger, with the recovery from them retarded (Fig. 20E). The acid - induced constrictions were reduced and the recovery from them enhanced. The reverse was the case in an acidic  $pH_0$ . At first sight, these results might suggest that non-neutral  $pH_0$ 's favoured  $pH_i$  changes in the same direction. One must recall however, that starting tone in an alkaline  $pH_0$  was

higher than in an acid one. I shall demonstrate in the next subsection that this difference of starting tone was itself sufficient to ensure that the relaxations obtained in alkaline  $pH_0$  would be larger, with slower recoveries and smaller overshoots, than those in acid media - and that the washout constrictions should behave conversely.

#### Relationship Of Starting Tone To $NH_4^+$ Dilatation and washout constriction

Replacing  $Cl^-$  with  $PhSO_3^-$  and different smaller anions (Cameron 1985, Cameron and Spurway 1985) raised mean tone but enhanced  $NH_4^+$  relaxation while reducing the washout constrictions. On the other hand  $12-K^+$  and  $0-Ca^{2+}$  both lowered mean tone and reduced the  $NH_4^+$  dilatation while greatly enhancing the washout constriction. In simultaneously  $0-Ca^{2+}$  and  $0-K^+$ , metabolically inhibited and also in the non-activated preparations mean tone was sometimes so low as to prevent further dilation with  $NH_4^+$ , allowing only the washout constriction, (Fig. 8). The results obtained with amiloride (decreased mean tone, reduced  $NH_4^+$  dilatation and enhanced washout constriction:) are comparable to those discussed above. So are the effects of  $pH_0$  on the  $NH_4^+$  response (last subsection). Although there was inevitably a large biological variation in the tones of the arterial preparations, the facts just, collected - all of which are based on comparisons of at least two conditions within an

individual preparation, give use to the generalization that the ratio of the  $\text{NH}_4^+$  dilatation to the washout constriction,

$\frac{\text{NH}_4^+ \text{ dilatation}}{\text{Washout constriction}}$  increases with starting tone.

This relationship between the starting tone and the  $\text{NH}_4^+$  effects can be explained in terms of a typical activation curve (Fig. 32). If one assumes that a change in  $\text{pH}_i$  alters relative  $\text{Ca}^{2+}$  availability within the VSM by a fraction which does not depend greatly on the starting value (For diagramatic purposes, does not depend on it at all), then  $\text{pH}_i$  effect on tone will depend on the starting value, in the way observed. With a small degree of or no activation, starting tone is small therefore  $\text{NH}_4^+$  relaxation is small, with fast spontaneous recovery and a big overshoot on washout. On the other hand, with a high degree of activation starting tone is large therefore  $\text{NH}_4^+$  relaxation is enhanced with slower recovery and smaller overshoot on washout. In Table H are a list of various experimental conditions that either increase or decrease starting tone in which the above generalization applies.

Note that this hypothesis represented in Fig. 32 implies that intracellular acidification increases available  $[\text{Ca}^{2+}]_i$ . This concept will be elaborated below.

Fig. 32: Diagrammatic interpretation of the dependence of  $\text{NH}_4^+$ -dilatation and washout constriction upon mean tone; vascular tone against  $\text{pCa}_i$  and  $\text{pNA}$ .  $\text{pCa}_i$  represents activation (variously); ' $\text{pNA}$ ' (log conc. of NA) that would produce the equivalent  $\text{pCa}^{2+}$  in normal Ringer's. Arrows indicate the effects of  $\text{Ca}^{2+}$  excursions (presumably induced by entry) and subsequent washout of  $\text{NH}_3$  on different starting values. Excursions to the left ( $\text{NH}_4^+$  application) and right (washout) are chosen to give similar amplitudes of change in tone in the two directions in  $10^{-6}\text{M}$  - NA. The same excursions will give unequal changes in tone at other starting points on the activation curve.

**Table H:** List of experimental conditions that would reduce ( $\downarrow$ ) or raise ( $\uparrow$ ) mean tone (M.T.) and satisfy the sigmoid curve (cf Fig. 32) generalization.

