11 ## ABSTRACT

12 The use of low fishmeal/fish oil in marine fish diets affects dietary essential fatty acids
13 (EFAs) composition and concentration and subsequently, may produce a marginal
14 deficiency of those fatty acids with a direct impact on the fish intestinal physiology.
15 Supplementation of essential fatty acids is necessary to cover the requirements of the
16 different EFAs, including the ones belonging to the n-6 series, such as arachidonic acid
17 (ARA). ARA, besides its structural role in the configuration of the lipid classes of
18 intestine, plays an important role on the functionality of the gut associated immune
19 tissue (GALT).

20 The present study aimed to test five levels of dietary ARA (ARA0.5 (0.5%), ARA1
21 (1%), ARA2 (2%), ARA4 (4%) and ARA6 (6%) for European seabass (*Dicentrarchus*
22 *labrax*) juveniles in order to: (a) determine its effect in selected distal intestine (DI) lipid
23 classes composition; and (b) how these changes affected gut bacterial translocation rates
24 and selected GALT-related genes expression pre and post challenge.

25 No differences were found between distal intestines of fish fed the graded ARA levels
26 in total neutral lipids and total polar lipids. However, DI of fish fed the ARA6 diet
27 presented higher ($P<0.05$) level of phosphatidylethanolamine (PE) and sphingomyelin
28 (SM) than those DI of fish fed the ARA0.5 diet. In general terms, fatty acid profiles of
29 DI lipid classes mirrored those of the diet dietary. Nevertheless, a selective retention of

ARA could be observed in glycerophospholipids when dietary levels are low (Diet ARA0.5), as reflected in the higher glycerophospholipids-ARA/dietary-ARA ratio for those animals. Increased ARA dietary supplementation was inversely correlated with eicosapentaenoic acid (EPA) content in lipid classes, when data from fish fed the diets with the same basal composition (Diets ARA1 to ARA6). ARA supplementation did not affect intestinal morphometry, goblet cells number or fish survival, in terms of gut bacterial translocation, along the challenge test. However, after the experimental infection with *Vibrio anguillarum*, the relative expression of *cox-2* and *il-1β* were up-regulated ($P<0.05$) in DI of fish fed the diets ARA0.5 and ARA2 compared to fish fed the rest of the experimental diets. Although dietary ARA did not affect fish survival, it altered the fatty acids composition of glycerophospholipids and the expression of pro-inflammatory genes after infection when included at the lowest concentration, which could be compromising the physical and the immune functionality of the DI, denoting the importance of ARA supplementation when low FO diets are used for marine fish.

Keywords

Aquaculture. *Dicentrarchus labrax*. Arachidonic acid. Gut Polar lipids. Distal intestine. Gut health.

1. INTRODUCTION

Nowadays, due to economic and environmental reasons aquafeeds include important levels of vegetable oil (VO), rich in 18:C polyunsaturated fatty acids (PUFAs) (Hardy et al. 2010). In marine finfish, contrarily to freshwater species, in some cases these substitutions are critical, since they have a limited capacity of elongate and desaturate PUFAs into their long chain families (Tocher 2003). Thus, presenting dietary requirements of long chain PUFA (LC-PUFAs), in particular for eicosapentaenoic acid (EPA, 20:5 n-3), docosahexaenoic acid (DHA, 22:6 n-3), and arachidonic acid (ARA, 20:4 n-6) (Tocher 2015), due to their important role into growth performance, nervous system or immune system development and functioning, for what they are recognized as essential fatty acids (EFA) for marine fish (Tocher et al. 2008).

LC-PUFAs are selectively esterified into cell surface glycerophospholipids (GPs) by fatty acyltransferase enzymes, affecting signaling processes as regulation of nuclear receptors and transcription (Crowder et al. 2017), membrane stability and

fluidity, and, eventually, cell functions (Tocher 2003; Fernandez and West 2005; Yaqoob and Calder 2007). These functions can be exerted directly by GPs as phosphatidylcholine (PC) and phosphatidylserine (PS) which are activators of protein kinase C (Tocher et al. 2008), or through derivates as phosphoinositides, diacylglycerol, lysophosphatidic acid or oxidized PC, to bind and activate receptors as, for instance, peroxisome proliferator activated receptor (Davies et al. 2001). Similarly, GPs constitute a reservoir of fatty acids (FA) that are released by phospholipase A2 (Pla2) to be used by cyclooxygenase (Cox) and lipoxygenase (Lox) enzymes for eicosanoid production (Tocher 2003) as prostaglandins (PGs), thromboxanes or leukotrienes, among others. Eicosanoids are a group of highly active hormone-like molecules that exert their biological effects in a paracrine manner in many physiological processes as the inflammatory response (Tocher 2003; Yaqoob and Calder 2007).

