#### On the duration and cost variability of construction activities: an empirical study

Ballesteros-Pérez, P. Ph.D.<sup>1\*</sup>; Sanz-Ablanedo, E. Ph.D.<sup>2</sup>; Soetanto, R. Ph.D.<sup>3</sup>;
González-Cruz, M<sup>a</sup>.C. Ph.D.<sup>4</sup>; Larsen, G.D. Ph.D.<sup>5</sup>; Cerezo-Narváez, A. Ph.D.<sup>6</sup>
Abstract

5	The unique nature of construction projects can mean that construction activities often
6	suffer from duration and cost variability. As this variability is unplanned it can present a
7	problem when attempting to complete a project on time and on budget. Various factors
8	causing this variability have been identified in the literature, but they predominantly refer to
9	the nature and/or context of the whole project, rather than their specific activities.
10	In this paper, the order of magnitude of and correlation between activity duration and
11	cost variability is analyzed in 101 construction projects with over 5000 activities. To do this,
12	the first four moments (mean, standard deviation, skewness and kurtosis) of actual versus
13	planned duration and cost (log) ratios are analyzed by project, phase of execution and activity
14	type. Results suggest that, contrary to common wisdom, construction activities do not end
15	late on average. Instead, the large variability in the activity duration is the major factor
16	causing significant project delays and cost overruns. The values of average activity duration
17	and cost variability gathered in this study will also serve as a reference for construction

managers to improve future construction planning and project simulation studies with morerealistic data.

Keywords: scheduling; activity variability; merge event bias; network topology; project delays

#### 22 Introduction

Construction activities usually suffer from variability in terms of both duration and
cost. With each construction project being unique, factors of this variability are plentiful
(Ballesteros-Pérez et al. 2017). These factors include project location, clients, regulations,
labor, equipment, technology, subcontractors, experience, stakeholders, even the project
team, are likely to change, at least partially, among projects (Chudley and Greeno 2016). All
these factors, plus many other, make of the duration and cost estimation exercise, a
challenging task for construction managers.

30 It may be easy to believe, though, that construction activities are apparently more
31 likely to end later and cost more than the other way around. In fact, this would constitute a
32 compelling reason why so many construction projects end late and exceed their initial budget.

Factors that cause projects to end late or result in cost overruns have been studied in 33 the construction literature for a long time. Some of the most recurrent are poor planning and 34 control practices, deficient construction site management, shortages of labor and/or low 35 productivity, problems with the supply chain and/or procurement practices, contractor's 36 and/or client's financial problems, project specifications or design changes, communication 37 38 and/or co-ordination problems among stakeholders, interferences with onsite services, adverse weather conditions, and legal disputes and contract claims (Ballesteros-pérez et al. 39 2015, 2018b). Among all these, however, poor planning and control practices are consistently 40 41 among the most pervasive (AlSehaimi and Koskela 2008).

Ballesteros-Pérez et al. (2018a) recently showed how the most common scheduling 42 techniques (Gantt chart, Critical Path Method and Project Evaluation and Review Technique, 43 44 PERT) consistently underestimate the actual project duration and cost. One of the major causes of this underestimation came precisely from neglecting activity duration variability. 45 Apart from the classical scheduling techniques, more advanced techniques for getting 46 47 improved project duration and/or cost estimates have been proposed over the years (e.g. fuzzy logic, neural network analysis, Monte Carlo simulations, artificial intelligence methods, 48 many variants of PERT, and even more extensions of Earned Value Management 49 (Ballesteros-Pérez, 2017a)). What all these methods have in common, classical and modern 50 51 alike, is that they all require some prior estimates of the potential activity durations and costs. For example, PERT-related techniques generally resort to three-point estimates (pessimistic, 52 optimistic and most likely durations and costs); Monte Carlo simulations require the 53 54 statistical distributions of each activity as input; and neural network analysis and artificial intelligence methods require training sets of similar construction projects. Access to this 55 information is often the major limitation of these methods. Similarly, realistic data on the 56 correlation between activity duration and costs is also a rare commodity, which forces these 57 techniques to either assume independence between activities and costs, or resort to subjective 58 correlation factors (Banerjee and Paul 2008; Cho 2009). Consequently, when enough quantity 59 or quality of information is not available, the forecasting accuracy of the actual project 60 duration and/or cost is expected to be unreliable. 61

Unfortunately, despite its importance, there is a dearth of research into activity duration
and cost variability in the construction management literature. Maybe, the only exception
would be the work of Trietsch et al. (2012) who attempted to establish a distribution that
satisfactorily describes construction activity durations. However, as early suggested by
MacCrimmon and Ryavec (1964), trying to find a universal distribution that fits all types of

activities is a futile effort because each type of activity is unique. Furthermore, its context
might also have a significant influence which is difficult, if not impossible, to parameterize
mathematically.

