1 **Abstract**

2 This study examined the potential of six aliphatic and aromatic amides, commonly found in natural waters or used
3 as chemical aids in water treatment, to act as organic precursors for nine haloacetamides (HAcAms), five
4 haloacetonitriles (HANs), regulated trihalomethanes (THMs) and haloacetic acids (HAAs) upon chlorination and
5 chloramination. The impact of key experimental conditions, representative of drinking water, including pH (7 &
6 8), retention time (4 & 24 h) and bromide levels (0 & 100 µg/L), on the generation of the target DBPs was
7 investigated. The highest aggregate DBP yields upon chlor(am)ination were reported for the the aromatic and
8 hydrophobic hydroxybenzamide; 2.7% ±0.1% M/M (chlorination) and 1.7% M/M (chloramination). Increased
9 reactivity was observed in aliphatic and hydrophilic compounds, acrylamide (2.5±0.2% M/M) and acetamide
10 (1.3±0.2% M/M), in chlorination and chloramination, respectively. The addition of bromide increased average
11 DBP yields by 50-70%. Relative to chlorination, the application of chloramines reduced DBP formation by 66.5%
12 (without Br⁻) and by 46.4% (with Br⁻). However, bromine incorporation in HAAs and HAcAms was enhanced
13 following chloramination, of concern due to the higher toxicological potency of brominated compounds.

26 **1. Introduction**

27 Natural water resources intended for human consumption are usually characterised by organic and
28 inorganic constituents that stem from physicochemical, biological and anthropogenic activities. The
29 disinfection of natural waters, variably enriched with these organic and inorganic constituents, referred
30 as precursors, leads to the formation of disinfection by-products (DBPs), which have been the focus of
31 a significant amount of investigation since the mid-1970s (Bellar et al., 1974; Rook, 1974). To-date,
32 literature refers to more than 700 DBPs resulting from the most common disinfection methods (Han
33 and Zhang, 2018; Krasner et al., 2006). Some of these DBPs are known or suspected to constitute risks
34 to public health (Richardson et al., 2007; Plewa et al., 2008; Zhang et al., 2020) and are currently
35 regulated, e.g. by the US Environmental Protection Agency (THMs: 80 µg/L, HAAs: 60 µg/L) and the
36 European Union (THMs: 100 µg/L), with water companies required to keep their concentrations as low
37 as possible without compromising the effectiveness of disinfection (DWI, 2012).

38 To control the formation of regulated THMs and HAAs, some water utilities are switching from
39 chlorination to chloramination, since it has been widely reported to minimise DBP formation in both
40 real and artificial water matrices (Bougeard et al., 2010; Cowman and Singer, 1996; Parsons and Goslan,
41 2009). However, chloramination has also been associated with increased levels of nitrogenous DBPs
42 (N-DBPs), namely N-nitrosodimethylamine (NDMA) (Mitch et al., 2009), cyanogen chloride (Krasner
43 et al., 2012), and perhaps haloacetonitriles (HANs) and haloacetamides (HAcAms) (Huang et al., 2017),
44 even studies on the formation of the latter two groups are conflicting (Mitch et al., 2009; Templeton et
45 al., 2012). A recent study that included halonitrophenols, amongst other halogenated aromatic DBPs,
46 highlighted the potential occurrence in drinking water and their significant in vitro toxicity (Zhang et
47 al., 2020)

48 HAcAms were initially identified as DBPs in drinking water in the US N-DBP survey in 2000-2002
49 (Krasner et al., 2006; Weinberg et al., 2002). Although they occur in low concentrations, usually ten
50 times lower than HAAs (Krasner et al., 2006), HAcAms are currently the focus of research, due to their
51 reported potential risk of carcinogenicity and mutagenicity (Plewa et al., 2008; Richardson et al., 2007).
52 According to Plewa et al. (2008), HAcAm are 142× and 12× more cytotoxic and genotoxic,

53 respectively, than the five HAAs that are regulated in the US, and 2× more cytotoxic than the
54 unregulated HANs. Limited information is available regarding HAcAm precursors and formation
55 mechanisms, since it is a relatively new DBP group identified in drinking water. Several studies
56 postulate that HAcAms are ‘intermediate products’ of HANs hydrolysis, which can further transform
57 into the corresponding HAAs (Bond et al., 2014; Glezer et al., 1999; Reckhow et al., 2001). However,
58 recently Huang et al. (2012) found that DCaAm can be generated independently from DCAN during
59 both chlorination and chloramination. That study suggested the need for investigating alternative
60 pathways and potential nitrogenous and non-nitrogenous N-DBP precursors in drinking water during
61 the application of chlor(am)ine (Chu et al., 2010a, 2010b; Kimura et al., 2013; Le Roux et al., 2016;
62 Nihemaiti et al., 2016).

63 Interestingly, the DCaAm yields reported from model precursor studies, that include amino acids, are
64 significantly lower than those of DCAN (Chu et al., 2010b), whereas in studies that include real water
65 matrices the levels of the two N-DBP groups are similar (mean: 1.4 µg/L and 1 µg/L, respectively)
66 (Krasner et al., 2006). The majority of reported HAcAm occurrence seems to be as a result of unknown
67 precursors (Bond et al., 2012). The highest formation potential for DCaAm has been linked to natural
68 waters with significant hydrophilic acid fractions in the organic matter (Chu et al., 2010a), especially
69 those characterised by protein-like structures. Several researchers have investigated the potential of
70 these nitrogen-rich species, often associated with wastewater-impacted or algal-rich water matrices,
71 such as amino acids (both aliphatic and aromatic), proteins, pyrroles, pyrimidines, lignin phenols to act
72 as N-DBPs precursors by chlorinating and chloraminating model precursor compounds (Bond et al.,
73 2014; Chu et al., 2010a; Chuang et al., 2015; Le Roux et al., 2016; Nihemaiti et al., 2016). Bond et al.
74 (2014), assessed the effect of both chlorination and chloramination of seven model amine compounds
75 at three pH values (6, 7 and 8), and quantified the concentrations of DCAN, TCAN, chloroform and
76 TCNM. Chu et al. (2010a) investigated the formation of DCaAm from 20 amino acids during
77 chlorination and chloramination, of which the most reactive was aspartic acid, followed by histidine
78 with yields of 0.23 and 0.19 % M/M, respectively. Le Roux (2016) highlighted that the presence of
79 aromatic moieties in the precursor pool, encourages the formation of N-DBPs during chloramination,
80 in comparison with samples of high aliphatic content. In fact, the most reactive precursors were the

81 non-nitrogenous compounds, resorcinol and phenol, that yielded, respectively, 1.14 %M/M and 4.4 %
82 M/M of DCAN, while 0.83 % M/M and 0.22 % M/M of DCaAm, respectively, were also formed.

83 Amine-containing and amide-containing substances may be important N-DBP precursors, since they
84 are abundant in natural surface water and sediments, represent a substantial fraction of dissolved organic
85 nitrogen and around 2-3% of total natural organic matter (Świetlik et al., 2004). Amides are also present
86 in around 25% of pharmaceuticals and other medicinally important compounds (Ghose et al., 1999),
87 which have been found in trace concentrations in the water cycle (Bull, 2014; WHO, 2011). In addition,
88 it has been previously reported that their polarity and the presence of hydrogen atoms of the amide
89 groups not only facilitate but also accelerate halogen substitution during oxidation (Yu and Reckhow,
90 2017).

91 The presence of bromide in water has been widely associated with elevated halogenated DBPs in both
92 chlorinated and chloraminated systems (Baribeau et al., 2006; Chu et al., 2013; Cowman and Singer,
93 1996; Krasner et al., 2008), and increasing bromide levels results in changes in chlorine to bromine
94 ratios and shifts speciation towards more brominated DBP species (Krasner et al., 2008; Symons et al.,
95 1993); suspected to be of greater health significance than their chlorinated counterparts (Plewa et al.,
96 2008). Therefore it is crucial to understand the role of bromine incorporation in both regulated and
97 unregulated DBPs (Amy et al., 1991; Baribeau et al., 2006; Cowman and Singer, 1996; Symons et al.,
98 1993). Hua and Reckhow (2012) calculated the bromine incorporation factor (BIF) for four DBP classes
99 (THMs, di-HAAs, tri-HAAs and di-HANs) and postulated that these decreased with increasing contact
100 time and temperature during both chlorination and chloramination. Even though pH had no effect in the
101 bromine incorporation, the order of BIFs was di-HAN > THM & di-HAA > tri-HAA upon chlorination,
102 whereas upon chloramination HAAs exhibited higher BIF values. Otherwise however, there is little
103 information on the role of bromide in the formation of N-DBPs, since the majority of model compound
104 studies omit bromide spiking. An exception is the studies by Bond et al. (2015, 2009), that calculated
105 BIF values and concluded that during chlorination of amines di-HAcAms present higher BIF than di-
106 HANs, whereas during chloramination, even though BIFs for di-HAcAms were lower than di-HANs
107 BIF, both were significantly higher than from chlorination.

108 Another important parameter is disinfectant contact time, since in occurrence studies with variable
109 retention times, HAAs and HANs have been reported to increase overall with increasing contact time,
110 between 2 and 100 hours, but with intermediate decreases between 24-72 hours (Bougeard et al., 2010;
111 Chen and Weisel, 1998; Goslan et al., 2009; Koch et al., 1991; Templeton et al., 2012). Information
112 about the fate of N-DBPs as a function of contact time, and especially for HAcAms is very limited,
113 although, it is suggested that HAcAms (DCAcAm, DBAcAm, TCACAm) levels may slightly increase
114 in distribution (Bond et al., 2015).

115 Therefore, the objectives of this study were to compare the effects of chlor(am)ination under controlled
116 laboratory conditions to examine the importance of variables such as bromide, contact time, pH,
117 precursor characteristics and disinfectant type, with a specific focus on amides and their role in all nine
118 HAcAms formation, with simultaneous measurement of the formation of HANs, HAAs, and THMs.
119 An improved understanding regarding the tendency of amides to form DBPs in drinking water will
120 highlight their relative importance compared to other precursors and have implications for DBP
121 minimisation strategies in water treatment practice.

122

123 **2. Materials and Methods**

124 All six selected amide model compounds were tested for the formation potential of 9 HAcAms, 5 HANs,
125 and 9 HAAs during both chlorination and chloramination; at pH 7 and 8, after 4 and 24 hours of contact,
126 with the absence or presence of bromide (100 µg/L), representative of the typical conditions in drinking
127 water treatment and distribution (Bond et al., 2015). THM yields, which were not the main focus of this
128 study but were included for completeness, were quantified at 24 hours contact time at pH 7 and 8, both
129 with and without bromide upon chlorination and chloramination.

130 **2.1 Selection of amides**

131 The selection of the amides was based on the following: their functional groups, structure, molar mass,
132 hydrophilicity and previous reported DBP formation potential (Table 1).