Given the fact that dietary oils and fats affect FA profile in fish tissues, especially in marine species (Tocher 2015), the organ function will be also influenced by dietary lipids (Tocher 2003). For instance, reductions of dietary EFA for gilthead seabream (*Sparus aurata*) together with changes on other FAs by the different dietary lipid sources are responsible for alterations in the morphology of intestine (Caballero et al. 2003 and 2004). The digestive tract of teleosts is one of the main entrances for pathogens (Zapata & Cooper, 1990), and particularly the gut-associated immune system (GALT) has a great importance in maintaining its health status (Rombout et al., 2011; Torrecillas et al. 2012). Fish gut houses a regional immune specialization and it is considered an important place for antigen uptaking, playing a key role achieving oral immune-protection (Rombout et al. 2011). In distal intestine (DI), lymphocytes, granulocytes and leukocytes, are spread on the epithelium and constitute the GALT, a local immune system that reacts to disturbances of homeostasis as those that occur during an infectious process or inclusion of terrestrial sources in diet (Torrecillas et al. 2014; Salinas 2015). These immune cells can produce eicosanoids to induce immune-cell proliferation, cytokine-release or to chemo-attract other immune cells (Zou and Secombes 2016). Hence, dietary imbalances of EFAs can lead to modifications on cell membranes composition and, therefore, alter gut morphology, growth performance and fish health (Tocher 2003; Montero et al. 2001, 2003, 2005, 2008, 2010).

Recent studies are demonstrating that ARA plays an important role on fish growth performance (Bessonart et al. 1999; Carrier et al. 2011; Koven et al. 2003; Lund et al.

95 2007; Bae et al. 2010; Luo et al. 2012; Torrecillas et al. 2018a), lipid metabolism (Luo
96 et al. 2012; Xu et al. 2018), or fish health and disease resistance (Xu et al. 2010;
97 Torrecillas et al. 2017c), among others. Besides, the essential role of ARA and its
98 relative low levels compared to n-3 LC-PUFAs in the marine environment and in fish
99 tissues, have probably led to the strong preference of enzymes involved in eicosanoid
100 synthesis, at the expense of EPA (Liu et al. 2006; Yaqoob and Calder 2007; Furne et al.
101 2013). Indeed, the ratio ARA/EPA on the target organ, affects the synthesis of
102 eicosanoids (Ganga et al. 2005,2006; Xu et al. 2018). Similarly, ARA-derived
103 eicosanoids compete with those from EPA for the same cell membrane receptors
104 (Sargent et al. 1999a; Ganga et al., 2005; Adam et al., 2017; Tian et al., 2017) although
105 those originated from ARA seem to be more biologically active (Leslie 2004). Beyond
106 eicosanoid production, the ARA role on immunity covers a great number of other
107 mechanisms in cells as the activation of the NADPH oxidase enzyme in leukocytes to
108 trigger the respiratory burst (Brash et al. 2001).

109 Farmed European seabass presents reduced ARA tissue levels when compared with
110 wild specimens (Alasalvar et al. 2002; Bell et al. 2007; Fuentes et al. 2010 Lenas et al.
111 2011) indicating a necessary increase of dietary ARA. Indeed, studies of optimum
112 levels of ARA have been made in larval stages of these species (Koven 2001, 2003;
113 Atalah et al. 2011; Montero et al. 2015c) but scarce information exists in juveniles
114 regarding ARA content in GPs and its influence in the intestinal immune response
115 (Torrecillas et al. 2017c,d).

116 Therefore, an experiment was conducted out using graded levels of dietary
117 ARA- for European seabass juveniles to determine the influence and the content of this
118 EFA in lipid classes of DI and the related effects on gut morphology, expression of
119 intestinal immune-related genes, survival and resistance to intestinal infection.

120 2. MATERIAL AND METHODS

121 2.1. Experimental diets

122 Five isolipidic and isoproteic experimental dry pelleted diets based on a
123 commercial formulation were prepared to contain graded levels of ARA (total FA in
124 diet, %) as follows: ARA0.5 (0.5%), ARA1 (1%), ARA2 (2%), ARA4 (4%) and ARA6
125 (6%). Diet ingredients, proximate composition, and FA) profiles are reported in Table 1

126 and 2. This basal diet was supplemented to achieve desired ARA content in diets
127 ARA2, ARA4, and ARA6 with increasing quantities of Vevodar® (DSM Food
128 Specialties, the Netherlands), a commercial fungal-oil rich in ARA obtained from
129 *Mortierella alpine* (authorized in European Union by Commission Decision
130 2008/968/CE). Diet ARA0.5, was formulated with defatted fish meal (FM) and without
131 fish oil (FO) to reduce the presence of ARA and supplemented with vegetable oils to
132 reach requirements. When necessary, supplementation of DHA and EPA was done
133 using DHA50 and EPA50 (CRODA, East Yorkshire, UK).