Experimental variation	Activation point on sigmoid curve	
	Low ( $\downarrow$ M.T.)	High ( $\uparrow$ M.T.)
O - K <sup>+</sup> , O - Ca <sup>2+</sup> Non activated preparations Acid pH <sub>o</sub> medium Alkaline pH <sub>o</sub> medium Cl <sup>-</sup> substitution with pHSO <sub>3</sub> <sup>-</sup> Na <sup>+</sup> substitution with K <sup>+</sup> sucrose choline lithium	$\downarrow$ $\downarrow$ $\downarrow$	$\uparrow$ $\uparrow$ $\uparrow$ $\uparrow$ $\uparrow$
O - Ca <sup>2+</sup> Application of amiloride High K <sup>+</sup> (30, 50mM) + NA 12 -K <sup>+</sup>	$\downarrow$ $\downarrow$ $\downarrow$	$\uparrow$

Which Cells Are The Loci Of Action Of  $\text{NH}_4^+$  Induced  $\text{pH}_i$  Changes?

It is assumed in other sections of this Thesis (including the one immediately above) that the site of action of  $\text{pH}_i$  is the smooth muscle cytoplasm. In the present subsection arguments will be given to justify this, by showing that the site is not neural and probably not endothelial.

Exogenous activators such as noradrenaline and high potassium greatly accentuate the  $\text{NH}_4^+$  phenomena and therefore virtually eliminate the possibility that they might depend on variations in vasomotor activation. The results obtained with chemically sympathectomised preparations support this view; The 10-fold increase in sensitivity to noradrenaline of the OH - dopaminised animals is indicative of a substantial degree of functional denervation. Yet in these groups of animals the responses to  $\text{NH}_4^+$  and its withdrawal were not detectably changed.

The results obtained with Hb, MeB and dist.  $\text{H}_2\text{O}$  in investigating the possibility that the  $\text{NH}_4^+$  effects depend on the endothelium - derived relaxing factor (E.D.R.F.) were less conclusive. However, those with MeB suggest firmly that the  $\text{NH}_4^+$  effects do not depend on E.D.R.F. Therefore the results obtained with dist.  $\text{H}_2\text{O}$  and to a lesser extent those with Hb (very old stock) may be taken to indicate that endothelial and direct muscular responses are not as easily separated by these agents in the vascular bed of the rabbit ear as in the aortae used by Furchgott et al (1985). The aorta, unfortunately was the least susceptible to

$\text{NH}_4^+$  of the variety of blood vessels studied by Taggart (1986) who performed similar  $\text{NH}_4^+$  experiments to my own but on a variety of other blood vessels. Therefore  $\text{NH}_4^+$  experiments in a preparation which E.D.R.F. - dependent mechanisms can be more clearly separated do not seem likely to be easy. Nevertheless, in the light of the results obtained with MeB, a reasonable assumption is that the site of action of  $\text{pH}_i$  upon vascular tone is neither nerve nor endothelium but the smooth muscle cell itself.

#### Within V.S.M. Cells, Where Does pH Act?

It cannot be at cell - surface NA receptor site that  $\text{NH}_4^+$  acts, since there was a full response also in  $\text{K}^+$  - activated [O-NA] vessels, and at the appropriate part of the response in non - activated ones.

A further conclusion from the results in this Thesis is that the critical  $\text{pH}_i$  action which produces the  $\text{NH}_4^+$  effects is not an action on the plasma membrane permeability or potential. If it was dependent on these two, the basic  $\text{NH}_4^+$  effects would not have been only quantitatively but also qualitatively different in the wide variety of membrane active agents employed, and compared with normal Ringer's. These agents include,  $\text{K}^+$  (various concentrations),  $\text{Li}^+$  and choline; permeant 'lyotropic' (Cameron & Spurway 1985) and impermeant very weakly lyotropic ( $\text{PhSO}_3^-$ ) anions; Sucrose, in which over 90% of the total ions were

displaced - all agents listed representing different kinds of permeability- and potential-modifiers. Such quantitative differences as these various substitutions caused, in the relative magnitudes of  $\text{NH}_4^+$  - dilatation and washout constriction phases, could all be adequately accounted for in terms of the shifts; They caused in the degree of background, pre- $\text{NH}_4^+$  activation; They did not give reason to think that the  $\text{pH}_i$  effect itself was a membrane one.