Nonetheless, these difficulties should not be a deterrent to, at least, attempting to measure
the average level of variability of construction activity durations and costs. As argued, this
would be an extremely valuable input for future project duration and cost forecasting
techniques, as well as providing powerful baseline information for enhancing project control
and monitoring.

Hence, the present paper precisely attempts to fill this research gap in the construction 75 management literature: measure the average level of activity duration and cost variability. It 76 77 will also justify how and why, given this level of activity variability in common project networks, it is expected that most construction projects end late and go over budget. To 78 achieve this, the actual/planned (log) ratios of many project and activity durations and costs 79 80 will be analyzed. The correlation between activity durations and costs will also be studied. Finally, the most common network topologies (descriptors of what the project networks are 81 like, that is, how activities are arranged and connected with each other) will be summarized 82 and the potential impact of activity variability on these networks described in detail. 83

The paper will be structured as follows. The *background* section will provide an overview of the importance of the first four moments of the activity duration and costs impacting the final project duration and cost. This section will introduce the concept of merge event bias and describe how it may cause project delays and cost overruns depending of each project network topology. The *materials and methods* section will describe how a dataset of 101 projects was classified according to different activity categories, and then their log actual vs planned durations and cost deviations analyzed activity by activity. The *discussion* section will provide insights on to what the numerical results mean and how they are connected to the
project network topology in common construction projects. Finally, the *conclusions* will
summarize the whole analysis, highlight the major contributions to the body of knowledge,
state the study limitations, and propose future research continuations.

95

#### 96 Background

97 There have been numerous studies analyzing delays and cost overruns in construction 98 projects at project level (e.g. (Hamzah et al. 2011; Keane and Caletka 2008; Mahamid et al. 99 2012; Ogunlana et al. 1996; Orangi et al. 2011; Senouci et al. 2016)). Most studies have 100 focused on either establishing the causes of delays and cost overruns, and/or proposing some 101 regression analyses to avoid slippages in the future. Generally, these studies have been 102 aligned with a more reductionist perspective, seeking to emphasize a particular context (same 103 region, client, type of projects, or a combination of these).

104 Conversely, there have not been hardly studies measuring the 'activity' durations and 105 costs, let alone their variability in real construction projects. With the exception of Trietsch et 106 al. (2012) mentioned earlier, perhaps the closest are a handful of studies analyzing the 107 sensitivity of the project duration to different levels of activity mean duration and dispersion 108 (e.g. Elmaghraby & Taner (1999) and Elmaghraby (2000)).

Additionally, but from a purely mathematical and simulation perspective, some studies have tried to gauge to what extent the adopted activity statistical distributions have a significant repercussion on the final project duration. In this regard, a recent study by Hajdu and Bokor (2014) concluded that the maximum project duration deviation when using alternative activity distributions was generally well below 10%. This finding resonated with observations from an earlier study on the limitations of PERT. MacCrimmon and Ryavec (1964) showed that, if triangular distributions for modelling activity durations had been
chosen instead of Beta distributions, the probabilistic project duration would have produced
almost identical results.

118 The reason why the choice of a particular statistical distribution does not seem that relevant is because the third and fourth moments (skewness and kurtosis) are blurred very 119 120 quickly in Stochastic Network Analysis (SNA) (Hajdu and Bokor 2016). At the time of writing, SNA is considered the most accurate approach to model project schedule networks 121 (Ballesteros-Pérez, 2017b). In SNA, activity durations and costs are modelled by statistical 122 distributions (with or without correlation with each other). More precisely, distributions are 123 124 summed when computing the total costs of activities, or the total duration of activities arrayed in series. On the other hand, the maximum of distributions (instead of a sum) is 125 calculated whenever we calculate the total duration of a set of activities placed in parallel. In 126 either case, the third and fourth moments (skewness and kurtosis) have a minor influence on 127 the resulting distribution (of a path or project duration). 128

However, the first two moments (mean and variance, or alternatively, standard
deviation) play a major role in the resulting distribution modelling the total project duration.
When there is some correlation between durations and costs (virtually always in construction
projects), they also have an indirect but still significant, influence on the final project cost.

To sum up, when two or more distributions are convoluted (summed for computing the project cost or the duration of activities in series) the resulting distribution, by the Central Limit Theorem, quickly converges to a Normal distribution. The mean and variance of this Normal distribution correspond to the sum of means and variances, respectively, of the individual activity distributions. Therefore, the first two moments will mostly determine what the resulting distribution looks like. When some activities are arranged in parallel and they all need to finish before the project can continue, the resulting distribution quickly converges to an extreme value distribution of maxima (normally a Fréchet or a Gumbel distribution) (Dodin and Sirvanci 142 1990). Again, the first two moments of the involved activity distributions will determine the 143 location and scale of the resulting extreme value distribution. This phenomenon is commonly 144 known as the 'merge event bias' (Khamooshi & Cioffi, 2013; Vanhoucke, 2012) and it is 145 indeed the major source of inaccuracy of all deterministic scheduling techniques.