134 **2.2. Fish and experimental conditions**

135 For this feeding trial, eight hundred and forty European seabass juveniles reared
136 in a commercial farm were maintained in quarantine in the facilities of Marine Science-
137 Technology Park (PCTM) of University of Las Palmas de Gran Canaria (ULPGC), for 4
138 weeks before the experience, and fed a commercial diet. Tanks were supplied with
139 seawater at a natural temperature of 22.8–24.9 ºC in a flow-through system and kept at a
140 natural photoperiod (12L:12D). Dissolved oxygen ranged between 5-8 ppm. Fish were
141 fed the experimental diets for 70 days and, at the end of this feeding trial, fish were
142 submitted to a challenge test against *Vibrio anguillarum* via intestinal inoculation.

143 All animal manipulation in this trial complied European Union Council
144 guidelines (86/609/EU) and Spanish legislation (RD 53/2013) and had been approved
145 by Bioethical Committee of the ULPGC (Ref. 007/2012 CEBA ULPGC).

146 **2.3. Feeding trial**

147 With an average weight and length of 13.4 ± 0.3 g and 9.9 ± 0.1 cm respectively
148 (mean ± SD), animals were randomly allocated in 15 fiberglass 200 L tanks (55
149 fish/tank; 4 kg m^{-3} of stocking density). Diets were assayed in triplicate and animals
150 were fed by hand for 70 days until apparent satiation, three times a day, 6 days a week.
151 After 70 days, samples of DI were taken for biochemical, histologial and gene-
152 expression analyses. Survival was recorded during the whole period of the feeding trial.

153 **2.4. Challenge trial**

154 After 70 days of experiment, fish were transferred to the Biosecurity Facilities of
155 ULPGC in PCTM (Telde, Las Palmas, Canary Island, Spain). After 2 weeks of
156 adaptation to the new experimental conditions, fish were inoculated with a sublethal
157 dose (10^7 CFU ml^{-1} per fish) of *V. anguillarum* using the method of anal cannulation
158 assayed previously in similar experimental conditions (Torrecillas et al. 2007). Fish
159 were fed their corresponding experimental diets for 7 days, as frequent than before. At 2
160 days after the infection, samples of DI were taken for immune-related genes analyses.
161 Survival was recorded along this trial.

162 **2.5. Lipid class and fatty acid content of selected glycerophospholipids of distal**
163 **intestine**

164 At day 70, eight fish per tank (N= 24 fish/diet), were used for biochemical
165 analysis. The intestine was extracted out for analysis and distal section was separated as
166 previously described by Torrecillas et al. (2013). Fish tissues were kept at -80º C until
167 the analysis. Biochemical composition of distal intestine and diets were conducted
168 following standard procedures from Association of Official Analytical Chemists
169 (AOAC, 2016). The analysis of lipid class and fatty acid composition of selected
170 glycerophospholipids (GPs) was conducted in the Institute of Aquaculture, Stirling
171 University (UK). Separation of main lipid classes was realized in 10 × 10 cm plates
172 (VWR, Lutterworth, UK) by double development high-performance thin-layer
173 chromatography (HPTLC) using the technics described by Tocher and Harvie (1988),
174 and Olsen and Henderson (1989). Firstly, plates were pre-run in diethyl ether and then
175 activated at 120° C for 1 hour. The lipid classes were visualized after spraying with 3%
176 (w/v) copper acetate, containing 8% (v/v) phosphoric acid by charring at 160° C for 20
177 min. Quantification was made by densitometry using a CAMAG-3 TLC scanner
178 (Version Firmware 1.14.16; CAMAG, Muttenz, Switzerland) with winCATS Planar
179 Chromatography Manager. Samples and authentic standards run alongside, in the same
180 conditions, on high-performance thin layer chromatography (HPTLC) plates, as the way
181 to determine the identities of individual lipid classes by contrasting Rf values. Total
182 GPs, including PC, PS, phosphatidylethanolamine (PE), and phosphatidylinositol (PI)
183 were isolated from HPTLC plates and subjected to acid-catalyzed transesterification
184 according to the method of Tocher and Harvie (1988). Afterwards, extraction and
185 purification were performed as described by Christie (1982). To separate and quantify
186 fatty acid methyl esters (FAMEs) of selected GPs, a gas-liquid chromatography was

187 executed using a Fisons GC-8160 (Thermo Scientific, Milan, Italy) with the conditions
188 determined previously (Izquierdo et al. 1992).

189 **2.6. Histological studies**

190 Samples from DI (N= 6 fish/diet) obtained after 70 days of feeding and taken as
191 described by Torrecillas et al., (2013) were fixed in neutral-buffered formalin (4%).
192 After 48 hours, tissues were dehydrated with an increased graded series of ethanol,
193 submerged in xylene and embedded in paraffin blocks. Sections of 4µm were cut and
194 stained with hematoxylin and eosin (H&E) and Alcian Blue-PAS (pH= 2.5) (Martoja
195 and Martoja-Pierson 1970), for optical examinations and to differentiate mucus-
196 secreting cells, respectively. Micrographs analyzed were obtained with a Nikon
197 Microphot- FXA microscope (objective lens 20X plus eyepiece 10X) equipped with an
198 Olympus DP50 camera. Cell count and measures of DI were made according to
199 Torrecillas et al. (2007), using Image-Pro Plus v5 software (Media Cybernetics Inc.,
200 Rockville, MD, USA). Structural measures of DI were studied with a light microscope
201 (N=72; 12 sections per fish × 6 fish per tank × 3 tanks per diet) and using individual fish
202 weight as co-variable. Following measures were calculated: fold area, FA; fold
203 perimeter, FP; fold length, FL; fold width, FW; submucosa width, SW. To estimate
204 mucus production, the number of mucus-secreting cells by unit of area was counted (N=
205 288; 48 folds per fish × 2 fish per tank × 3 tanks per diet).