Despite Wahlstrom's (1973-4) evidence that a major part of the response to NA consisted in an increase of  $P_{\text{Cl}}$ , the results illustrated in Fig. 29 provided no evidence that  $\text{Cl}^-$  flux or  $\text{Cl}^-$  - dependent  $\text{K}^+$  flux is responsible for the fundamental pH effects.  $P_{\text{Ca}^{2+}}$  does not look as though it is changing either (otherwise one would expect  $^{45}\text{Ca}$  efflux to respond to  $\text{pH}_i$ ). Additionally the possibility that  $\text{pH}_i$  might modulate tone via an action on metabolism is excluded. The  $\text{NH}_4^+$  effects were not altered by hypoxia or hyperoxia. However, Namm & Zucker (1973); and Coburn et al, (1979) have shown that rabbit blood vessels can draw sufficient energy from store for contraction during anoxia. Perhaps therefore the more telling finding is that the severe metabolic inhibition produced by 3mM  $\text{CN}^-$  and 1mM  $\text{F}^-$  produced no alterations in the relative tone effects of  $\text{NH}_4^+$  application and it's subsequent withdrawal (Fig. 14), except the small reduction of the dilatation/constriction ratio which was to be expected on the basis

of diminished mean tone. There are signs that  $[Ca^{2+}]_i$  is responding to  $pH_i$ . The O- $Ca^{2+}$  equilibration, followed by only 3 mins.  $^{45}Ca$  loading, is bound to give much less striking  $NH_4^+$  - dependent differences (Fig. 31A) because much of the 3 mins. will be taken up with reloading of the ECS with  $^{45}Ca$ . However, there is decreased uptake during  $NH_4^+$  washout. This could be attributed to the cells having higher free  $[Ca^{2+}]_i$  during this phase. In NA - activated tissues,  $[Ca^{2+}]_i$  (ionised calcium, free in the cytoplasm) should be higher at all phases than it was in the above situations. So any greater cellular uptakes must be onto intracellular stores. In the non - activated tissues, there is less complication due to exchange with intracellular stores of unionized  $Ca^{2+}$  going on throughout the 3 mins. A tentative explanation of my results with NA - activated tissues (Fig. 31C) (in which uptake was greatly reduced in both the  $NH_4^+$  - and post  $NH_4^+$  - phases) is that the passage of  $^{45}Ca$  through cytoplasm onto those stores was optimal at normal  $pH_i$ . At high  $pH_i$  these stores would not have released much unlabelled  $Ca^{2+}$ , so would take up little  $^{45}Ca$ . At low  $pH_i$  they would have little affinity for any  $Ca^{2+}$  labelled or otherwise. (Such an hypothesis has the merit that it could be checked by investigating the effects of pH on  $^{45}Ca$  uptake by isolated smooth - muscle microsomes.) My  $^{45}Ca$  experiments while far from conclusive, do therefore appear compatible with the concept that a change in  $pH_i$  induces a change in  $[Ca^{2+}]_i$ .

### Proposed Intracellular Loci of $H^+$ - $Ca^{2+}$ Interaction

Changes in  $pH_i$  can alter  $[Ca^{2+}]_i$  (Bers & Ellis 1982) and vice versa (Vaughan - Jones et al 1983), due probably to the fact that  $Ca^{2+}$  and  $H^+$  both share and compete for common intracellular buffering sites (Meech & Thomas 1977).

Intracellular  $H^+$  can displace  $Ca^{2+}_i$  from all binding sites, therefore the effect of intracellular  $H^+_i$  on tone would most certainly depend on the dominant site. As discussed earlier (pp- 5, 12) a displacement from (1) the myofibrils themselves would tend to decrease tone. However, (2) displacements from the sequestering sites e.g. mitochondria, sarcoplasmic reticulum (S.R.) and inner surface of plasma membrane would all tend to raise tone. Both (1) and (2) must occur in parallel in the various muscle types, though (1) has been better documented; Smooth, (Mrwa et al, 1974) or both classes of striated muscle (Fabiato & Fabiato, 1978). Since intracellular acidification reduces the force of contraction generated by intact skeletal (Pannier et al 1970; Curtin & Rawlinson, 1984;) and cardiac (Pannier & Leusen, 1968; Allen & Orchard, 1983), fibres, the predominant displacement of  $Ca^{2+}_i$  would be considered to be from the myofibrils. Both the myofibrils and the  $Ca^{2+}$ -regulation of smooth muscle force-generation is chiefly via calmodulin and myosin light chain kinase (MLCK) bringing about phosphorylation of MLC's - not  $Ca^{2+}$  detecting thin filaments.  $Ca^{2+}$  stores of smooth muscle respond orders of magnitude more strongly to 2nd messengers (released by membrane actions of NA etc) than those of cardiac

cells, let alone skeletal. However the results I have obtained in the vascular preparations studied would be readily explicable if, in these cells (2) above predominated. So my suggestion is that  $[Ca^{2+}]_i$  is increased by an acidic  $pH_i$ , so much that the calmodulin binds more  $Ca^{2+}$ , inspite of it's reduced affinity; the ultimate consequences being greater myosin phosphorylation and higher tone not lower.