133 Acetamide has been previously reported as THM and HAA precursor (Bond et al., 2012, 2009), as well
134 as of the following N-DBPs: DCAN, TCAN and TCNM (Bond et al., 2009). Acetoacetamide contains

135 a beta-dicarbonyl group, which is known to act as a reactive THM and HAA precursor group
136 (Dickenson et al., 2008). Polyacrylamide is a polymeric coagulant aid used in water treatment, however,
137 despite approximately 95% of the polymers being absorbed in the floc during water treatment, a 5%
138 remains dissolved in the water and may pass to the disinfection stage of treatment (Guzzo and
139 Guezennec, 2015). Its susceptibility to multiple degradation pathways is high; the amide group can
140 undergo hydrolysis or dehydration (Caulfield et al., 2003) that leads to the release of acrylamide.
141 Acrylamide is a compound of health concern, readily mobile in aqueous environments and highly
142 leachable in soil (WHO, 2004), with reported concentrations of <5 µg/L in river and tap water samples
143 in the US (WHO, 2004). Both acrylamide and polyacrylamide, apart from being used in water and
144 wastewater treatment, are grouting agents in the construction of drinking water reservoirs and wells
145 (IPCS and WHO, 1985). β-Alaninamide derives from the amino acid, β-alanine acid, known for
146 generating significant yields of THMs and HANs (Hureiki et al., 1994). Hydroxybenzamide is an
147 aromatic moiety and selected aromatic precursors have been previously shown to exhibit high N-DBP
148 formation potentials (Le Roux et al., 2016).

149 This study included compounds ranging from slightly hydrophobic (log Kow <0.5) to highly
150 hydrophilic (log Kow = -1.8) (Table 1). They were obtained at lab-grade purity or higher from Sigma-
151 Aldrich (Darmstadt, Germany) and Finetech Industry (London, UK).

152 **2.2 Sample preparation**

153 For the sample preparation, each amide was added at 10 µM and buffered at pH 7 or 8 (10 mM sodium
154 phosphate). Bromide was added at 100 µg/L for those samples which contained bromide. Next, either
155 chlorine or chloramine (N/Cl molar ratio: 1.4/1) was added at a formation potential dose of 20 M/M.
156 Both chlorine (0.25 M) and chloramine (0.1 M) solutions, were measured by DPD-FAS titration in at
157 least triplicate on the day of sample preparation (Apha et al., 1999). Sample bottles were then filled
158 headspace-free before being left for 4 or 24 hours at room temperature. When the selected contact times
159 were completed amide samples were quenched with 100 mg/L of ammonium chloride (chlorinated
160 samples) and 50 mg/L of ascorbic acid (chloraminated samples), to preserve the individual analytes,
161 and were extracted immediately (Domino et al., 2003; Liew et al., 2012; Munch and Hautman, 1995).

162 Yu and Reckhow (2017) showed that the HAcAms (DCAcAm, BCACAm and DBACAm) identified to-
163 date using the most commonly employed analytical techniques are N-Cl-HAcAms; kinetic experiments
164 indicated that HAcAms generated from chlorination are unstable and thus undergo instant N-
165 chlorination. The result is a hydrogen bond between the amino hydrogen and hypochlorite oxygen that
166 leads to the formation of equal amount of N-Cl-HAcAms, highly stable in water, detected at the same
167 retention time. In this study though, the use of quenching agents (ammonium chloride and ascorbic
168 acid) was assumed to rapidly reduce the nitrogen-bound chlorine in the N-C-HAcAms back to simple
169 HAcAms. All reagents used were of analytical purity or higher and all samples were prepared and
170 extracted in duplicate.

171

172 **2.3 DBP Analyses**

173 The determination of all target DBPs in this study was performed by liquid-liquid extraction and gas
174 chromatography – electron capture detector (GC-ECD) (Perkin Elmer Clarus 500), using two separate
175 methods, a modified EPA Method 551.1 (for THMs, HANs and HAcAms) with a fused silica capillary
176 column (RXi 5Sil MS, 30m·0.25mm ID, 0.25 µm film thickness, Restek, USA) and added temperature
177 increase rates up to 280°C, and EPA Method 552.3 (for HAAs) (Domino et al., 2003; Munch and
178 Hautman, 1995). The method detection limits of THMs, HAAs, HANs and HAcAms were respectively,
179 0.4, 0.5, 0.2 and 0.1 µg/L. Approximately 240 samples were extracted and analysed for the four target
180 DBP classes.

181 **2.4 Bromine incorporation factor (BIF)**

182 BIF is the ratio of the molar concentration of incorporated bromide into a given class of DBP divided
183 by the total molar concentration of chlorine and bromine in that class (Hua and Reckhow, 2012). The
184 degree of incorporation is a useful indicator to compare the degree of bromination of the DBP classes
185 in the presence of chlor(am)ine, since brominated DBP species may be more genotoxic and carcinogenic
186 than their chlorinated analogues (Richardson et al., 2007). The BIFs were calculated using Equations
187 (1-5), where concentrations are on a molar basis, excluding HANs due to limited occurrence:

$$188 \text{ BIF (THMs)} = \frac{[\text{CHBrCl}_2] + 2[\text{CHBr}_2\text{Cl}] + 3[\text{CHBr}_3]}{[\text{CHCl}_3] + [\text{CHBrCl}_2] + [\text{CHBr}_2\text{Cl}] + [\text{CHBr}_3]} \quad \text{Equation 1}$$

189
$$\text{BIF (di-HAAs)} = \frac{[\text{BCAA}] + 2 \cdot [\text{DBAA}]}{[\text{DCAA}] + [\text{BCAA}] + [\text{DBAA}]}$$
 Equation 2

190
$$\text{BIF (tri-HAAs)} = \frac{[\text{BDCAA}] + 2 \cdot [\text{DBCAA}] + 3 \cdot [\text{TBAA}]}{[\text{TCAA}] + [\text{BDCAA}] + [\text{DBCAA}] + [\text{TBAA}]}$$
 Equation 3

191
$$\text{BIF (di-HAcAms)} = \frac{[\text{BCAcAm}] + 2 \cdot [\text{DBAcAm}]}{[\text{DCAcAm}] + [\text{BCAcAm}] + [\text{DBAcAm}]}$$
 Equation 4

192
$$\text{BIF (tri-HAcAms)} = \frac{[\text{BDCAcAm}] + 2 \cdot [\text{DBCAcAm}] + 3 \cdot [\text{TBAcAm}]}{[\text{TCAcAm}] + [\text{BDCAcAm}] + [\text{DBCAcAm}] + [\text{TBAcAm}]}$$
 Equation 5

193 The results of the above calculations were normalised by the number of halogens, i.e. di-halogenated
 194 and tri-halogenated compounds were divided by two and three, respectively. This normalisation
 195 produces BIF values between 0 (only chlorinated species presented) and 1 (only brominated species
 196 present).

197 **3. Results and Discussion**

198 **3.1 Formation of nitrogenous disinfection by-products (HAcAms and HANs)**

199 The direct chlor(am)ination of the selected amide precursors resulted in the detection of HAcAms under
 200 all experimental conditions (Fig.1 a-b), while HANs species were rarely detected, primarily at 24 h of
 201 retention time (Table 1). Generally, in the few samples that HANs were detected (pH 8), those yields
 202 were higher following chlorination and lower in chloramination than those of total HAcAm; with the
 203 exception of acetoacetamide. This pattern was in agreement with previous precursor studies of organic
 204 acids and natural organic matter solutions, that reported favouring of HAcAm formation via
 205 chloramination in the absence of bromide (Chu et al., 2016; Huang et al., 2017). In this study, of note,
 206 amide compounds at pH 7 generated undetectable levels of HANs upon chlorination, whereas upon
 207 chloramination TCAN (0.17 %M/M) was the only species at 24 hours in the β -alaninamide samples.
 208 Under the same conditions, the corresponding HAcAms species were present in the majority of the
 209 amide samples even at low contact time (4 h). The most abundant species was DCAcAm, ranging
 210 between 0.05-1.32%M/M and 0.01-0.08 %M/M, upon chlorination and chloramination, respectively.
 211 Unlike at pH 7, when the six amide precursors were chlorinated at pH 8 both DCAN and TCAN levels
 212 were detected. This was only observed at 24 hours of retention time, however (Table 2). The above
 213 indicated that DCAcAm and TCAcAm yields were not solely due to the hydrolysis of DCAN and
 214 TCAN (Chu et al., 2010b; Reckhow et al., 2001) and that they could also have formed independently

215 (Huang et al., 2012). In the absence of bromide, the most reactive amides for both chlorination and
216 chloramination were β -alaninamide (1.32 ± 0.09 % M/M) and acetoacetamide (0.45 ± 0.07 %M/M), after
217 both pH 7 and 24 hours of retention time. Total HAcAm yields were reduced by 60-92% among the
218 chloraminated amides, relative to the chlorinated ones. The molecular structure of the selected amides
219 was considered an important formation factor. Acetoacetamide contains a β -dicarbonyl group,
220 previously reported to be a reactive structural moiety with halogens (Dickenson et al., 2008), whereas
221 β -alaninamide includes a beta carbon. At the same time, these amides were two of the most hydrophilic
222 moieties ($\log K_{ow}$) in this study (Table 1), meaning that if they are present in water the likelihood to
223 reach the disinfection stage of treatment is high, unless selective pre-treatment is in place (e.g granular
224 activated carbon, biological filtration and advanced oxidation) (Bond et al., 2011).

225 Polyacrylamide had a similar HAcAms formation in both pH and retention times, with mean yields of
226 0.064 ± 0.003 % M/M (pH 7) and 0.051 ± 0.008 % M/M (pH 8) (Table 2). On the other hand, its
227 monomer, acrylamide, formed undetected yields of HAcAms at pH 7, whilst at pH 8 HAcAm yields
228 were significantly reduced after 24 hours (by 89%). Recent studies confirm these findings for the above
229 amide-based coagulants (Ding et al., 2018; Wang et al., 2018); polyacrylamide samples yielded 0.040%
230 M/M of DCaAcAm in chlorination and undetectable in chloramination, against 0.034% M/M and
231 undetectable, respectively, in the current study. Similarly, with respect to acrylamide, DCaAcAm were
232 0.11 % M/M during chlorination and undetectable during chloramination, against 0.15 % M/M and
233 undetectable, respectively, in this study (Fig 1.b). Acetamide presented relatively low HAcAms yields,
234 stable between the retention times (0.09 ± 0.0 % M/M) in pH 8, and decreasing between 4 and 24 hours
235 from 0.05 ± 0.01 % M/M to undetectable at pH 7 upon chlorination (Fig. 1). The decrease was due to
236 HAcAm hydrolysis and was related to a corresponding increase of HAAs during the same conditions
237 (Fig. 1 a).