206 **2.7. RNA extraction, cDNA synthesis and Quantitative Real-Time PCR analysis**

207 After 70 days of feeding and during challenge trial (2 days), DI (N= 9 fish/diet)
208 samples were collected in order to realize real time (RT) qPCR analyses. Tissues were
209 submerged into Invitrogen™ RNAlater™ Stabilization Solution (Thermo Fisher
210 Scientific Inc., USA) and conserved at -20°C. Then, using TRI-Reagent (Sigma-
211 Aldrich, Saint Louis, MO, USA) and RNeasy® mini Kit (QUIAGEN, Germany), total
212 RNA was extracted from 100 mg of pooled tissues, (N=3 fish/tank). RNA was
213 quantified by spectrophotometry using Nanodrop 1000 (Thermo Fisher Scientific Inc.,
214 USA) and integrity was evaluated on a 1.4% agarose gel with Gel Red™ (Biotium Inc.,
215 Hayward, CA). The synthesis of cDNA was realized from 1µg RNA with iScript™
216 cDNA Synthesis Kit (Bio-Rad Hercules, California) in 20µl final volume. Selected
217 genes related to GALT functioning and eicosanoid production were as follows and

218 respectively: interleukin 10 (*il-10*), interleukin-1beta (*il-1β*), tumor necrosis factor alpha
219 (*tnfα*), and cyclooxygenase 2 (*cox-2*). RT-qPCR reactions were performed by triplicate
220 and conditions were 1X (95°C, 10min), 35x (95°C, 45s/corresponding annealing
221 temperature, 45s/72°C, 45s) 1X (72°C, 30s). Conditions, sequences and references are
222 registered in Table 3. Two genes, elongation factor 1 (*ef-1*) and *β-actin*, were tested as
223 housekeeping but *ef-1* was found to be more stable to make calculations. Reactions
224 were performed in an iCycler Optical Module (Bio-Rad, USA), the final volume used
225 was 15µl, containing 2µl of cDNA (diluted 1/10), 0.6µl of each primer (10 mM) and
226 7.5µl of Brilliant SYBR Green QPCR Master Mix (Bio-Rad Hercules, CA, USA).
227 Blank samples, with 2µl of water replacing cDNA, were included in each assay as a
228 contamination control. The Livak & Schmittgen (2001) method was used to calculate
229 relative expression of each gene.

230 **2.8. Statistical analysis**

231 All statistical analyses were performed using SPSS 21 software package for
232 Windows (IBM, Chicago, IL, USA). All data, presented as mean ± SD, were tested for
233 normality and homoscedasticity. Statistical analyses followed methods outlined by
234 Sokal and Rolf (1995). Data were submitted to a One-way analysis of variance
235 (ANOVA). When F values showed significance, individual means were compared using
236 post hoc tests for multiple means comparison. When data were not normally distributed,
237 data analysis was made by non-parametric test (Kruskal-Wallis and U Mann-Whitney).
238 When Levene's test showed P<0.05, but ANOVA and Wells test showed P<0.05, post
239 hoc test used was Games-Howell. Pearson coefficient was used for correlations and
240 statistical significance was set at P<0.05. Survival curves were performed and analyzed
241 using the method described by Kaplan-Meier (Kaplan and Meier 1958).

242 # 3. RESULTS

243 **3.1 Growth parameters**

244 The growth study has been previously reported (Torrecillas et al., 2018a) but it is
245 important to point out that fish growth presented differences at the end of feeding trial.
246 Briefly, fish fed the lowest dietary ARA levels showed significantly lower (P<0.05)
247 weight (g) (ARA0.5 =33.0 ± 1.1) than those from the other diets, that are those diets in
248 which ARA was supplemented on the same base diet (ARA1= 44.4 ± 1.1; ARA2= 43.8

249 ± 1.0; ARA4= 43.9 ± 3.7; ARA6= 42.8 ± 2.5) (mean ± SD). Dietary ARA levels did not
250 affect (P>0.05) cumulative survival percentages for European sea bass fed the
251 experimental diets for 70 days (over 95% for all diets).