In skeletal muscle,  $Ca^{2+}_i$  release is supramaximal, therefore a mechanism equivalent to that of (2) above could not possibly operate in normally activated skeletal muscle. On the other hand, cardiac muscle exhibits the two conflicting effects, though the opposite one from that of the vascular smooth muscle normally predominates. Gesser (1984) has also observed that fish heart increased its contractility at a high  $P_{CO_2}$  in low  $[Ca^{2+}]_o$  and hypoxia, which indicates that even in cardiac muscle two conflicting mechanisms exist. By contrast in frog blood vessels the  $NH_4^+$  effects were opposite to those in VSM and were in the same direction as  $pH_o$  (Fig. 17).

### Experimental Details

The responses to  $CO_2$  were relatively slower than those to  $NH_4^+$ . The reason for this may lie in the occurrence of a period of equilibration of the  $P_{CO_2}$  between the perfusing solution and the polythene tubing, about a metre in length, which lay between the gassed reservoir and the preparations. It seems likely that this

equilibration process would last many times longer than any equivalent for  $\text{NH}_3$ .

Most of the experiments were carried out at room temperature, however there need be no thought that pH effects on tone occur only at subphysiological temperatures since (a) a series of experiments carried out at  $37^\circ\text{C}$  did not alter these basic pH effects (Fig. 16) on tone qualitatively, (b) the rabbit's ear (which functions as a cooling apparatus) maintains vascular control at considerably lower temperature than room temperature. The ear artery has almost identical sensitivity to catecholamines throughout the temperature range  $37^\circ\text{-}20^\circ\text{C}$  and retains detectable sensitivity even at  $5^\circ\text{C}$ . (Glover et al 1967).

In considering the relationship between vascular smooth muscle tone and vascular wall tone the possible influence of the connective tissue must not be overlooked. However, in the muscular arteries and arterioles which are the main source of resistance in the preparations studied, it is probable that the connective tissue contribution becomes significant only when the smooth muscle tone itself is lowest. This might be an alternative explanation to that represented in Fig. 32, for the weak responsiveness to  $\text{NH}_4^+$  application of non-activated (O-NA) preparations (Fig. 4). Most probably, both factors contribute.

The late overshoot or undershoot observed in some experiments best described in terms of results typically obtained with long (10-20mins)  $\text{NH}_4^+$  pulses, are perhaps not obviously

explicable. A likely explanation however is that membrane distribution ratio of  $\text{NH}_4^+$  can only come to equilibrium when it equals that of  $\text{K}^+$ . So more  $\text{NH}_4^+$  will enter in phase A of (Fig. VI) and be available to leave in B, than was required to neutralize the  $\text{NH}_3$  concentrations required (cf p. 10). Thus during phase A  $\text{NH}_4^+$  entry displaces intracellular  $\text{K}^+$  - with consequent depolarizing, and therefore tone - enhancing, effect on the cell. In addition, analogies from other tissues make it almost certain that the presence of  $\text{NH}_4^+$  ions reduces  $P_K$  from its normal value (Hagiwara & Takahashi 1974, Zeiske & Van Driessche, 1983). This would be a further depolarizing influence as  $[\text{NH}_4]_i$  builds up. A reinforcing feature of this explanation, for the tendency of tone not merely  $\text{NH}_4^+$ , is that the overshoot effects ought to be both more marked and more rapid when tone is itself  $\text{K}^+$ - induced than when it depends predominantly on  $\text{K}^+$  - activated preparations.

#### Relevance of $\text{pH}_i$ for Vascular Control

The effect of acidosis is of paramount importance in the brain summarised by Severinghaus (1968): "The arteriolar smooth muscle taste their extracellular fluid pH and pucker up when is not sour enough." Several vascular beds, notably not only the cerebral (see also Kontos, 1981) but probably also the coronary (Case & Greenberg, 1976) are dilated by  $\text{CO}_2$ . However it's effect on skeletal muscle blood flow is small in mammals (Sparks & Belloni,

**Fig. VI**

1978) despite the fact that Gaskell (1880) first observed dilator effects of extracellular acidity in skeletal muscle beds of frogs. On the other hand vasoconstrictive effects of  $\text{CO}_2$  have actually been reported in the extracranial vessels of the head (Hachinski, et al 1981) and in denervated vessels of bat's wing (which depend only on the chemical responses of the smooth muscle), [Harris, et al 1976]. By contrast,  $\text{CO}_2$  dilated innervated bat wings. Kontos, et al (1977) have shown, by pooling their own results with those of others, that in the cerebral circulation itself, a given reduction of  $\text{pH}_0$  produced greater dilatation when  $[\text{HCO}_3^-]_0$  was lowered than when  $\text{P}_{\text{CO}_2}$  was elevated.