238 Decreasing but similar HAcAms yields at pH 7 and pH 8 were also observed for acetoacetamide, after
239 4 hours (0.26% and 0.22%, respectively) and 24 hours (0.12% and 0.13%, respectively). Interestingly,
240 the aromatic nature of hydroxybenzamide did not favour HAcAm formation as much as expected during
241 both chlorination and chloramination. Literature suggests that a ring-cleavage reaction is triggered when
242 the aromatic ring is activated by the hydroxyl group, encouraging chlorine electrophilic substitution

243 (Chu et al., 2010b; Hureiki et al., 1994; Nihemaiti et al., 2016). However, either chloramine cannot
244 trigger the rapid opening of the benzene ring (Chu et al., 2009) or the HAcAms previously formed at
245 lower contact times, regardless of their amount, were prone to hydrolyse at a faster rate. As such,
246 hydroxybenzamide samples upon chlorination yielded $0.45 \pm 0.17\%$ M/M (pH 7) and $0.14 \pm 0.04\%$
247 M/M (pH 8) of HAcAms after 4 h, which then decreased to undetectable (pH 7) and 0.05% M/M (pH
248 8) after 24 h. On the other hand, upon chloramination hydroxybenzamide yielded 0.08% M/M (pH 7)
249 and 0.01% M/M (pH 8) of HAcAms after 4 h, which then decreased to 0.03% M/M (pH 7) and remained
250 the same in pH 8 after 24 h.

251 The average DCACAm yields reported in the chloraminated amide samples ($0.06 \pm 0.01\%$ M/M) from
252 the aliphatic precursors in this study (Fig. 1b) were similar to a previous study on aromatic nitrogenous
253 amino acids ($0.09 \pm 0.03\%$ M/M) (Le Roux et al., 2016), and higher than those reported in a study on
254 low molecular weight non-nitrogenous organic acids (0.011% M/M) (Chu et al., 2016).

255 Based on the experimental conditions used in this study, the presence of HANs was not necessarily
256 expected (Clayden et al., 2001; Schreck, 1968). According to a recent publication (Wang et al., 2018),
257 however, acrylamide can degrade during chlorination, via the Hoffman rearrangement, to form HANs
258 and then HAcAms between 4 and 24 hours of contact time. In fact, this was not confirmed neither from
259 the acrylamide nor from the other amide samples, since the general observation was that, with the
260 exception of acetoacetamide, HAcAm yields peaked at 4 hours and then degraded at 24 hours during
261 chlor(am)ination at both selected pH values. More specific, when acrylamide presented $0.12 \pm 0.02\%$
262 M/M of HANs at 24 hours of retention time, HAcAms had decreased between 4 and 24 hours from 0.36%
263 M/M to 0.04% M/M. Likewise, in the three cases that TCAN was the only species detected in
264 chloramination, this is not associated with any simultaneous increase of TCACAm or any other HAcAm
265 species. Since there is not a known reaction pathway from an amide to form a haloacetonitrile, further
266 investigation is needed to confirm whether any reagent used functioned as reducing agent.

267

268 **3.2 Formation of carbonaceous disinfection by-products (HAAs and THMs)**

269 The highest HAA yields were identified in the chlorinated samples at pH 7 (Fig.1a). Under these
270 conditions hydroxybenzamide generated $1.05\% \pm 0.2$ M/M in 4 hours, followed by β -alaninamide and

271 polyacrylamide samples that both generated $0.70\% \pm 0.4$ M/M after 24 hours. With the exception of the
272 aromatic samples in pH 8, it is noteworthy that the HAAs generated from aliphatic amide samples were
273 statistically significant higher than the other DBP classes, representing 47-100 % of the aggregate DBP
274 yields during both chlorination and chloramination. When amide samples switched to chloramination,
275 significantly lower amounts of total HAAs were generated, under all experimental conditions, with
276 reductions ranging 42-75%, already expected from literature (Bougeard et al., 2010; Goslan et al.,
277 2009). The most reactive precursor became acetamide that generated $0.63\% \pm 0.11\%$ M/M at pH 8 and
278 4 hours, followed by hydroxybenzamide that generated $0.53\% \pm 0.09$ M/M at pH 7 and 24 hours,
279 attributable to TCAA and MCAA yields, since DCAA was rarely identified above detection limits
280 (Fig.3). This is possibly due to the low stability and faster degradation of TCACAm to form TCAA in
281 comparison with the mono and dichloro-compounds (Glezer et al., 1999). However, the absence of
282 DCAA yields and the higher yields of TCAA than TCACAm, designated that apart from HAcAms
283 hydrolysis, chloramination favoured further halogenation of the supposed dihalogenated intermediate
284 instead of oxidation or hydrolysis to form DCAA (Cowman and Singer, 1996). From a practical
285 standpoint, it is highlighted that if the aliphatic and hydrophilic amides are still present in the water
286 matrix prior disinfection, the regulated HAAs are likely to present the highest contribution in total DBPs
287 pool of the treatment works, even with the absence of bromide.

288 Prior the addition of bromide, the most reactive precursor was β -alaninamide, which generated
289 respectively 0.28 ± 0.02 %M/M and 0.026 ± 0.02 %M/M of chloroform, upon chlorination and
290 chloramination at 24 hours (Fig.1 a,b). In fact, upon chlorination, chloroform yields were observed
291 above the detection limit only at pH 8, whereas upon chloramination only at pH 7 in 4/6 amides. The
292 formation selectivity between the two pHs and disinfection process are consistent with research on
293 natural water and organic precursors (Bond et al., 2014; Diehl et al., 2000; Stevens et al., 1989). The
294 electron donating group (Dickenson et al., 2008) present in β -alaninamide seemed to favour formation
295 against all the other aliphatic precursors which in chloramination yielded ≤ 0.07 %M/M (Fig.1b).
296 Previous studies using amines demonstrated that during chloramination chloroform generation was
297 reduced by 66-93% in comparison with the yields during chlorination (Bond et al., 2014). Chloroform

298 formation in 24h from acrylamide/ polyacrylamide was previously reported to be 0.07/0.15 %M/M
299 upon chlorination and 0.14/0.22 % M/M upon chloramination, respectively (Ding et al., 2018); against
300 0.09/0.09 %M/M in chlorination (pH 8) and 0.05/0.03 %M/M in chloramination (pH 7) in this study.
301 The differences are most likely due to the fivefold initial amide concentration and lower pH used in the
302 earlier study (50 μ M and pH 6, rather than 10 μ M). The presence of chloroform in varying degrees was
303 explained by two mechanisms (Reckhow et al., 1990): either as a hydrolysis product of tri-HAAs,
304 favoured by base-catalysed hydrolysis of the halogenated leaving group (Ding et al., 2018), or as an
305 independent by-product of amide oxidation via a currently unknown pathway.

306 **3.3 Bromide addition in amide precursors**

307 The incorporation of bromide in the amide samples resulted in a significant increase in total HAcAms
308 yield, for all the amides tested, without exception, in both chlorinated and chloraminated samples, with
309 increases ranging between 35-98%. It also shifted speciation towards DBAcAm and DBCAcAm
310 (Fig.2). All chlorinated amides were evidently more reactive at pH 7 during both retention times
311 (Fig.2a), whilst chloraminated amides became more reactive at pH 8 after a retention time of 24 hours
312 (Fig.2b), due to the known increased selectivity of each disinfectant at the two-different pH of this study
313 (Bowman and Mealy, 2007). Upon chloramination at pH 8, total HAcAms concentrations were similar
314 or higher than those upon chlorination. The most reactive precursor following chlorination became
315 acetamide with $2.17 \pm 0.02\%$ M/M, closely followed by hydroxybenzamide that reached a peak of
316 HAcAms yield of 2.08% M/M at 4 hours and acrylamide of 2.03% M/M in 24 hours, all at pH 7 (Fig.2a).
317 In samples with polyacrylamide and acetoacetamide, a slight decrease (by median 8%) of HAcAms
318 yield with time was observed in pH 7 but a significant increase was observed in pH 8 (by median 48%).
319 On the other hand, β -alaninamide behaves in the opposite way; HAcAms yields were increasing in pH
320 7 (by 26%) and decreasing in pH 8 (by 36%) with regards to retention time. During chloramination,
321 HAcAms formation followed the same pattern in all the amide samples; In pH 7, yields decreased
322 whereas in pH 8 increased with time. During chloramination in brominated samples, the most reactive
323 amides were acetamide (pH 7 - 4 h) and β -alaninamide (pH 8 - 24 h) yielding 0.81 and 0.80% M/M,
324 respectively (Fig.2b). It is noteworthy that when bromide was spiked at pH 7, HAcAm yields increased

325 at least two-fold from those observed at pH 8, due to the increased stability at lower pH (Chu et al.,
326 2016). Namely, acetamide samples under the same conditions generated 0.81% and 2.2% M/M upon
327 chlorination, whereas generated 0.40% and 0.81% M/M upon chloramination, at pH 8 and 7
328 respectively. Interestingly, at pH 7 HANs species were not detected during chlorination even with the
329 presence of bromide, however were detected during chloramination in low yields in four amide samples.
330 The presence of bromide ion resulted in increased HAAs formation (10-80%) during chlor(am)ination
331 essentially at the low retention times (4 hours) and was characterised by a shift in speciation towards
332 BCAA, DBAA and TBAA ($0.036\% \pm 0.002$ M/M, $0.042\% \pm 0.009$ M/M and $0.015\% \pm 0.001$ M/M,
333 respectively) (Fig.3 a,b). It is known that bromine-containing species, prominent after bromide spiking
334 in this study, are more prone to degrade against the chlorine-containing (Baribeau et al., 2006; Zhou
335 and Xie, 2002). Indeed, at 24 hours of retention time and pH 8 it was observed that HAA yields were
336 statistically lower or similar to those of 4 hours during both disinfection practices, due to the combining
337 degradation; namely, polyacrylamide: $0.79\% \pm 0.07$ M/M (4 h) – $0.46\% \pm 0.02$ M/M (24 h). On the
338 other hand, in pH 7, HAA yields generally increased significantly with time, except for acrylamide
339 during chlorination and acetoacetamide samples during both disinfection practices. This trend may be
340 associated with the dominance and degradation rate difference of the HAA species between the two
341 pHs and/or the simultaneous conversion of HAcAms to HAAs under the same conditions (Ding et al.,
342 2018). Even though the last assumption may explain the HAAs increases with time in the chloraminated
343 samples of pH 7, it cannot function as an explanation for the chlorinated ones where the corresponding
344 HAcAms species presented resistance in degradation. This indicated that amides may also function as
345 independent precursors for HAAs via alternative pathways. The most reactive amides were
346 acetoacetamide ($0.67\% \pm 0.08\%$ M/M) and acetamide ($0.57\% \pm 0.10\%$ M/M), in chlorination and
347 chloramination, respectively. Following bromide spiking, total THM yields increased by 36-85% upon
348 chlor(am)ination, and yields were finally identified at both pH values, with the most abundant species
349 being BDCM and DBCM (Fig.4 a,b). The most reactive precursor became the aromatic
350 hydroxybenzamide, which generated $0.91 \pm 0.05\%$ M/M and $0.57 \pm 0.09\%$ M/M of THMs, in chlorination
351 and chloramination, respectively.