Real construction project schedules (networks) generally involve many subsets of activities both arranged in parallel and in series. Hence, multiple convolutions (sums) and maxima of distributions need to be computed so that the final project duration and cost can be calculated. The influence of each activity's first two moments (mean and standard deviation) will be key in this final result. This justifies why an order of magnitude of these two moments is worth collecting from a representative dataset of real construction activities.

Finally, another factor that determines how the activity distributions are merged with 152 each other is dependent on the project network topology itself. Network topology refers to the 153 logical layout of a network (a project schedule). It defines the way different activities (often 154 referred to as nodes) are placed and interconnected with each other. Many metrics have been 155 proposed for describing the network configuration. Some well-known examples are the 156 Coefficient of Network Complexity (Davies 1973; Pascoe 1966), the Order Strength (Mastor 157 1970) and the Complexity Index (Bein et al. 1992). However, these only capture the project 158 complexity and will not be used here. 159

Instead, this study will make use of four topology measures that describe the structure
of an activity-on-the-node network, not just its complexity. These measures were initially
proposed by Tavares et al. (1999) and later improved by Vanhoucke (2008). The four
measures (also named *indicators*) used are: serial-Parallel (SP) indicator, Activity

164	Distribution (AD), Length of Arcs (LA) indicator, and Topological Float (TF) which will be
165	explained in the following sections. All these indicators range between 0 and 1 and constitute
166	simple measures describing to what extent the first two moments of the construction activities
167	may condition the final duration and cost of a project.

168

#### 169 Materials and methods

In this section, the characteristics of the projects and activity datasets analyzed are described first. The details of how the activity and project data was filtered and categorized, under multiple levels of analysis, is also presented. Next, the first four moments of activity durations and costs are reported and commented separately. Finally, the correlations between activity durations and costs are reported along with their statistical significance.

175

#### 176 Projects and activities dataset

This research used two different project datasets. The first (and main) one is analyzed at both activity- and project-level. The second dataset contains project level information (planned and actual project durations and costs) and will be used for illustrative purposes in the *discussions*.

In order to obtain representative values of the first four moments of the activity durations and costs, a significant amount of activities is necessary. In the first dataset, 101 construction projects are analyzed initially encompassing 5,697 activities.

Projects are classified in four types: Building, Civil engineering, Industrial and
Services. Building projects are mostly aimed at constructing a building or parts of a building.
Civil engineering refers to infrastructure construction in general. Industrial projects refer to

installations and/or electromechanical equipment. Services refer to projects with a significantoperational and/or production component.

The 101-project dataset was retrieved from a real projects dataset originally developed by Batselier and Vanhoucke (2015) and Vanhoucke et al. (2016). Although the exact location of those projects is not disclosed in most cases (due to a confidentiality clause with the information donors), it is known that most of them belong to Belgium, the Netherlands, Italy, USA and Azerbaijan.

At the time of writing, the complete project dataset is curated by the Operations Research & Scheduling Research Group at Ghent University and comprises 125 projects. 24 projects out of the 125 were not used as they did not include tracking information (actual activity durations and costs). All 125 projects, however, can be accessed at the website of OR-AS.be (2018). The major features of the 101 construction projects selected for this study are summarized in Table 1. The last four columns of Table 1 include some project network topological information (indicators SP, AD, LA, and TF) that will be used later.

201

#### <Insert Table 1 here>

We deem the variety and number of project types, costs, durations, topologies and number of activities as sufficiently representative for a first representative analysis. Yet, further details and specific project information can also be found as individual project cards at OR-AS.be (2018).

206

207 Analysis outline

This analysis focuses first on the activity-level deviations of durations and costs.
Project-level data will also be analyzed later, but from a complementary point of view to

activities analyses. The activity duration and cost deviations are calculated for each activity *i*in the first dataset according to these two expressions, respectively:

212 Activity duration deviation of activity 
$$i = LOG_{10} \left( \frac{Actual duration of activity i}{Planned duration of activity i} \right)$$
 (1)

213 Activity cost deviation of activity 
$$i = LOG_{10} \left( \frac{Actual \ cost \ of \ activity \ i}{Planned \ cost \ of \ activity \ i} \right)$$
 (2)

It is worth emphasizing that both ratios above are expressed in logarithmic scale. This is important, as ratios of variables which are always positive (e.g. durations and costs) are not symmetrical respect to the value 1. The scale distortion of these ratios (they range between 0 and 1 when the denominator is bigger than the numerator, but between 1 and + infinity when the numerator is bigger than the denominator) creates an artificial positive skewness in the data distribution that can only be removed by taking the log ratios beforehand. Additionally, in log scale, the variable variances are additive, rather than multiplicative.

Therefore, we will take the logarithm of every ratio before analyzing their activity duration and cost moments. We resorted to logarithms with base 10 because their orders of magnitude are a little more familiar, but any other base would have been possible.