252 **3.2 Lipid class composition of distal intestine**

253 No differences were found between diets in the Σ neutral lipids or the Σ polar
254 lipids of DI (Table 4). Regarding polar lipids, PC, followed by PE, were in higher
255 proportion than the rest of lipid class (Table 4). Lysophosphatidylcholine (LPC)
256 presented the lowest proportion (Table 4). Among polar lipids, SM and PE were the
257 only lipid class affected by dietary ARA (P=0.041 and P=0.049; respectively) (Table 4).
258 Fish fed diet ARA6 had significant (P<0.05) higher level of PE than control diet
259 (ARA0.5) (Table 4). Similarly, SM was more abundant in ARA6 than in ARA0.5,
260 ARA1 and ARA2 (Table 4). Besides, significant correlations between dietary ARA and
261 lipid classes in DI were found for PE (0.743/P=0.001), PC (0.640/P=0.010) and SM
262 (0.700/P=0.004), (Pearson coefficient/P value).

263 **3.3 Fatty acid composition of selected glycerophospholipids in distal intestine.**

264 The FA composition of four main GPs (PC, PE, PS and PI) was analyzed in DI
265 (Table 5 a, b, c & d). Increasing dietary ARA levels mirrored in the content of ARA in
266 GPs (GPsARA). However, the lowest dietary ARA level (ARA0.5) induced a selective
267 incorporation of ARA in all the GPs, reflected in the content of ARA (P<0.05; Tables
268 5a to 5d). The higher GPsARA/dietary ARA ratio (P<0.05) found for PC, PE and PS in
269 fish fed ARA0.5 diet in comparison to the values obtained for the animals feeding either
270 of the rest of the diets, was also reflecting the selective incorporation of ARA (Tables 5a
271 to 5c). For PI, no differences (P>0.05) were found in the GPsARA/dietary ARA ratio
272 between fish fed ARA0.5 and ARA1 diets (Table 5d). The GPsARA/dietary ARA ratio
273 in all GPs analyzed in DI, reflected that content of ARA was higher than dietary ARA.
274 Significant (P<0.05) correlations were found in DI between dietary ARA levels and the
275 GPsARA in all analyzed polar lipids: PC (0.992/P<0.001), PS (0.872/P<0.001), PE
276 (0.969/P<0.001), PI (0.750/P=0.001) (Pearson coefficient/P value) (Tables 5a to 5d).

277 Fish fed to ARA 0.5 diet presented high content of Σn-6 PUFA and Σn-3 PUFA due to
278 the higher content of 18:2n-6 and 18:3n-3 from the diet, respectively. For the rest of the
279 experimental diets, where ARA was supplemented on the same basal diet from diet

280 ARA1 to ARA6), all GPs analyzed in DI, increasing dietary ARA induced an
281 accumulation of Σn-6 PUFA (P<0.05), mainly due to the increased GPsARA in the
282 different GPs, (Tables 5a to 5d). Moreover, in PC, PE and PS, dietary ARA induced a
283 significant (P<0.05) reduction of Σn-3 PUFA (Tables 5a to 5c). The increment of
284 dietary levels of ARA was inversely correlated with the EPA content in GPs, although
285 negative correlations were not significant (P>0.05), except for PE (data not shown), due
286 to reduced dietary EPA level in diet ARA0.5 compared to the other diets (Table 2).
287 Negative and significant (P<0.05) correlations between dietary ARA level and EPA
288 content were found for all GPs when ARA0.5 diet was excluded from the statistical
289 analysis: PC (-0.904/P<0.001), PS (-0.777/P=0.003), PE (-0.941/P<0.001), and PI (-
290 0.807/P=0.002) (Pearson coefficient/P value) (Tables 5a to 5d). Besides, differences of
291 Σ saturated and Σ PUFA were found in PC, with the higher (P< 0.05) Σ PUFA level and
292 the lower (P<0.05) level of Σ saturated in those fish fed ARA0.5 diet, due to significant
293 increases of oleic, linoleic and alpha-linolenic acids, (Table 5a). Differences in DHA
294 content were found in PS and PE among fish fed the different dietary treatments (Tables
295 5b and 5c). In PS, lower (P<0.05) level of DHA was found in fish fed ARA0.5 diet than
296 ARA1, ARA2, and ARA4 (Table 5b). In PE, lower (P<0.05) level of DHA was found in
297 fish fed ARA0.5 and ARA6 diets when compared with the rest of experimental diets
298 (Table 5c).

299 **3.4 Histological studies**

300 Morphometric analysis of DI showed no significant (P>0.05) differences in any
301 intestinal measure (Table 6) when related to fish real weight. Similarly, no effect of
302 dietary ARA was observed in the density of goblet cells by unit of area in relation to the
303 real fish weight (Table 6).

304 **3.5 Relative expression of selected genes after feeding trial and challenge test**
305 **against *Vibrio anguillarum*.**

306 The cumulative mortality after challenge test against *V. anguillarum* was not
307 affected by dietary ARA (P>0.05). Despite the differences in the survival percentages
308 were not significant, there was a trend to lower mortality in fish fed diet ARA6, which
309 did not present mortality along the experimental intestinal infection, whereas the

survival percentage of fish fed the experimental diets ranged between 76.5 and 88.2%, for diets ARA0.5 and ARA4 respectively).