The concept of  $\text{pH}_i$  and  $\text{pH}_0$  affecting tone oppositely seems potentially applicable to all the cases discussed above with perhaps, the conflicting actions having different potencies in different sites/species. However, only a careful comparison of  $[\text{HCO}_3^-]$  - variation with  $\text{P}_{\text{CO}_2}$  - variation, conducted within a single laboratory, will prove the relevance of this concept to physiological control of blood flow in intact animals.

### $\text{pH}_i$ Homeostasis

Most studies of the mechanisms involved in the regulation of  $\text{pH}_i$  have been carried out only during recoveries from acid loads. One advantage of the  $\text{NH}_4^+$  pulse technique over that of  $\text{CO}_2$  as an experimental tool is the convenience with which  $\text{pH}_i$  regulation

can be studied after both intracellular alkalization and acidification.

### Recovery From Alkaline Load

None of the substitutes for  $\text{Na}^+$  alone (Table E) significantly retarded the recovery of tone from the alkali - induced relaxation. Sucrose did retard it but sucrose substitutes for  $\text{Cl}^-$  as well as  $\text{Na}^+$ . This suggests that the main mechanism of tone - adaptation after  $\text{NH}_4^+$  entry is anion exchange.

In contrast to the effects of the  $\text{Na}^+$  substitutes, replacement of  $\text{Cl}^-$  with impermeant  $\text{PhSO}_3^-$ , substitution of  $\text{HCO}_3^-$  for  $\text{H}_2\text{PO}_4^-$  and the application of S.I.T.S. or amiloride all clearly retarded the recovery from alkali - induced relaxation. These results, with the exception of that involving amiloride, suggest the involvement of a  $\text{Cl}^-$  -  $\text{HCO}_3^-$  exchange system in the adjustment of tone from an intracellular alkali - induced relaxation. The results with amiloride may indicate that  $E_m$  also influences this recovery. Among the many actions attributed to this drug, one is that it decreases  $P_{\text{Na}}$  (e.g. by blocking specific Na - channels in isolated distal nephron segments: Stoner 1979). A hyperpolarizing effect due to amiloride decreasing  $P_{\text{Na}}$  would impede recovery of tone. No other recognized effect of amiloride would act in this direction. Amiloride in a  $\text{HCO}_3^-$  - buffered medium infinitely inhibited recovery - an indication of additive influences of anion exchange and the presumed hyperpolarization. The reduction of adaptation -

rate increased with increasing  $[\text{HCO}_3^-]_o$ , thus a  $[\text{HCO}_3^-]_i / [\text{HCO}_3^-]_o$  gradient appears to act to retard recovery when it is low and vice versa when it is high.

The  $\text{Cl}^- - \text{HCO}_3^-$  exchange appears to control tone by regulating intracellular pH. An inhibition of this exchange would result in the accumulation of  $\text{HCO}_3^-_i$  and therefore an increase in  $\text{pH}_i$ . This would occur even in the  $\text{HCO}_3^-$  - free media, due to metabolic production of  $\text{CO}_2$  (Aicken & Brading 1983). S.I.T.S. the anion exchange inhibitor, applied in  $\text{H}_2\text{PO}_4^-$  - buffering medium, permitted 7% recovery of tone. The fact that this was indistinguishable from the recovery in the  $\text{HCO}_3^-$  - buffered medium (Table E) is assumed to be a coincidence.

$\text{K}^+$  on the other hand actually accelerated recovery rate. In preparations activated purely with  $\text{K}^+$ , tone recovered and overshoot reference value during the  $\text{NH}_4^+$  phase (Fig. 3). This was the case also when starting tone was very low (O-NA) or when the  $\text{NH}_4^+$  phase was long. Now, since  $\text{pH}_i$  could not possibly recover to overshoot its control level while  $\text{NH}_4^+$  was still present, the adaptation of tone may depend, in addition to anion exchanges, on plasma membrane permeability or potential. Depolarization could result from three sorts of  $\text{NH}_4^+ - \text{K}^+$  competitions. These include (1) an intracellular displacement of  $\text{K}^+_i$  by  $\text{NH}_4^+$  resulting in a decreased equilibrium potential for  $\text{K}^+$  ( $E_K$ ) due to a decreased

$[K^+]_o / [K^+]_i$ . (2)  $NH_4^+$  equilibrium potential ( $E_{NH^+}$ ) can never be as negative inside as resting  $E_K$  since  $[NH_4^+]_o$  is more (30mM) than  $[K^+]_o$  (6mM). (3)  $P_{NH^+}$  itself is less than  $P_K$ , (Hagiwara & Takahashi 1974; Zeiske & Van Driessche, 1983). It is also probable that  $NH_4^+$  would decrease  $P_K$ . Both these factors would allow  $Na^+$  gradient to exert a greater depolarizing influence on the membrane. All of mechanisms (1)-(3) would be most relevant when  $K^+$  - depolarization was the only activating influence on the preparation.