224 Lastly, it is important to note that ratios in natural scale from 0 to 1 correspond to values from -infinity to 0 in any log scale. Whereas ratios in natural scale from 1 to +infinity 225 226 correspond to the  $(0, +\infty)$  range. Both ranges also have a symmetrical correspondence with each other in log scale (e.g. ratios  $\frac{1}{2}$  and 2 in natural scale have the same values with opposite 227 signs in log scale, that is -0.301 and 0.301, respectively) which makes the interpretations of 228 variability results easier. Bearing this in mind, the next step consists of describing how the 229 activities were grouped to analyze their ratios and produce robust results. The progressive 230 classification levels can be found in Table 2. 231

232	<insert 2="" here="" table=""></insert>
233	From top to bottom, three levels of activity classifications are presented. Each level
234	consists of three types of activities:
235	• Planned and Performed (P&P). These activities correspond to activities that were
236	initially planned and were also finally executed in the projects analyzed. These are the
237	most frequent and the only ones that are considered in the analysis.
238	• Unplanned but Performed (UbP). These activities correspond to activities that were
239	not initially planned but that were deemed necessary and had to be eventually carried
240	out. These activities were removed from the analysis because their ratios converged to
241	+ infinity (as the planned values in the denominators equal 0), and because most of
242	the time they come from planning mistakes or omissions.
243	• Planned but not Performed (PbnP). These activities correspond to activities that were
244	initially planned, but that were not executed in the end. These activity ratios would
245	equal zero in natural scale but their logarithmic values would converge to - infinity.
246	They also represent bad estimates of the planned schedule like UbP activities, hence,
247	they were also removed from the analysis.
248	Concerning activity grouping, four levels of analysis (0 to 3) were considered:
249	• Level 0 comprises all activities analyzed from all projects. This allows drawing
250	general average conclusions without paying attention to proportions nor types of those
251	activities.
252	• Level 1. Activities are classified under the same four types of projects stated in Table
253	1 (building, civil engineering, industrial and services). As expected, this level allows
254	analyzing how the activity durations and costs deviations differ by (generic) types of

projects. Some group average and dispersion results of activity durations and costs arealso included for reference on the right columns of Level 1 sub-table.

Level 2. Within the previous four project type categories we further classify activities 257 into three standard phases of the every project lifecycle according to the PMBoK: 258 Planning, Execution and Closure (Project Management Institute 2017). Classifying 259 activities into these three categories is straightforward with the activity descriptions 260 available in almost all projects. The fourth phase considered by the PMBoK 261 262 (Monitoring and control) is not relevant for this analysis, therefore not considered. Level 3. For the *execution* phase of *Building* and *Civil engineering* projects only 263 activities are further classified into five generic groups, called here activity types 264 (auxiliary works, substructure, superstructure, specialized works, and facilities). 265 These are also common and relatively straightforward groups of activities in most 266 construction projects. For a more detailed description of the scope of each group the 267

reader is referred to Chudley and Greeno (2016).

Level 3 allowed classifying activities into one last level right above the nature of the 269 activity itself. Activities in this level were classified mostly thanks to the descriptions of the 270 271 project summary activities (that were indeed not used for anything else in the analysis). Finally, as highlighted at the beginning of level 3, only activities from the *execution* phase of 272 273 building and civil engineering projects were used. This is due to the number of execution 274 activities in Industrial projects being considered too low. Also, because Execution activities belonging to Services projects, despite higher in number, were found too heterogeneous. The 275 latter made hard to classify these activities within similar self-contained categories (Services 276 277 projects are indeed much more varied regarding the nature of its activities).

278

#### 279 Activity duration results

The first four moments (average, standard deviation, skewness and kurtosis) of the activities log ratios were analyzed according to the four levels described in Table 2. Table 3 shows now the results for the activity *duration* log ratios (LOG<sub>10</sub> (*actual / planned*)).

283

#### <Insert Table 3 here>

For each case and level analyzed, four numerical values are displayed: *n* (the sample 284 size, that is, the number of activities used to calculate the four moments), and the four 285 moment values (in logarithmic scale). However, due to the major relevance of the first two 286 moments (average and standard deviation) these two have also been included in natural scale 287 within parentheses right below their respective logarithmic values. Values in natural scale are 288 expected to help the reader to better grasp the order of magnitude of these moments. With 289 this information, Table 3 is self-explanatory. The number of readings and details in this table 290 are numerous, so attention is given to the most relevant findings. 291

Concerning Averages, it is striking to observe how most values remain very close to 0 292 (in log values) or 1 (in natural values). Some exceptions may be Services projects and the 293 Planning phase activities (Level 2) from Building and Civil engineering projects. Yet, in the 294 latter, average ratios values remain close to 5% (in log values) or 11% (in natural values). 295 Overall, as these log ratios are so close to zero, this suggests that construction activities do 296 *not* end late (on average). This may be an unexpected finding, as the easier explanation for 297 projects ending late was that its activities ended late on average. This result seems to suggest 298 the problem lies somewhere else. 299

Concerning the *Standard Deviation* (SD) values, results are very different. SD, by definition, can only be positive but it is quite clear that, unlike the averages, SDs are not close to zero. Instead, with a few exceptions, SD values are almost always above 0.15 (in log scale) or 43% (in natural scale) between the actual and planned durations. This is an extremely high level of variability and, despite construction activities do not end late *on average*, they do
suffer from wide dispersions which condition to a big extent the project-level delays, as will
be justified later. On a secondary note, *Industrial* and *Services* projects also have a bigger
variability than the other types of projects. Interpretations by project phase (level 2) and
activity type (level 3) are more varied.