352 In chlorinated amide samples, the BIF calculations indicated that the amount of bromine incorporation
353 in di-HAcAms (0.7 ± 0.1) was significantly higher than that of di-HAAs (0.4 ± 0.1). However, bromine
354 incorporation in di-HAcAms remained similar or increased with contact time by 15%, with that being
355 more significant for di-HAAs, since bromine-containing DBPs form slower than the chlorinated.
356 Likewise in chloraminated samples, BIFs were 0.8 ± 0.1 and 0.6 ± 0.1 in di-HAcAms and di-HAAs,
357 respectively, with a tendency to increase between 4 and 24 hours, by averages of 25% and 41%, with
358 the exception of di-HAAs in acetoacetamide and acrylamide. The different levels of incorporation in
359 those two classes suggest a potential alternative pathway to the formation of HAAs from the model
360 amides, rather than hydrolysis of HAcAm alone. Unlike the di- species, incorporation of bromine in tri-
361 HAcAms (0.7) was lower than that of tri-HAAs (0.9 ± 0.1), under the same conditions upon
362 chlor(am)ination. It has to be noted that this trend was observed due to the limited detection of TCAA
363 in amide samples, the only exclusive chlorine-containing tri-HAA. The BIFs of THMs were generally
364 significantly lower than those of HAAs and HAcAms, and decreased between chlorinated and
365 chloraminated amide samples, from 0.4 to 0.1, respectively. A recent study, though, reported that BIFs
366 of THMs were higher than those of HAcAms in chloramination (Huang et al., 2017); this deviation is
367 mainly due to the inclusion of four HAcAms species against all nine in this study. Since similar patterns
368 (and similar percentages) with contact time were observed during both disinfection processes, the effect
369 of disinfectant was found to be of secondary importance, and bromine reactions were more dependent
370 on contact time and precursor characteristics. The order of mean BIFs upon chlor(am)ination of the
371 selected DBPs groups in the amide samples quantified; was tri-HAAs > di-HAcAms > tri-HAcAms >
372 di-HAAs \geq THMs, in agreement with bromine incorporation in amines (Bond et al., 2015). In agreement
373 with previous literature, with the exception of THMs, BIF values in chloraminated samples for HAAs
374 and HAcAms, were generally slightly higher than in chlorinated samples (Bond et al., 2015). This trend
375 was most prominent for di-HAAs, from the highly reactive acetoacetamide and hydroxybenzamide,
376 where mean BIFs were respectively 65% and 26% higher in chloraminated than in chlorinated samples.
377 Even though chloramination reduced DBP yields in absolute terms, it enhanced bromide incorporation
378 into classes such as HAAs and HAcAms, and switches speciation towards more brominated species,
379 suspected of being of greater health significance.

380

381 **3.4 Aggregate DBP formation**

382 The aggregate DBP yields (i.e. the sum of all individual precursor yields) of HAcAms, HANs, HAAs
383 and THMs, which varied significantly between the disinfectants and the presence/absence of bromide.
384 This revealed some important trends for drinking water treatment; Relative to chlorination, the median
385 aggregate formation was reduced by respectively 66.5% and 50.9% across the two pH levels (8 and 7)
386 without the presence of bromide, and by 46.4% and 45.5% with the presence of bromide, by instead
387 applying pre-formed chloramines. The formation of total HAcAms dramatically decreased with
388 increasing pH during both chlorination and chloramination, however the formation of the other DBP
389 classes was relatively insensitive to pH alteration. As expected, the presence of bromide levels resulted
390 in significant increases of the selected DBPs in pH 7 by 70% and 64 %, during chlorination and
391 chloramination, respectively, whereas in pH 8 these increases were 50% and 72%. The most reactive
392 amide precursor in chlorinated samples was hydroxybenzamide (2.7 % \pm 0.1 M/M) followed by
393 acrylamide (2.5% \pm 0.2 M/M) at pH 7 and β -alaninamide (2.1% \pm 0.2 M/M) at pH 8, whereas in
394 chloraminated samples the most reactive amides was hydroxybenzamide (1.7% M/M) and acetamide
395 (1.3 \pm 0.3 M/M) at pH 7. Aggregate yields were primarily attributable to HAcAms and HAAs
396 generation, and to a lesser extent to HANs and THMs. This highlighted that the main formation
397 mechanism for HAcAms was the oxidation of amide structures; the alpha carbon of amide group was
398 substituted by halogens, followed by the cleavage between alpha and beta carbon. Overall, the aromatic
399 and hydrophobic moiety functioned as the most significant THM precursor, rather than HAAs and
400 HAcAms, for which aliphatic and hydrophilic amides were more significant. This suggested that if
401 water utilities consider enhanced precursor removal as an operational strategy for DBP control, the
402 success in minimising the individual classes may differ based on the success in removing their
403 individual precursors.

404

405 **4. Conclusions**

406 This study investigated the relative effect of six model amide precursor compounds to act as precursors
407 for various DBPs upon chlorination and chloramination, under a range of water quality conditions
408 (bromide presence/absence, pH and contact time).

- 409 ▪ The direct chlor(am)ination of the six amide precursors generated HAcAms, HANs, HAAs and
410 THMs yields in varying degrees, with maximum yields being respectively, 2.2, 0.2, 1 and 0.9 %
411 M/M.
- 412 ▪ The presence of bromide resulted in significant increases in DBP formation respectively, by 50%
413 and 72%, in chlorination and chloramination.
- 414 ▪ The implementation of chloramines resulted in significant decreases in average THM, HAA, and
415 HAcAm yields by of 95%, 63% and 58%, respectively.
- 416 ▪ Even though chloramination reduces DBP yields (absolute terms), it enhances bromide
417 incorporation into HAAs and HAcAms, and favours speciation towards more brominated species
418 which are suspected of being of greater health significance.
- 419 ▪ HAcAm generation was not solely related to hydrolysis of HANs, and they were demonstrated
420 to form independently.
- 421 ▪ The aliphatic amides functioned as important precursors for HAcAms and HAAs, whereas the
422 aromatic hydroxybenzamide was more significant for THMs.

Table 1. Selected amide precursors and their properties.

Name	Structure	Molecular Weight [g/mol]	Log K_{ow} (and predicted fraction)
Acetamide		60	-1.26 (hydrophilic)
Acetoacetamide		101.1	-1.15 (hydrophilic)
Polyacrylamide		5×10^6 *	n/a
Acrylamide		71.0	-0.7 (hydrophilic)
β -Alaninamide		88.1	-1.81 (hydrophilic)
4-Hydroxybenzamide		137.14	0.3 (slightly hydrophobic)