Recovery was also faster in ouabain. Ouabain inhibits the  $Na^+$  pump and therefore could influence tone by influencing either  $pH_i$  or  $E_m$  or both. The  $E_m$  effects would simply be depolarization due to cessation of hyperpolarizing electrogenesis and decreased  $[K^+]_i$ . The  $pH_i$  effects will act via a reduction of  $H^+$  extrusion; if a significant rate of  $Na^+-H^+$  exchange is maintained even in an alkaline cell; this would otherwise have competed with and slowed the effect of  $HCO_3^- - Cl^-$  exchange in bailing out alkali load. Therefore decreased proton extrusion would allow  $H^+$  accumulation to act in parallel with alkaline extrusion, re-acidifying the cell faster.

The further mechanism which Aicken and Brading (1982) felt it necessary to postulate to explain certain complex phenomena in their experiments, namely  $Cl_o^-$  - dependent  $Cl^-$  transport, does not seem to be required for an understanding of the results

described in this Thesis.

$\text{Cl}^- - \text{HCO}_3^-$  exchange therefore seems to play a major role in  $\text{pH}_i$  modifications of vascular tone by means of elimination of alkaline load.

### Acid Load.

All the  $\text{Na}^+$  substitutes except  $\text{Li}^+$  retarded the recovery of tone from the acid - induced constrictions, an indication that  $\text{Na}^+$  influx is normally involved in the extrusion of excess protons. On the other hand, when  $\text{Li}^+$  substituted  $\text{Na}^+$ , recovery was actually accelerated. Thus the effects of cations upon proton extrusion - rates appears to correlate with anhydrous radius, suggesting that  $\text{Li}^+$  entry drives out protons more rapidly than  $\text{Na}^+$  entry, but larger cations drive them out more slowly if at all.  $\text{Li}^+$  also increases resting tone in this preparation (Fig. 10) as in others. This effect is widely attributed to  $\text{Li}^+$  being able to enter the cell rapidly ( Van Breeman et al, 1973) but not being extruded by the  $\text{Na}^+$  pump [by analogy with that of frog skeletal muscles (Keynes & Swan 1959).  $\text{K}^+$  being consequently displaced, the cells, it is argued are depolarised and therefore contract. Ellis and MacLeod, (1985) found  $\text{Li}^+$  a fairly good substitute for  $\text{Na}^+$  in sheep purkinje fibre cation -  $\text{H}^+$  exchange. But Aickin and Thomas (1977) found it barely able to drive out  $\text{H}^+$  at all from mouse soleus. So it looks as though there is a sequence of efficacies for Lithium's replacements of  $\text{Na}^+$  on the exchanger - skeletal muscle < cardiac muscle < vascular smooth muscle.

The effect of sucrose is not surprising. It reduces both  $\text{Cl}_0^-$  and  $\text{Na}_0^+$ , therefore effectively eliminating both cation - and anion - dependent mechanisms of  $\text{pH}_i$  compensation.

Amiloride almost completely blocked the recovery of tone from the acid constriction. Amiloride is known to inhibit  $\text{Na}^+ - \text{H}^+$  exchange. It is quite clear from the  $\text{Na}^+$  substitutions in other tissues which could be studied with  $\text{pNa}^+$  and  $\text{pCa}^{2+}$  electrodes. (Thomas, 1984; Aicken, 1986), that  $\text{Na}^+$  very generally exchanges for  $\text{H}^+$  in  $\text{pH}_i$  regulation. Thus the most tempting account of the mechanism of tone - reduction in vascular smooth muscle, after an acid - load constriction is that  $\text{H}^+$  ions are driven out by a  $\text{Na}^+ - \text{H}^+$  antiporter which is inhibited by large cations and by amiloride, but driven faster than normal by  $\text{Li}^+$ . However, in experiments such as described here, where it is tone that is directly observed, the possible involvement of  $2\text{Na}^+ - \text{Ca}^{2+}$  exchange should not be overlooked. Evidence for a similar mechanism in Purkinje fibres has been given by Bers & Ellis (1982); Ellis & McLeod (1985). I have proposed the model that the increase in tone due to intracellular acidification results from the displacement of calcium ions by protons from intracellular storage sites. According to this approach, the alternative interpretation of the relaxation, subsequent to an initial  $\text{NH}_4^+$  - withdrawal constriction, is that  $\text{Ca}^{2+}$  itself is extruded in exchange for  $\text{Na}^+$  entry. This cannot be excluded by the above results, therefore more specific amiloride analogues were employed ( see below).