The results on *Skewness* are relatively uniform. A common rule of thumb assumes that skewness values ranging from -2 to +2 are indicative of a low distribution asymmetry (George and Mallery 2010). This is the case in Table 3 with very few exceptions. Therefore, the log ratios distribution must be approximately symmetrical and, combined with averages also close to zero, we can conclude that there is approximately the same probability of finding early activities than tardy activities.

Concerning *kurtosis*, the picture is very different. Values are generally well above 3, which would describe the kurtosis corresponding to the Normal distribution. This result means that log ratio duration values resemble a peaked distribution with heavy tails. In other words, the majority of the actual durations are not close to their planned values. As stated earlier, many other readings may be extracted from Table 3. However, for the sake of clarity, only the most relevant high-level interpretations are presented.

321

#### 322 Activity cost results

Table 4 represents the first four moments of the activity actual versus planned *cost* log ratios. In parentheses, we can find the antilogarithmic (natural scale) values of the first two moments as well. Table 4 values differ substantially from those found in Table 3.

326

#### <Insert Table 4 here>

Concerning Average values, most of them are clearly positive and generally above 327 1.01 (in log values) or alternatively above 3% (in natural scale). A clear exception may be the 328 Industrial projects whose average is negative. This may be because Industrial projects are 329 frequently composed of electromechanical equipment whose procurement prices are 330 relatively easier to estimate more accurately ex-ante than other types of projects. 331 Additionally, Civil engineering and Services projects are among the ones whose activities 332 333 tend to suffer from more cost overruns. This may be due to *civil engineering* projects being (generally) less standard than Buildings whose average log ratios remain closer to 0. On the 334 335 other hand, services projects as indicated in Table 3, suffered from more delays on average than other types of projects. Being these types of projects frequently more labor intensive, it 336 seems logical that those extra durations are correlated with these extra costs. 337

Concerning *Standard Deviation* (SD), variability is even more evident than in the case of duration log ratios. On level 0 we can appreciate how the average activity SD reaches 0.25 (78% of variability in natural scale). On level 1, no project type has a variability below 0.16 (46% of variability, in the case of *Building* projects) and two of them (*Civil engineering* and *Services*) remain above 0.30 (>100% of variability). SDs on levels 2 and 3 offer similar readings but with wider values.

Concerning *skewness*, cost log ratios are more varied than their duration counterparts. In general, when *average* values are negative, the skewness values are also predominantly negative. Similarly, when the *average* costs are positive, the cost distribution is also positively skewed.

Concerning *kurtosis*, values are much higher than its duration ratios counterpart too. This would be indicative again that most activity actual costs substantially differ from their planned values (a high proportion of the actual costs tend to be substantially different from their planned costs). 352

353

#### Activity duration and cost correlation

354 Numerical results of the log ratios of the first four moments offered very interesting information about the nature of duration extensions and cost overruns at activity level. It is 355 not the intention of this study to find a distribution that fits these four moments, though. As 356 suggested by other researchers and also discussed earlier, each activity is different in nature 357 and it is quite likely that a fit-for-all distribution does not exist. Indeed, on observing the wide 358 range of skewness and kurtosis values in Tables 3 and 4, that seems to be exactly the case. 359

However, a pending but also equally relevant issue is to analyze the potential 360 correlation between activity duration variation and cost variation. For this aim, all activities 361 were grouped under the very same levels previously described and linear correlations were 362 calculated among the duration log ratios and the cost log ratios. A summary of this analysis is 363 presented in Table 5. Spearman's rho and Kendall's tau non-linear (rank) correlations were 364 also tested. However, they only very marginally improved the linear correlation results and 365 were considered not worth including as they did not seem to barely depart from the linear 366 case shown in Table 5. 367

368

#### <Insert Table 5 here>

Table 5 is divided in two major blocks. The upper block is devoted to activity-level 369 370 correlations. The lower block is reserved for project-level correlations. For each correlation it 371 has been specified how many datapoints were used (column labelled as *n*), Pearson's correlation coefficient (R), the coefficient of determination ( $R^2$ ), along with the gradient 372 (slope column) and intercept of the linear regression lines. Statistically highly significant 373 correlations have been marked with two asterisks (\*\*) separately for  $R^2$  tests (with the 374

Snedecor's F distribution) and *slope* tests (with the Student's T distribution). Significant statistical correlations have been marked with a single asterisk (\*).