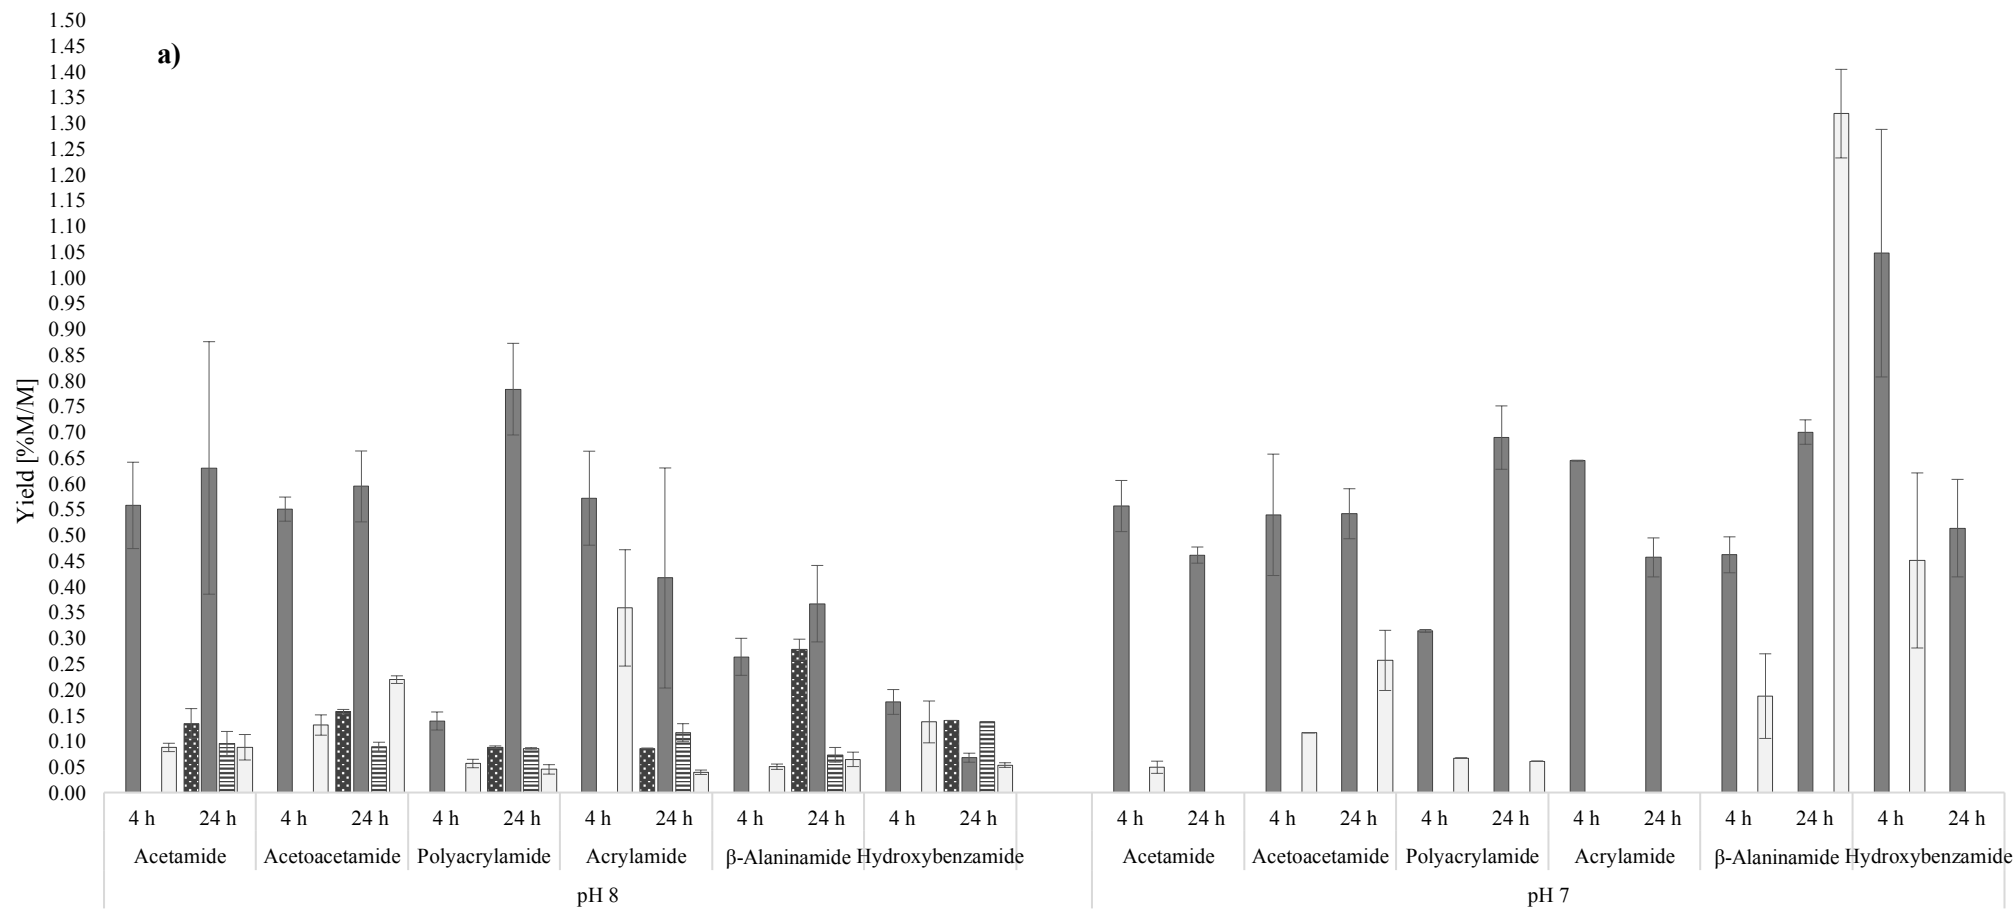

* The molecular weight of polyacrylamide used was provided by Sigma- Aldrich.
log K_{ow} values from PubChem database.

Table 2: N-DBPs yields from model amide compounds during chlorination and chloramination (Initial conditions: Amides conc. – 10 µM, Cl₂/ NH₂Cl dose – 20 M/M bromide = 0, pH 8).

Molar yield [%] (SD)

	RT [h]	Chlorination				Chloramination			
		DCAcAm	TCAcAm	DCAN	TCAN	DCAcAm	TCAcAm	DC AN	TCAN
Acetamide	4	0.04 (0.00)	0.05 (0.00)	-	-	-	-	-	-
	24	0.08 (0.02)	0.01(0.00)	0.02 (0.01)	0.07 (0.01)	0.02 (0.01)	-	-	-
Acetoacetamide	4	0.09 (0.01)	0.04 (0.01)	-	-	-	-	-	-
	24	0.14 (0.00)	0.08 (0.01)	0.03 (0.00)	0.06 (0.01)	0.04 (0.01)	0.40 (0.06)	-	0.02 (0.01)
Polyacrylamide	4	0.03 (0.01)	0.02 (0.00)	-	-	-	-	-	-
	24	0.04 (0.01)	-	0.03 (0.00)	0.05 (0.00)	0.04 (0.01)	0.03 (0.00)	-	-
Acrylamide	4	0.16 (0.10)	0.20 (0.01)	-	-	-	-	-	-
	24	0.04 (0.00)	-	0.03 (0.00)	0.09 (0.02)	0.15 (0.01)	0.01 (0.00)	-	-
β-Alaninamide	4	0.04 (0.01)	-	-	-	-	-	-	-
	24	0.06 (0.01)	-	0.03 (0.00)	0.05 (0.01)	0.02 (0.00)	0.02 (0.00)	-	-
Hydroxybenzamide	4	0.10 (0.03)	0.04 (0.01)	-	-	-	-	-	-
	24	0.02 (0.00)	0.04 (0.00)	-	0.14 (0.01)	-	0.01 (0.00)	-	0.17 (0.01)

Note: The use of (-) symbol indicates the individual DBP species that were not detected in the samples.