### Anionic Effect

$\text{PhSO}_3^-$  substitution for  $\text{Cl}^-$ , replacement of  $\text{H}_2\text{PO}_4^-$  - buffer with  $\text{HCO}_3^-$ , and S.I.T.S. in both  $\text{H}_2\text{PO}_4^-$  and  $\text{HCO}_3^-$  media all retarded recovery rate after acid load, (Table E); the greatest retardation being when  $\text{Cl}^-_o$  was totally removed. This suggests that acid extrusion or neutralization may also depend on  $\text{HCO}_3^-$  and  $\text{Cl}^-$ . Russell and Boron (1976) concluded from experiments with dialysed squid axon that  $\text{pH}_i$  recovery from acidification only occurred in the presence of  $\text{Cl}_i^-$  and  $\text{HCO}_3^-$ . Thomas (1977) has also shown this in snail neurones; in addition, there is in these cells a reduction of intracellular  $\text{Cl}^-$  activity during acid extrusion, the reduction being inhibited by S.I.T.S. (Russell, 1978). An exchange of  $\text{Cl}^-$  for  $\text{HCO}_3^-$  would increase  $[\text{HCO}_3^-]_i$  and therefore neutralization of the excess protons accumulated during the acidification process and therefore raise  $\text{pH}_i$ . In vascular muscle, the resulting effect on tone should then be an accelerated reduction of tone after the acid constriction. But in fact  $\text{HCO}_3^-$  retarded recovery of tone as did S.I.T.S. Thus the snail - neurone mechanism cannot be operating in vascular muscle. A possible alternative recalls the notion proposed some time ago by Spurway to explain extracellular pH effects - namely, that  $\text{K}^+$  passes through the membrane in some degree of association with  $\text{Cl}^-$ . Conceivably  $\text{PhSO}_3^-$ , S.I.T.S. or even 25mM  $\text{HCO}_3^-$ , by reducing the amount of  $\text{Cl}^-$  that is passing into the cell or just dwelling in the membrane,

in turn retard the  $K^+$  entry which would otherwise be occurring as  $NH_4^+$  moved out. With  $[K^+]_i$  not rising at the normal rate, any Em component of the washout tone - enhancement would last longer than in control conditions. Additionally, or alternatively, it seems just as probable that intra - membrane  $Cl^-$  should be necessary for the normal rate of  $NH_4^+$  flux - although there is no evidence for such a mechanism. If it did apply,  $pH_i$  itself would stay low longer when there was less  $Cl^-$  in the membrane.

In summary of the last two sections, it seems permissible to say that the regulation of  $pH_i$ , and therefore of vascular tone in circumstances such as those just described, depends on the movement of both anions and cations across the cellular membrane. Anion exchange ( $Cl^- - HCO_3^-$ ) predominates when  $pH_i$  is high and cation (probably  $Na^+ - H^+$ ) exchange predominates at low  $pH_i$ . After an alkali ( $NH_4^+$ )- induced relaxation, restoration of vascular tone is explicable by  $pH_i$  regulation brought about by  $HCO_3^-$  efflux in exchange for  $Cl^-$  influx. After an acid ( $NH_4^+$  withdrawal) - induced constriction, reduction of vascular tone is explicable principally by the loss of protons. Changes of membrane potential, and perhaps of buffering, associated with the movements of  $K^+$  and  $NH_4^+$ , may occur in parallel with the changing rates of antiportation, quantification of which will indicate any other significant qualitative influences. The results with amiloride and its analogues provide some answer to this.

### Amiloride And Its Analogues

Before discussing further the influence of these groups of drugs on  $\text{pH}_i$  homeostasis, it is necessary to discuss their effect on mean tone. These drugs exhibit concentration - dependent vasodilatory and vasoconstrictory effects. All except amiloride and the derivative regarded as a  $2\text{Na}^+ - \text{Ca}^{2+}$  exchange inhibitor, D, raised mean tone when applied in low concentrations. The "Na<sup>+</sup> channel blocker", A, raised mean tone even at  $10^{-4}\text{M}$ . Both amiloride and D lowered mean tone dose - dependently throughout the concentration range employed.