In the case of activity-level correlations, almost all correlation values are significant. This mean that values of  $R^2$  are very unlikely to have happened by chance. This is not the case at Project-level correlations where, apart from the level 0 of analysis (all 101 projects grouped together),  $R^2$  values have not been found to be statistically significant. This means we cannot count on the reliability of project-level duration-cost correlations, hence they will be ignored moving forward.

Correlations at activity-level do offer very interesting results. *R* and *R*<sup>2</sup> evidence weak to moderate correlations (*R*<sup>2</sup> ranging between 0.10 and 0.62), but the slopes of such correlations are rather close to 0.50 in some levels and almost all of them are significant (marked with \*\* or \*). More precisely, when there is no differentiation among activities (level 0), the slope is as high as 0.704. This means that a 100% activity duration extension (in log scale) would cause a 70.4% cost increment on that activity. This is quite a high gradient.

Differentiating by project type (level 1), the slopes become more informative. *Building* and *civil engineering* projects boast a gradient close to 0.5, that is, every 100% of duration increment is likely to cause a 50% of cost increment for that activity. For the other two types of projects we have no statistically significant slopes, despite it seems clear that *industrial* projects (probably due to the higher component of electromechanical equipment in the project budget) have lower slopes. On the contrary, *Services* projects, being more labor intensive, have higher slopes.

Results by project phase (level 2) seem more homogeneous. However, only the *execution* activities' slope is statistically significant. This level of correlation seems to replicate the results previously provided for level 0. Results at level 3 are again not that heterogeneous and they all are statisticallysignificant. However, there is nothing remarkable that has not been highlighted before.

A last note concerns the regression line intercepts (last column in Table 5). As can be seen, these values remain above 0.02 (in log scale) most of the time. That is approximately equivalent to an intercept of 5% in natural scale, which means that, no matter whether activity duration extensions are materialized or not, costs are likely to increase around 5% by default. These values are in line with the log ratio cost *averages* found in Table 4.

406

#### 407 Discussion

So far, almost all analyses have focused on individual activities. Yet, it is acknowledged that the construction process is not an exact science and construction managers are often 'judged' upon their capability to manage activity variability. Hence, the key concern is the whole project suffering from delays and cost overruns, not just some of its activities. It was proposed earlier that this is because activities suffer from variability (both positive and negative), not because they are delayed on average. This section is devoted to analyze whether this speculation seems acceptable.

Let us start by approaching the problem from a graphical perspective first. For that purpose, a second dataset of 746 road construction projects from the Florida Department of Transportation (USA) is used. Given the number of contracts, no descriptive table is included in the paper, but the complete dataset can be found as *supplemental online material*. This additional project dataset has been used here because they represent relatively similar (homogeneous) contracts, from the same client, and during a short period of time. Arguably, this is the closest to assuming that these projects are 746 different realizations (possible 422 outcomes) of the same generic type of project (in this case a road construction, that is, a *civil*423 *engineering* project).

Figure 1 represents the distributions of the log deviation ratios for durations and costs 424 for the 746 contracts (using expressions (1) and (2) at project-level, not activity-level). 425 <Insert Figure 1 here> 426 Concerning project duration deviations (curve with black circles), it closely resembles 427 an extreme value distribution of maxima (both Fréchet and Gumbel fits have been provided 428 for comparison in black colors). This means that the merge event bias takes an important role 429 when determining the actual project duration. Results in natural scale are, in this occasion, 430 almost identical but they have not been provided to avoid curve cluttering. 431 432 Furthermore, it is worth noting that the average project duration extension is around 0.21 (in log scale). For *Civil Engineering* projects in Table 3, the average of the duration log 433 ratio was negative (-0.008). This means the activities from civil engineering projects ended 434 sooner than planned (on average). It is unlikely then, that the projects represented in Figure 1 435 could have ended later because a significant proportion of their activities ended late. 436 437 However, the activity duration variability (the standard deviation) was 0.20. In extreme value 438 theory, the mean of the highest order statistic distribution of a Normal distribution with three or four draws is approximately one standard deviation. The Normal distribution represents 439 very well the distribution of the durations of each path (before they merge) (Ballesteros-440 441 Pérez, 2017a). Therefore, the average of the duration distribution coincides very closely with what is to be expected from the data from Table 3 for civil engineering projects  $(0.21 \approx 0.20)$ . 442 Later it will be shown how more than three paths are quite common in civil engineering 443

444 construction schedules.