The relative expression of immune related genes, including *il-1β, tnfα, il-10* and *cox-2*, were analyzed in DI at both basal and 2 days post infection (Fig.1). No effect was found on *tnfα* relative gene expression (Fig. 1a). After the feeding period (basal level), increased expression of pro-inflammatory *il-1β* (P=0.030) was found in fish fed ARA0.5 diet in comparison to fish fed ARA1 and ARA2 (Fig.1b). After 2 days post infection, there was an up-regulation of *il-1β* relative gene expression in fish fed ARA0.5 and ARA2 diets when compared with those fish fed the rest of the diets (P<0.001) (Fig.1b). An increment of *il-10* relative expression was found in fish fed ARA1 and ARA6 (P=0.002) at basal level compared to fish fed the other diets, whereas after infection a reduction was found in fish fed ARA2 compared to those fed the rest of the diets (P<0.001) (Fig.1c). No differences (P>0.05) were found at basal level for *cox-2* relative expression (Fig.1d). At 2 DPI, *cox-2* gene expression was up-regulated (P<0.05) in fish fed ARA2 (Fig.1d) when comparing to fish fed the rest of the dietary treatments.

4. DISCUSSION

Fish have dietary requirements of GPs for normal growth, homeostasis maintenance, survival, or immune system function (Tocher et al. 2008; Adam et al., 2017; Tian et al., 2017). Among other functions, GPs are related with lipid transport and plasticity of the cell membranes (Tocher et al. 2008). Besides, GPs, act as precursors of metabolism mediators as diacylglycerol or phosphoinositides, these last related with cell polarity to keep cytoarchitecture, which is determinant in epithelial barrier and transport functions allocated in the enterocyte-mucose layer (Shewan et al. 2011). GPs have described to be affected by the dietary fatty acid profile, both the amount of each GP and also the fatty acid composition of each lipid class (Olsen et al. 2003).

In this study, levels of dietary ARA were correlated with the concentration of the different lipid class levels in DI of European seabass. Although increased dietary ARA seemed to be related with increased the concentration of PE and SM in DI, with values higher in the diets supplemented with high (ARA4 or ARA6) content of ARA, it was also correlated to PC level, a lipid class that is required for SM synthesis (Patel and Witt

341 2017) and is related to PE through remodeling pathways (Tocher et al. 2008). Previous
342 studies have demonstrated the importance of SM in epithelial barriers of fish and other
343 vertebrates, despite the structural differences between marine and terrestrial epithelia
344 (Feingold 2007; Pullmannová et al. 2014; Cheng et al. 2018). In fact, this polar lipid,
345 disposed in the outer leaflet of the cell membrane with another choline-container lipid
346 as PC (Tocher et al. 2008), is more abundant in membranes of temperate-water fish
347 suggesting its role in the membrane fluidity (Storelli et al. 1998; Palmerini et al. 2009).
348 In Atlantic salmon, reductions in dietary EPA and DHA increased skin SM levels,
349 denoting alterations of the barrier function of the skin with reductions of these EFAs
350 (Cheng et al. 2018). Besides, SM has been linked with the regulation of the release of
351 ARA, by the inhibition of the c-Pla2α bind to the GPs (Nakamura and Murayama 2014).
352 In the present experiment, SM in DI increased when ARA increased in diet, with the
353 subsequent decrease of the n-3 LC-PUFA/ARA ratio. The increase of SM in the gut of
354 fish fed high dietary ARA could be ameliorating a possible increase of cPla2 activity
355 induced by the high amount of ARA in the GPs of those fish fed the higher levels of
356 ARA in diet.

357 It is known that high LC-PUFA content induces the decarboxylation of PS to PE
358 at membrane level of different organelles as mitochondria or Golgi (Kainu et al. 2013).
359 In the present study, PE levels in DI were increased by dietary ARA, with the highest
360 level corresponding to those fish fed the highest dietary ARA level. This could be
361 related to the fact that the generation of PE through the PS decarboxylation pathway
362 generated preferentially PE species with a PUFA at the sn-2 position (Bleijerveld et al.
363 2007). However, the synthesis of PE through decarboxylation of PS has been shown to
364 be promoted by DHA and not by ARA (Ikemoto et al. 1999), and thus, other metabolic
365 pathways different than PS decarboxylation cannot be rejected to explain the increases
366 of PE in the DI of the fish fed high ARA in diet.

367 Dietary ARA also influenced fatty acid profiles of lipid classes in the distal
368 section of the intestine. Olsen et al. (2003) showed that the effect of the type of dietary
369 lipid is reflected in the fatty acid profile of the intestine and it is dependent of the
370 section of intestine studied. In this study, correlations were found between dietary ARA
371 and content of ARA for the four GPs studied in DI.