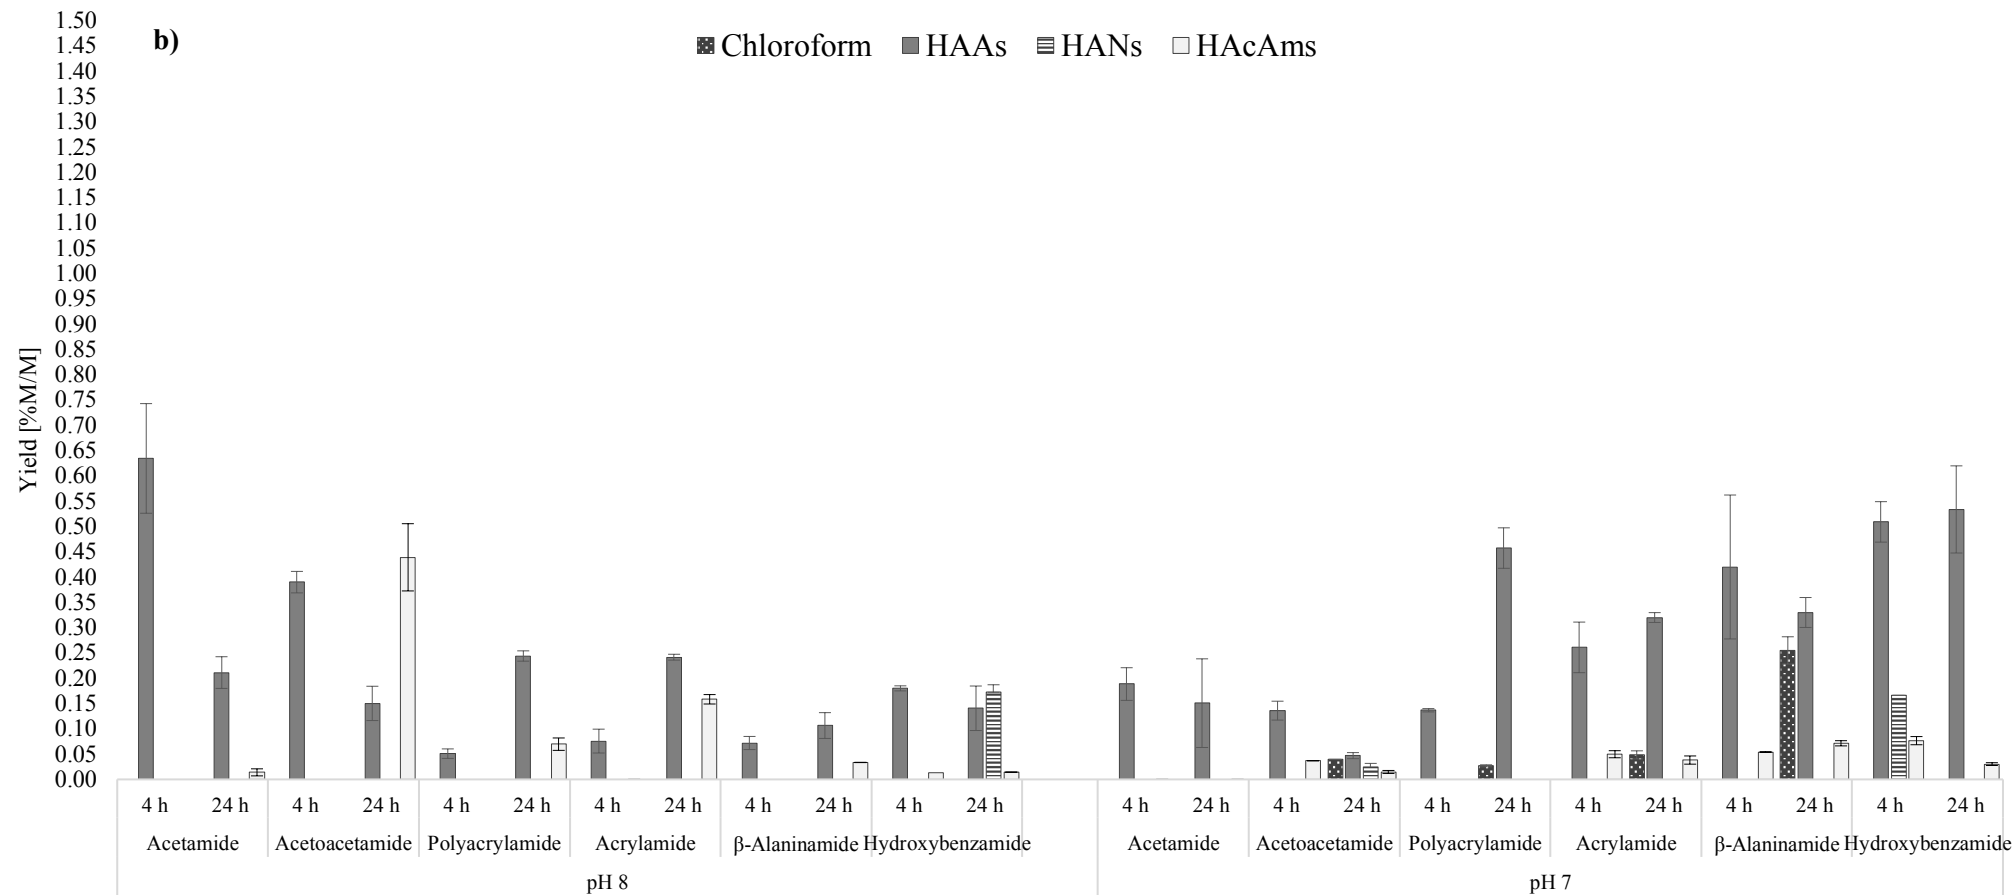

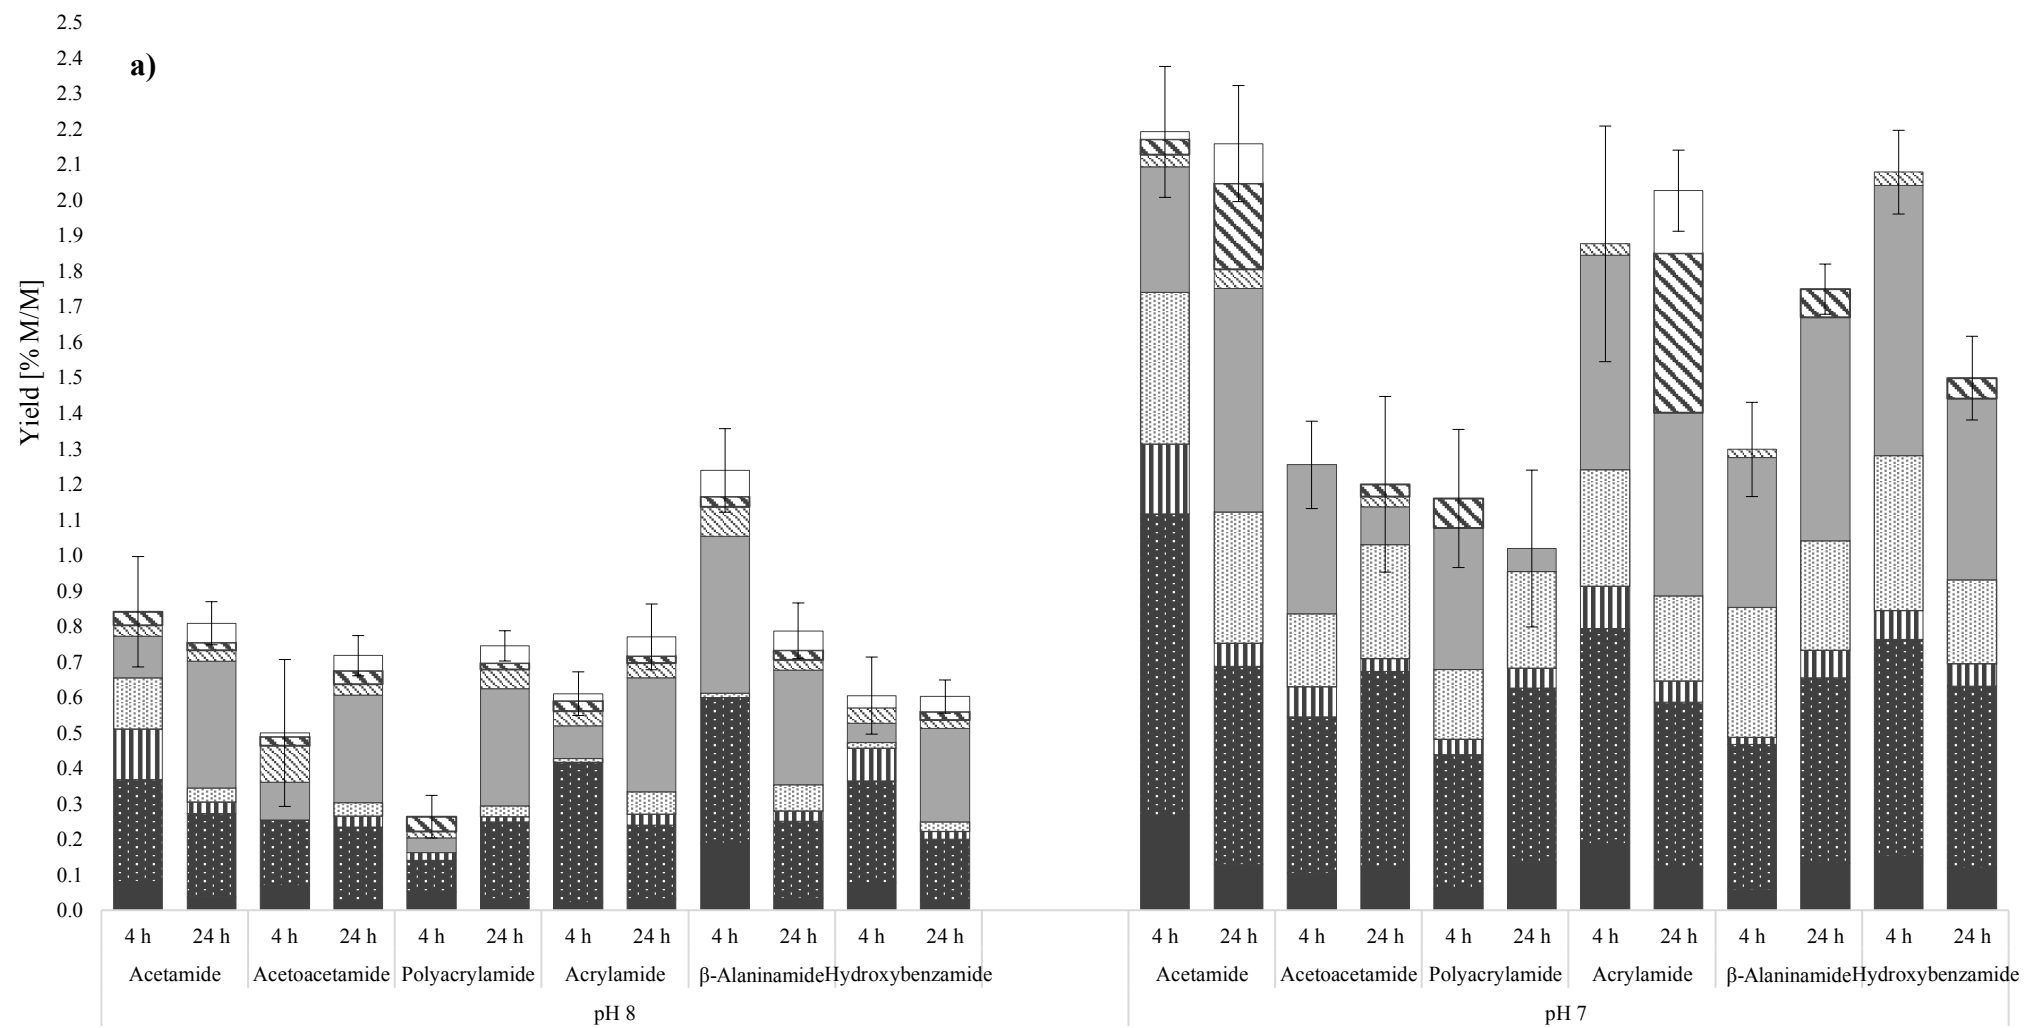

Fig 1. DBP yields of the six amide precursors from **a)** chlorination and **b)** chloramination without the addition of bromide. Error bars represent the range of duplicate experiments.

(Initial conditions: Amides conc. – 10 μ M, Cl_2/ NH_2Cl dose – 20 M/M, and bromide = 0)