Concerning project costs (curve with grey crosses), the situation is very different. The 445 distribution of costs (log scale) resembles a Gamma distribution. It is worth noting that when 446 a random variable X follows a Pareto distribution with parameter  $\lambda$ , the logarithm of X 447 follows an Exponential distribution with the same parameter  $\lambda$ . This is relevant because the 448 costs of individual activities are well known to resemble a Pareto distribution in almost all 449 construction projects (Love et al. 2014; Love and Sing 2013). Hence, as cost ratios are being 450 451 processed here in log values, our distribution should also resemble an Exponential distribution (continuous grey line in Figure 1). Additionally, as the sum of exponential 452 453 distributions is a Gamma distribution, that would offer some explanation, to why we are observing a Gamma distribution (dashed grey line) fitting almost perfectly the log cost 454 deviations in Figure 1. In this case the exponential distribution also provides a good fit, but 455 that is not always the case in other construction project datasets. 456

Having approached the problem from a graphical and statistical perspective, it will be addressed now from a topological perspective. Network topology describes the layout of project schedules. The values of four representative topological indicators are displayed on the last four columns of Table 1 for the 101 projects analyzed. Table 6 now shows the average values of each topological indicator listed in Table 1, but categorized by Project type (*building, civil engineering, industrial* and *services*), as well as for all projects together (last row).

464

#### <Insert Table 6 here>

The Serial-Parallel (SP) indicator is probably the most relevant of the four indicators for the purpose of this study. This indicator measures the closeness of a network to a serial or parallel network. Namely, SP = (m-1)/(n-1); where *n* is the total number of project activities in a project schedule, and *m* is the number of activities in the path with a higher number of activities (which may not necessarily be the longest in duration, as topological measures

ignore the activity durations). Hence, SP=0 means all activities are in parallel, whereas 470 SP=100% means all activities are in series. This indicator can also be considered as an 471 estimate of the amount of critical and non-critical activities in a network (Vanhoucke and 472 Vandevoorde 2009). Therefore, rounded up values of the inverse of the SP (that is  $\lceil 1/SP \rceil$ ) 473 provide us with an estimate of the minimum number of paths of a project schedule. Values of 474 SP below 50% would mean that construction schedules have (approximately) at least three 475 paths. This agrees with what we appreciated in the black curve of Figure 1. Industrial 476 projects, despite having on average at least two paths, generally have a dominant one (which 477 condenses, on average, 55% of the activities). In service projects schedules there are at least 478 five paths (on average), as only 20% (a fifth) of the activities are critical. 479

Activity Distribution (AD) measures the distribution of project activities along the 480 levels of the project. In network topology, the number of project levels can be loosely defined 481 as the number of activities that are arrayed in parallel in a project schedule. Hence, AD 482 measures the width of the network. However, it is worth noting that activities arrayed in 483 parallel do not necessarily have be executed simultaneously (because they may have different 484 time lags and/or activity durations). When AD=0 all levels contain a similar number of 485 activities and the number of activities is uniformly distributed over all levels. When 486 AD=100% there is one level with a maximal number of activities, and all other levels contain 487 a single activity. All four types of projects average AD values are close to 58% indicating 488 489 that the longest path has more activities than other paths, but still those other paths contain a significant number of activities, that is, they can potentially cause project delays. 490

The Length of Arcs (LA) indicator measures the tightness of each precedence
relationship between two activities as the distance between two activities in the project
network. When LA=0 the network has many precedence relationships between two activities
on levels far from each other such that the activity can be shifted further in the network.

When LA=100%, many precedence relationships have a length of one, resulting in activities
with immediate successors on the next level of the network and with little freedom to shift.
Average LA values are much closer to 0 than to 100% (overall average of 14.1%). This
means that activities tend to have many predecessors (on average) from different levels
(paths), which would reinforce the merge event bias effect.

500 Finally, the Topological Float (TF) measures the degrees of freedom per activity as 501 the amount of slack or float an activity has. When TF=0 the network structure is 100% dense 502 and no activities can be shifted within its structure. When TF=100% the schedule consists of 503 a single chain of activities without topological float. The average TF indicator value of 40.5% 504 means that the average activity structure of construction projects is rather dense.

Therefore, the highlights of this brief topological analysis above for construction projects are that: construction schedules are relatively dense (activity-wise), usually composed of at least three major paths, and with activities whose predecessors usually come, not just from activities located on the same path, but also from other paths. This means that the merge event bias plays a very important role in construction schedules. And, precisely thanks to the high level of duration variability existing at activity level, many delays are expected to cumulate every time two or more paths merge into a single successor.

However, mergers are much more frequent towards the end of the project compared to 512 the earlier stages of execution. This is as, for any paths to close, they have to open first. 513 Therefore, it is not a surprise that many construction projects get off to a good start (on time 514 and on budget), but half way across their duration, (local) delays start being detected 515 516 (whenever two or more paths are merged into one). As delays emerge, the cost of activities 517 will also increase proportionally as the correlation between duration deviations and cost deviations was quite substantial on average. As a result, it is not that surprising that projects 518 end later and cost more than initially anticipated. 519