372 As described for other species, PI was the lipid class with the highest content of
373 ARA (Bell and Sargent 2003). Moreover, due to the abundance of PC and PE in the

374 tissue studied, higher ARA content was found in those GPs in agreement with previous
375 studies (Bell et al. 1995). Besides, the increased content of ARA in studied GPs with
376 respect to the dietary level occurred in all diets and GPs analyzed, although with more
377 intensity in fish fed the lowest ARA level as reflected in the higher ratio GPs-
378 ARA/dietary for those animals. This selective retention can be considered as a way to
379 keep functionality during EFA deficiencies (Skalli et al. 2006) as negative effects of
380 EFA deficiencies can be magnified at chronic stressful situations. Indeed, ARA
381 reductions were found in liver polar lipids when gilthead sea bream were subjected to
382 high stocking densities probably due to its selective utilization in that stressful situation
383 (Montero et al. 2001). Moreover, DHA concentration was also higher than dietary DHA
384 levels in all studied GPs, particularly in PE and PS, although it must be taken into
385 account that DHA is preferentially esterified to PE and PS (Kim et al., 2004), and thus
386 DHA concentration in polar lipids depends not only on the DHA level in diets but also
387 on the esterification within those lipid classes. The relatively high levels of ARA and/or
388 DHA despite their dietary inclusion were in agreement to their preferential
389 incorporation previously found by other authors in European sea bass tissues (Farndale
390 et al. 1999; Eroldoğan et al. 2013; Torrecillas et al. 2015a) including in polar lipids
391 (Torrecillas et al. 2013) and in other species (Bell et al. 2001; Montero et al. 2001,
392 2003; Fountoulaki et al. 2003; Dantagnan et al. 2017). Furthermore, results from the
393 present study indicate that inclusion of EPA in GPs was negatively correlated by the
394 supplementation of ARA in diet (excluding from this correlation the results from diet
395 0.5 formulated with different ingredients and different fatty acid profile), suggesting
396 competition between EPA and ARA during phospholipid esterification, in agreement
397 with previous studies (Bell et al. 1991, Bessonart et al. 1999; Fountoulaki et al. 2003;
398 Atalah et al. 2011). Competition between both fatty acids as substrate for different
399 enzymes is of especial relevance during eicosanoid synthesis, as both fatty acids are
400 substrates for eicosanoid production, affecting different fish functions, including
401 immune system (Bell et al. 1996b, Montero et al., 2015c; Adam et al., 2017).

402 The graded dietary levels of ARA used in the present study did not affect
403 survival, in agreement with previous studies using graded dietary ARA levels in
404 European sea bass larvae (Atalah et al. 2011) or in other marine species such as gilthead
405 seabream, Senegal sole (*Solea senegalensis*) or Japanese sea bass (*Lateolabrax*
406 *japonicus*) (Fountoulaki et al. 2003; Villalta et al. 2005; Xu et al. 2010). Other studies in

407 gilthead seabream have found positive effects (Bessonart et al. 1999) related to stress
408 resistance (Koven et al. 2001; Willey et al. 2003). Besides, low or too high dietary ARA
409 has been described to induce a reduction of fish survival during a bacterial challenge in
410 Atlantic salmon (*Salmo salar*) (Dantagnan et al. 2017). In the present experiment, the
411 graded levels of dietary ARA did not affect survival after challenge test, but induced
412 changes in the expression of GALT-related genes, as described for other species such as
413 Atlantic salmon (Dantagnan et al. 2017) or guppy (*Poecilia reticulata*) (Khozing-
414 Goldberg et al. 2006). Indeed, a previous study has related dietary ARA with
415 mechanisms of protection against damage in the intestine (Tarnawski et al. 1989). In
416 this sense, intestine is an organ subjected to injury, intestinal barrier being highly
417 compromised and subsequently acting as one of the main entrances for pathogens (Ellis
418 2001; Campos-Pérez et al. 2000).

419 The relation between intestine and eicosanoid synthesis has been widely studied
420 in different fish species (Sargent et al. 1999a; Tocher 2003; Calduch-Giner et al. 2016).
421 Although ARA and EPA are substrates for COX and LOX enzymes to produce
422 eicosanoids (Bell & Sargent 2003, Tocher et al. 2008), these enzymes seem to have
423 stronger preference for released-ARA than for EPA at least in freshwater fish and
424 salmonids (Bell and Sargent 2003; Tocher et al. 2008; Furne et al. 2013). In this trial,
425 the supplementation of dietary ARA did not influence directly basal levels of *cox-2*
426 relative expression in gut, suggesting no effect on PGE2 production in intestine as
427 described for other vertebrates (Tateishi et al. 2014) which is also supported by the
428 absence of significant differences in PI levels, the main pool of ARA for eicosanoids
429 production (Yaqoob and Calder 2007). However, after infection with *V. anguillarum*, in
430 the present study European seabass juveniles fed 2% of ARA in diet increased *cox-2*
431 relative expression, which has been related with protection to gastric mucosal defenses
432 including stimulation of mucus secretion and maintenance of mucosal blood flow
433 (Wallace and Devchan 2005). The gastro-protective properties of Cox-2-derived PGs
434 have been demonstrated in eel (*Anguilla anguilla*) gastric mucosa (Faggio et al. 2000),
435 and *cox-2* expression in the intestine has been also associated to a response of Atlantic
436 salmon to acute stress, mainly in DI (Oxley et al. 2010).