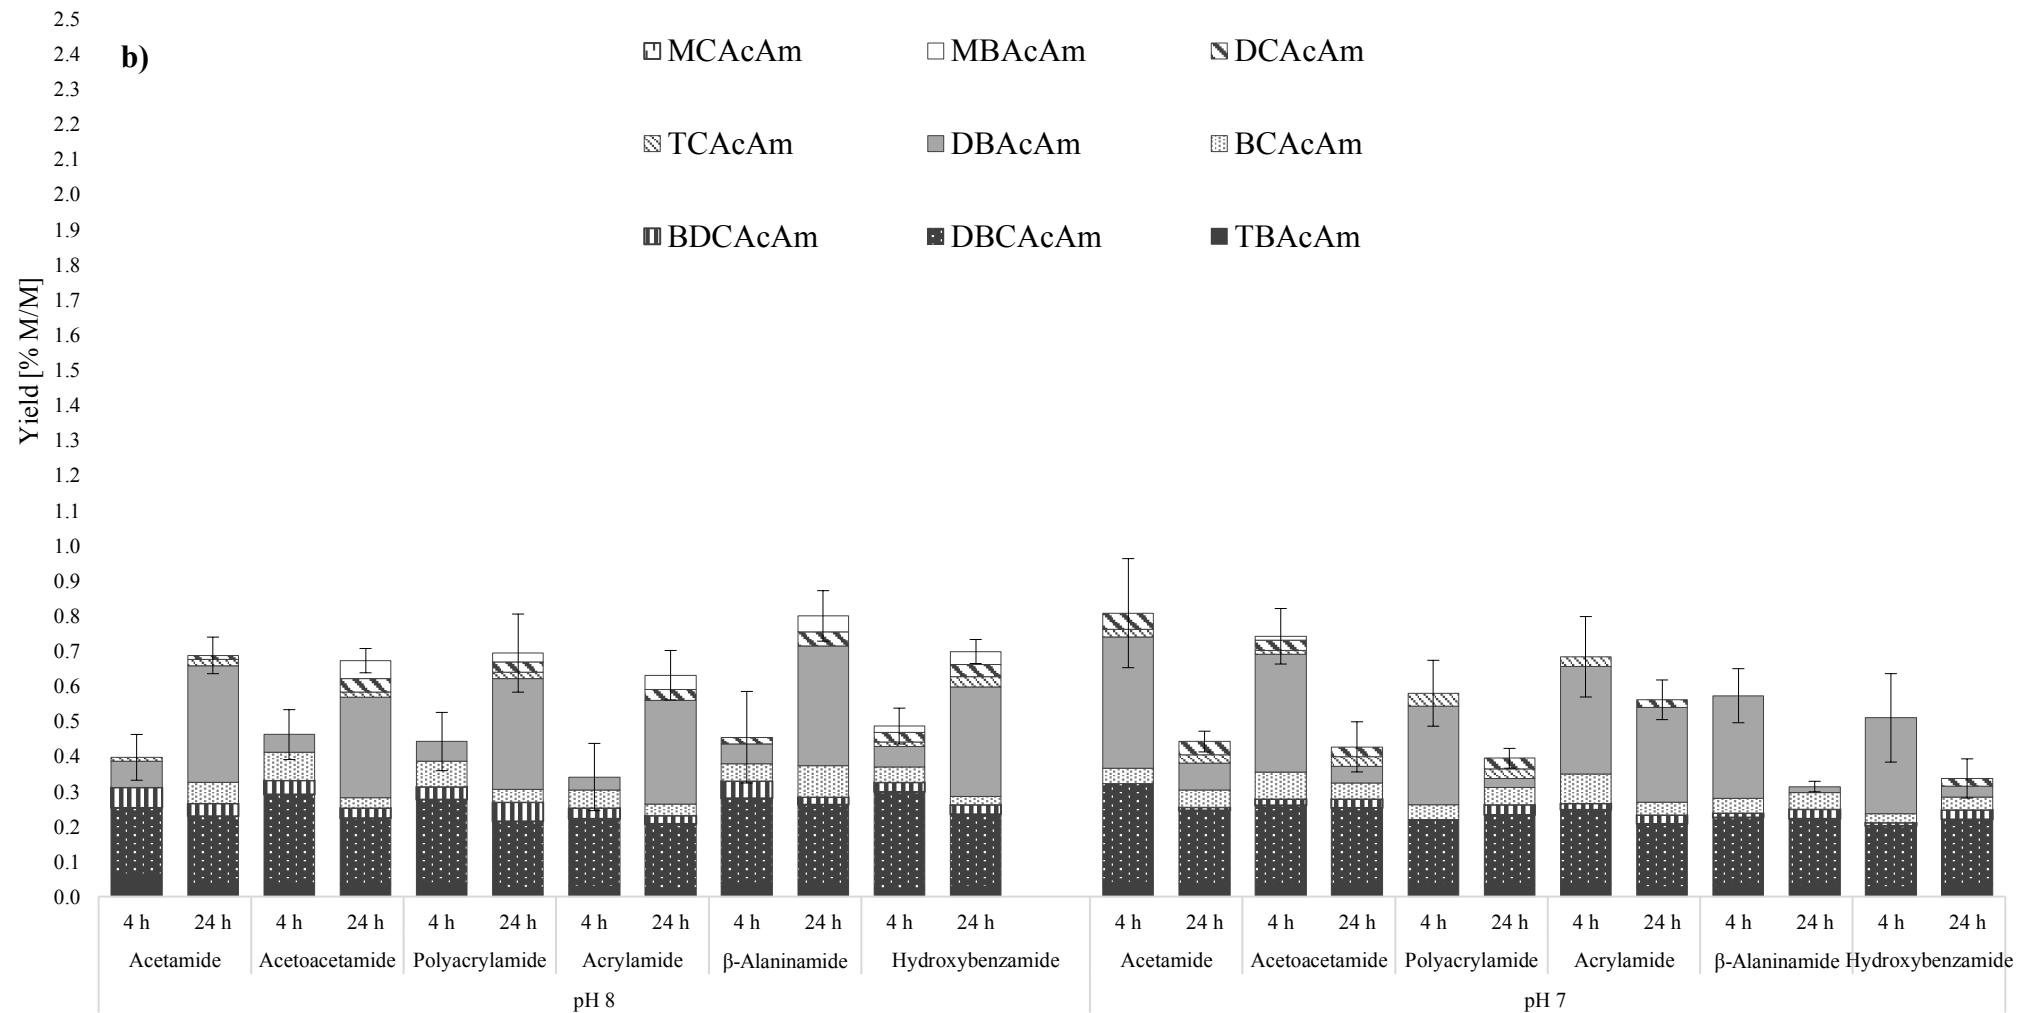

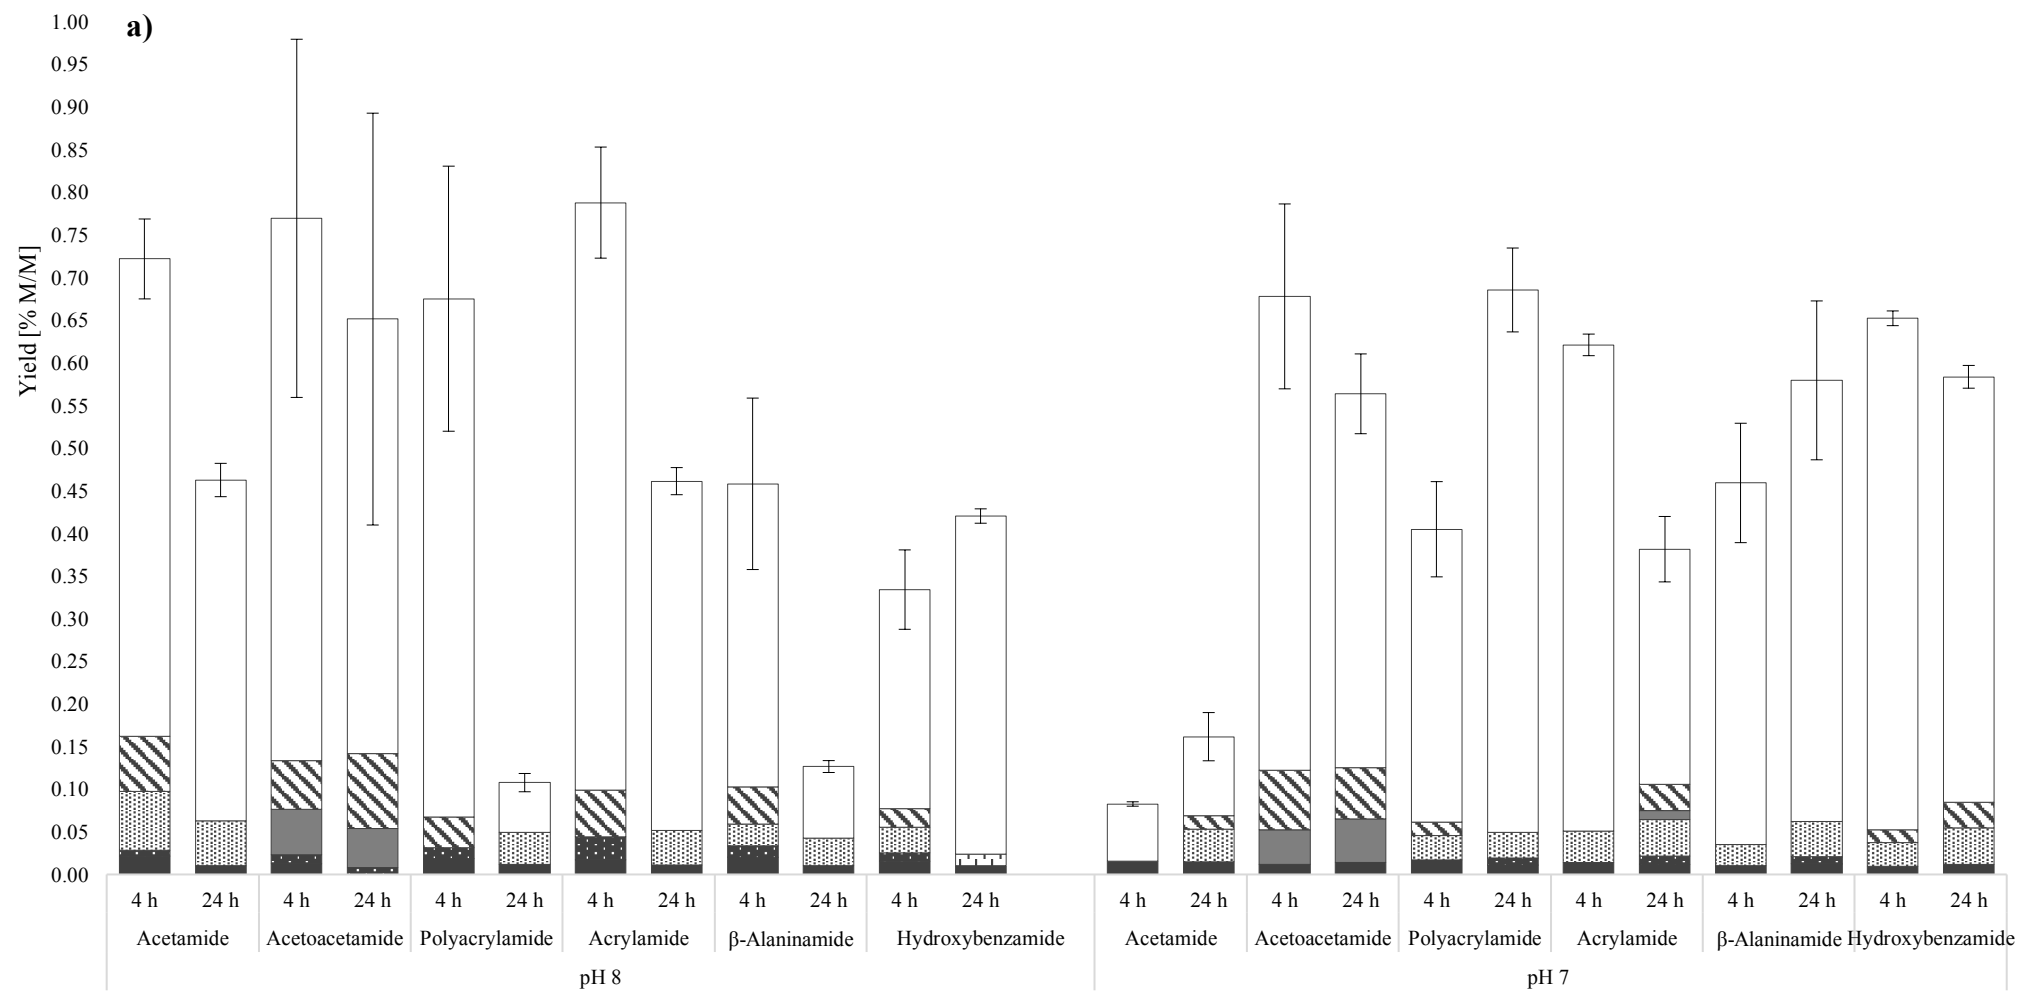

Fig. 2. HACams formation upon a) chlorination and b) chloramination with bromide addition. Error bars represent the range of duplicate experiments.

(Initial conditions: Amides conc. = 10 μ M, $\text{Cl}_2/\text{NH}_2\text{Cl}$ dose = 20 M/M, and bromide = 100 μ g/L).