521 Conclusions

522 The activity duration and cost variability of construction projects has been analyzed in this research by different types of projects (building, civil engineering, industrial and 523 services), project phase (planning, execution and closure), and activity type (auxiliary works, 524 substructure, superstructure, specialized works, and facilities). Correlation factors between 525 activity duration deviations and activity cost deviations have also been studied under the 526 same activity categories. The research is novel because it describes the first four moments 527 (average, standard deviation, skewness and kurtosis) of how actual versus planned durations 528 and costs differ at activity level in construction projects. A set of 101 projects and 5289 529 activities, plus another set with 746 projects have been used. 530

The first contribution of this study is providing construction managers with a first, yet 531 rather complete, set of actual-vs-planned average activity durations and costs deviations with 532 application in multiple contexts (project types, execution phases and types of activity). From 533 now on, a construction manager will be able to more realistically (thus accurately) anticipate 534 535 how likely and how much the activities in the project schedule will vary, that is, last or cost something different. This might potentially improve the quality and robustness of all 536 construction schedules, for example allowing them to feed more advanced (non-537 deterministic) scheduling and simulation tools with more representative data. These 538 techniques generally need a substantial amount of information from previous similar projects 539 which is rarely available. With the set of moments provided here, these techniques will be 540 541 able to resort to average values for their activity durations and cost distribution parameters 542 depending on the type and/or execution phase of the project. These distributions will also be able to assume non-independence between the stochastically-generated activity durations and 543 costs values (thanks to the set of duration-cost correlation values also published in this study). 544

520

This is expected to enhance future construction project monitoring and control, but alsoactual project duration and cost forecasting accuracy.

However, the analysis developed has also provided some interesting insights from its numerical perspective. One of the most relevant is that it has been shown that construction activities do not end late on average. Instead, it is their high level of variability (around 60% of its average duration) the key factor eventually causing project-level delays. Such high levels of activity variability exacerbate the merge event bias, a phenomenon by which whenever two or more schedule paths converge into a single one, the average completion times exceed the maximum average path durations.

Actual activity costs, on the other hand, do tend to be higher than what was planned (around 7%). This cannot be the result of price adjustments or inflation, as hardly any project lasted longer than a year. Instead, the major project-level cost overruns are expected to occur as a consequence of delayed start of activities located nearer the end of the project. This, as it has been demonstrated how most duration-cost correlation factors range within 0.40 and 0.70. The latter would cause that those activities that cannot start until their predecessors have finished, start incurring in costs before their actual execution.

561 Many other interpretations can arise from the numerical results of the four moments 562 describing activity duration and cost variability that refer to specific types of projects, phases 563 of execution or activity types that have not been recounted here. The reader is invited to refer 564 to Tables 3 and 4 for such a purpose.

A limitation of this study is mostly connected to the composition and sample size of the construction projects analyzed. 101 projects have been used here with a varied composition. However, this sample size could have been bigger. It must be clarified, though, that accessing actual duration and cost information is ontologically questionable and certainly methodologically challenging. Companies are not open to share this information because it
would clearly indicate how competent and efficient their operations are. Under that
perspective, the current sample size probably seems satisfactory, at least for a first
representative analysis.

A second limitation arises from having removed at the outset the Unplanned but 573 574 Performed (UbP) and Planned but Unperformed (PbU) activities. This was necessary as the ratios (either in natural or log scale) converged to infinity causing a distortion in the moments 575 calculation. However, we acknowledge that these activities can be found in almost all real 576 projects. Frequently, they are the consequence of scope changes, works reorganization or 577 changes in the available resources. Obviously, UbP and PbU activities add to the total project 578 variability (beyond the activity duration and cost variability analysed here). In our analysis, 579 though, there were only 279 UbP + 129 PbU = 408 activities out of the initial 5,697 (7% in 580 total). Hence, while we believe the influence of UbP and PbU activities needs to be duly 581 investigated, our analysis (with 93% of the activities) can still be considered representative 582 enough to draw valid conclusions. Additionally, it is also expected that some degree of 583 cancellation will occur among those 7% of activities (as frequently new activities replace 584 others which are not eventually performed). 585

In the same vein, there are many potential future research continuations after this 586 piece of research. Again, this study might be extended to analyze other types of projects 587 and/or other more specific types of activities (maybe at trade-level: concrete, steel, asphalt, 588 earthworks, etc.). The network topologies for other types of projects may also be studied to 589 590 anticipate to what extent current levels of activity variability might impact their final schedules. The statistical distribution of activity (duration and cost) variability may also be 591 analyzed. This was not possible at the general activity-level as discussed in this paper, but it 592 593 should be possible for activities at their trade level.

A last conclusion derived from this research is that activity duration variability is the 594 actual foe in project monitoring and control. This may not sound new to Lean Construction 595 researchers and practitioners. However, this research has provided compelling empirical 596 evidence suggesting that we do really need to start taking activity variability more seriously. 597 There is a need to develop more techniques that can effectively handle/restrain this 598 variability. Value stream mapping and Last planner have been some attempts to address this 599 600 problem, but more are needed. This will open the door to new and more effective approaches for tackling the widespread phenomenon of construction projects ending late. 601