437 The up-regulation of *cox-2* levels found in the present study after bacterial
438 infection was coincident with the increased *il-1β* gene relative expression. The Cox-2
439 enzyme and pro-inflammatory cytokines such as Il-1β seems to be linked through the

440 p38 mitogen-activated protein kinase (P38 mapk) (Camacho-Barquero et al. 2007),
441 which is known to be present in fish (Ribeiro et al. 2010; Yang et al. 2014b). The Mapk
442 can be activated by ARA metabolites in a dose-dependent manner (Alexander et al.
443 2001), which in turn can activate *cox-2* expression (Sui et al. 2014). Besides, Mapk
444 constitutes a signaling pathway involved in regulation of multiple cell functions
445 including autophagy, a cell process of self-degradation to maintain homeostasis in
446 which proinflammatory cytokines are implicated (Sui et al. 2014). PE plays an
447 important role in autophagy because it is utilized by proteins required for the formation
448 of autophagosomes to attach to cell membranes (Ichimura et al. 2000; Iula et al. 2018),
449 and, besides, these autophagic vesicles are utilized for secretion of cytosolic Il-1β (Iula
450 et al. 2018). At the same time, Il-1β has been suggested to be involved in the PE
451 synthesis via Mapk (Sluzalska et al. 2017). In this way, the modification of PE levels in
452 DI can be related with the secretion of Il-1β. In the present study, increased *il-1β*
453 relative expression at basal time in diet ARA0.5 could be related to PE reduction in that
454 diet, although other factors influencing the PE reduction cannot be rejected, as this diet
455 had lower amount of DHA and EPA. Besides, other authors have shown that increased
456 levels of Il-1β can reduce SM synthesis without affecting other choline-GPs as PC
457 (Kronqvist et al. 1999). In this experiment, and when considering only the diets with
458 same basal composition and graded ARA (diets from ARA1 to ARA6), the reduced
459 levels found in SM levels could be related to increments in ARA release in those fish
460 fed lower ARA level or to regulation of its synthesis, both mechanisms affected by Il-1β
461 release.

462 In conclusion, ARA is selectively retained in the GPs of DI of European seabass,
463 supporting its important physiological role in this tissue. This ARA selective retention is
464 especially evident when low dietary ARA levels are fed (Diet ARA0.5), as reflected in
465 the higher glycerophospholipids-ARA/dietary-ARA ratio found. However, these
466 variations were not enough to alter DI morphology or/and bacterial translocation rates,
467 regardless of the ARA-deficiency related up-regulation of DI pro-inflammatory genes.
468 Altogether pointing to a long-term compromised physical barrier integrity and immune
469 functionality of the DI, denoting the importance of ARA supplementation when low FO
470 diets are used for marine fish.

471 **Funding information:** This research was financed by the Spanish Ministry of Economy
472 and Competitiveness (MINECO) in the Project AGL2012-39919 (PROINMUNOIL).

473 Additionally, Rivero-Ramírez F. was financed with a predoctoral fellowship (ULPGC-474 2013) and Torrecillas S. received a ULPGC postdoctoral fellowship (PICULPGC-2013-475 CIENCIAS, concept 643.00.06).

476 **Compliance with ethical standards:** The handling of animals at this experiment 477 complied the guidelines of the European Union Council (86/609/EU) and Spanish 478 legislation (RD 53/2013) and was approved by the Bioethical Committee of the ULPGC 479 (Ref. 007/2012 CEBA ULPGC).

901 **Captions to figures**

902

903 **Figure 1**. RT-qPCR of immune-related genes in distal intestine of D. labrax juveniles,
904 at basal time and at 2 days post infection: (a) *tnfα*; (b) *il-1β*; (c) *il-10*; (d) *cox-2*. N= 9
905 fish/diet. All values of relative expression are represented as mean ± SD. Differences
906 were significant when $P<0.05$, after One-way ANOVA. Significant ($p<0.05$) differences
907 among diets within same sampling point indicate with letters: lowercase for Basal and
908 uppercase for 2DPI.

909

963 **Table 6.** Morphometric analysis and number of goblet cells in distal intestine of European sea bass
964 fed graded levels of ARA in diet. All measures considering individual fish weight (g) as co-variable. All
965 results are expressed as mean±SD. FA =fold area (μm^2/g), FP=fold perimeter (μm/g), FL= fold length
966 (μm/g), FW= fold width (μm/g), SW= submucosa width ([μm/g] * 100). GC= goblet cells/area (arbitrary
967 units * 10^4)