I have therefore to consider the likely effects on tone of blocking, respectively

- (1) the  $\text{Na}^+$  channel
- (2)  $\text{Na}^+ - \text{H}^+$  exchange and
- (3)  $2\text{Na}^+ - \text{Ca}^{2+}$  exchange.

(1) Blocking of membrane  $\text{Na}^+$  channels would directly increase  $E_m$  and consequently decrease voltage - dependent  $\text{Ca}^{2+}$  influx. Therefore tone would decrease.

(2) An inhibition of the  $\text{Na}^+ - \text{H}^+$  exchange would raise cytoplasmic  $\text{H}^+$  and effectively increase tone;  $\text{H}^+_i$  displacing  $\text{Ca}^{2+}_i$  from intracellular stores and making more  $\text{Ca}^{2+}_i$  available for contraction.

(3) Blocking "the  $2\text{Na}^+ - \text{Ca}^{2+}$  exchanger" would raise  $[\text{Ca}^{2+}]_i$  and so increase tone.

The drug doses which relaxed vessels must have been working by mechanism (1). The drug doses which constricted them could have been working by either (2) or (3).

With 'C' both (2) and (3) above are said to be inhibited and if these were the only mechanisms the direction of the change in tone must be an increase. The decrease observed with lower concentrations thus clearly indicates that some other effect such as (1) is present too.

When  $\text{Na}^+_o$  was reduced by substitution with  $\text{Li}^+$  or  $\text{K}^+$ , amiloride reduced tone to about 1/3rd (Fig. 28). If  $\text{Li}^+$  enters the cell by the  $\text{Na}^+$  conductance channel, it is possible that this entry is blocked by mechanism (1) above. With 140mM  $\text{K}^+$ , there is no workable mechanism for which there is independent evidence. Possibly, in  $\text{O-Na}^+_o$ ,  $\text{K}^+$  would enter partly by the  $\text{Na}^+$  channel that is blocked by amiloride. However, if  $\text{K}^+$  was say only about 50mM, a block of  $P_{\text{Na}}$  will allow  $\text{K}^+$  a freer reign, and relative hyperpolarization will occur by the basic mechanism (1) above.

Ouabain had little effect on tone Fig. 11A indicating that inhibition of  $\text{Na}^+/\text{K}^+$  ATPase which should increase  $[\text{Na}^+]_i$  had little effect on  $\text{Ca}^{2+}$  influx rate (cf Van Rossum, 1970 b).

I turn now to the effects of the drugs upon the rates at which tone adapts after  $\text{NH}_4^+$  - induced dilatations and acid - induced constrictions. Generally amiloride and all the analogues employed inhibited to varying degrees both these adaptations. It is impossible to separate the various influences ( (1)-(3) above) in

most of the instances; none of the drugs seem to have acted as specifically as had previously been claimed. However, the most important point, for the general theme of this Thesis, is that the relative retarding effects, on the recovery from acid constriction of the " $2\text{Na}^+ - \text{Ca}^{2+}$  inhibitor" was far less than that of "the  $\text{Na}^+ - \text{H}^+$  inhibitor"; therefore  $\text{Na}^+ - \text{H}^+$  exchange is (as in all other cells) the predominant mechanism, if the prior experiments (Cragoe et al 1984) were correctly interpreted. In fact, as probably neither inhibitor is 100% specific,  $\text{Na}^+ - \text{H}^+$  may be the only one.

## CONCLUSION

In all normal circumstances extracellular acidity reduces vascular tone whereas with mammalian vessels intracellular acidity does the opposite. Therefore  $\text{pH}_o$  and  $\text{pH}_i$  affect vascular tone via different mechanisms. It is proposed that the basic mechanism where by  $\text{pH}_i$  modifies tone is that increased  $[\text{H}^+]_i$  displaces  $\text{Ca}^{2+}$  from intracellular stores therefore raising  $[\text{Ca}^{2+}]_i$  and increasing the activation of the contractile proteins.

$\text{pH}_i$  is regulated by two main ion exchange mechanisms. These are

- (i) a  $\text{Cl}^- - \text{HCO}_3^-$  exchange, operative particularly in the extrusion of excess alkali and
- (ii) a  $\text{Na}^+ - \text{H}^+$  exchange with a predominant role in eliminating excess acid<sub>i</sub>.