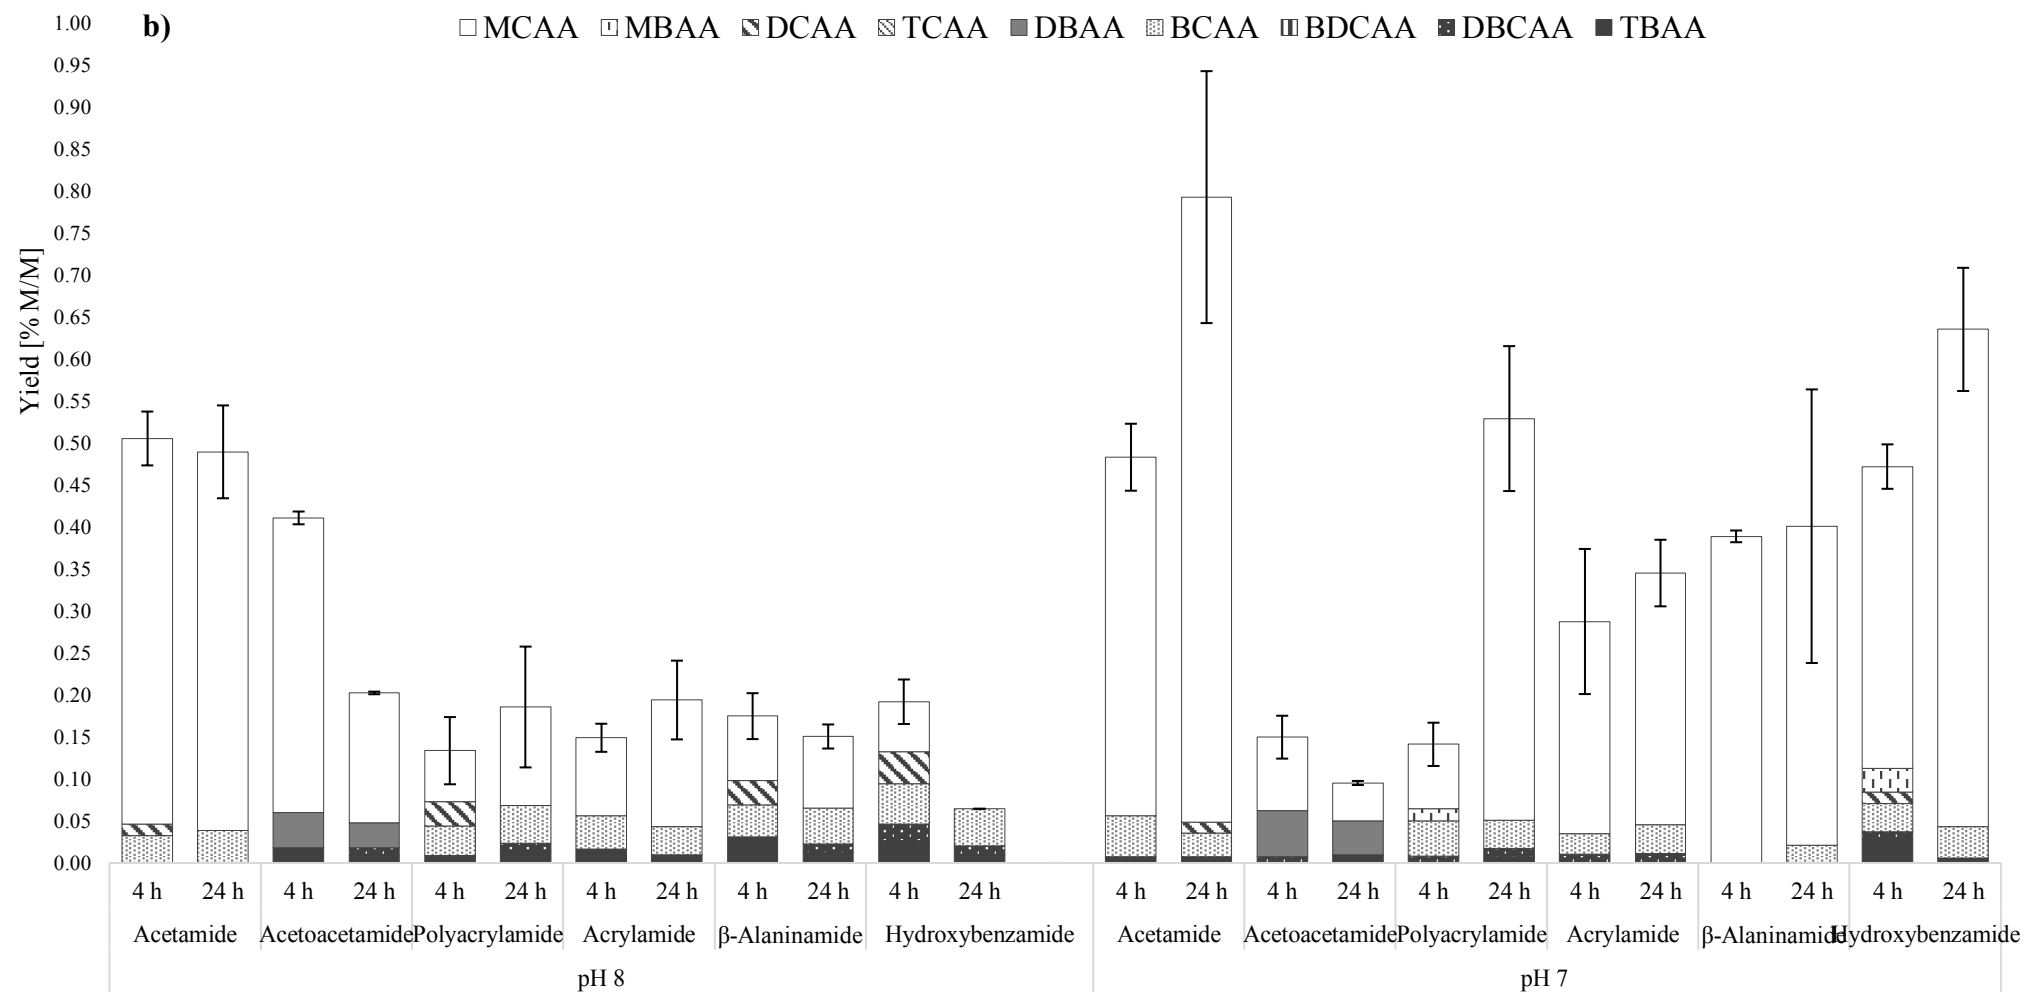

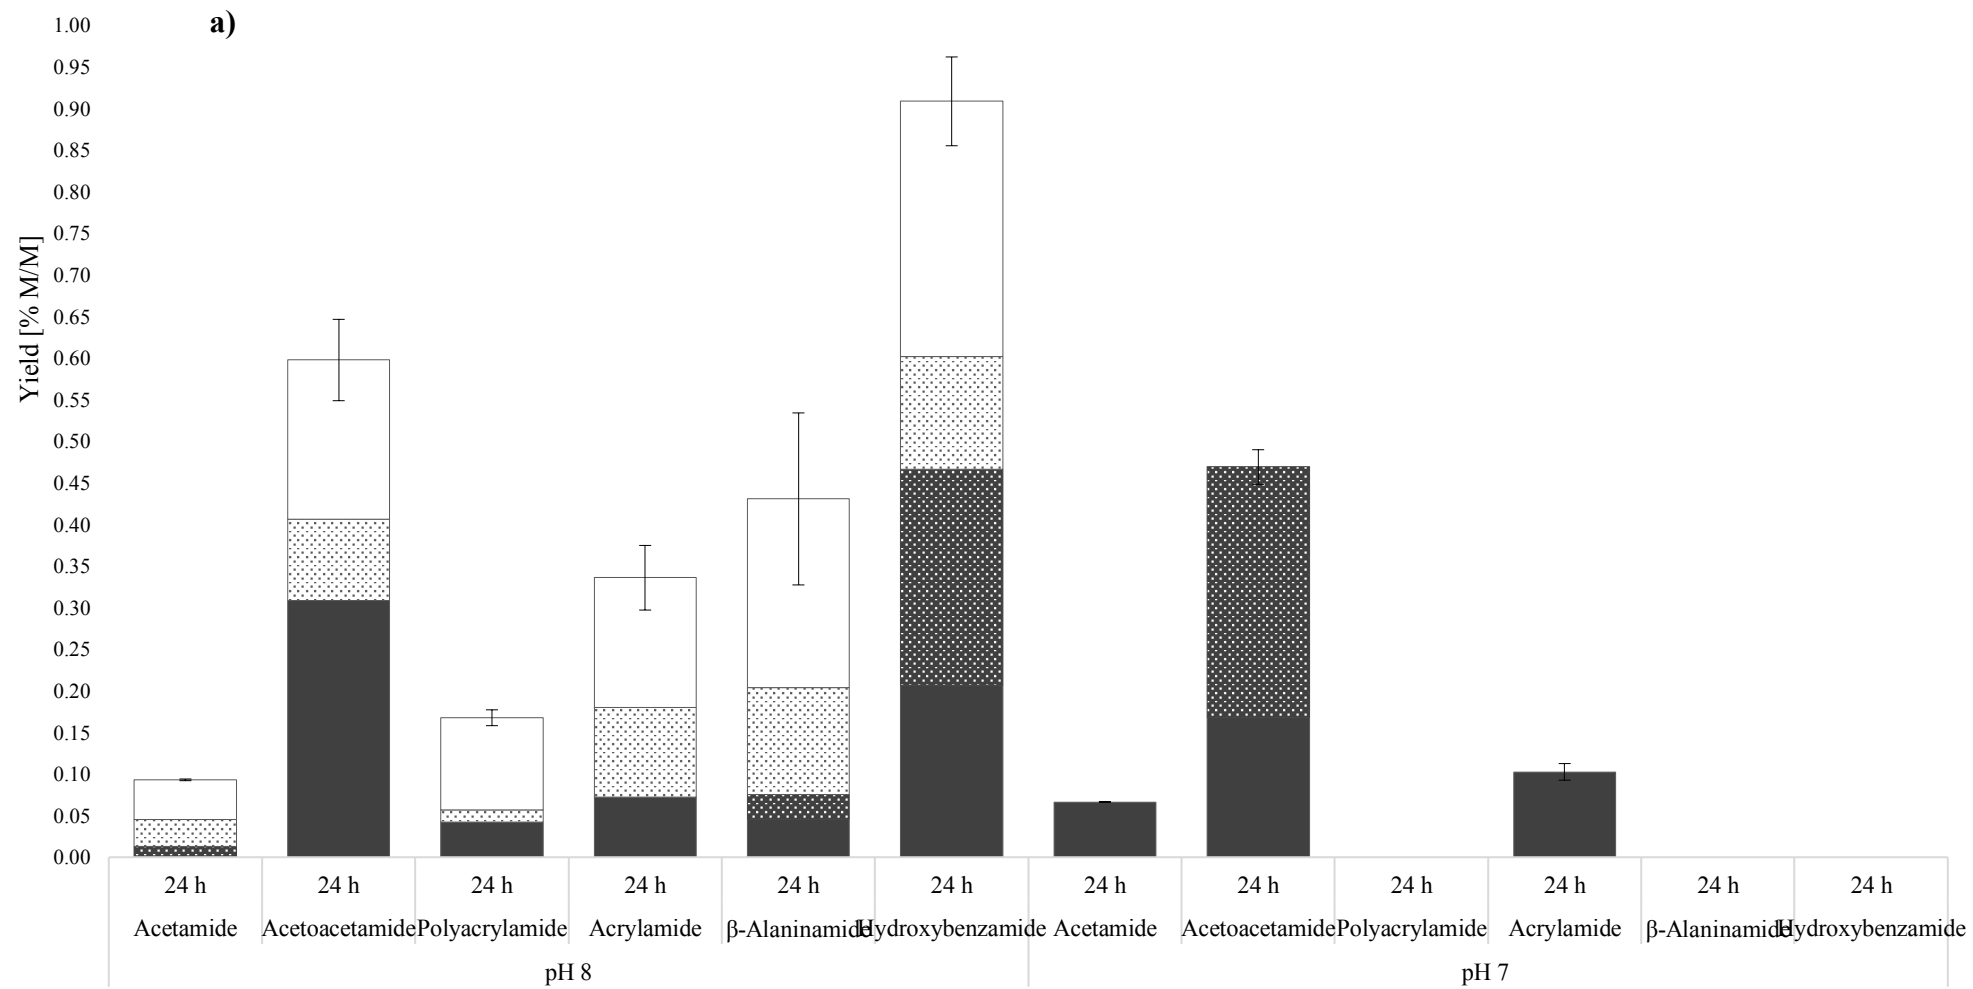

Fig. 3. HAAs formation upon a) chlorination and b) chloramination with bromide addition. Error bars represent the range of duplicate experiments.

(Initial conditions: Amides conc. = 10 μ M, $\text{Cl}_2/\text{NH}_2\text{Cl}$ dose = 20 M/M, and bromide = 100 μ g/L).

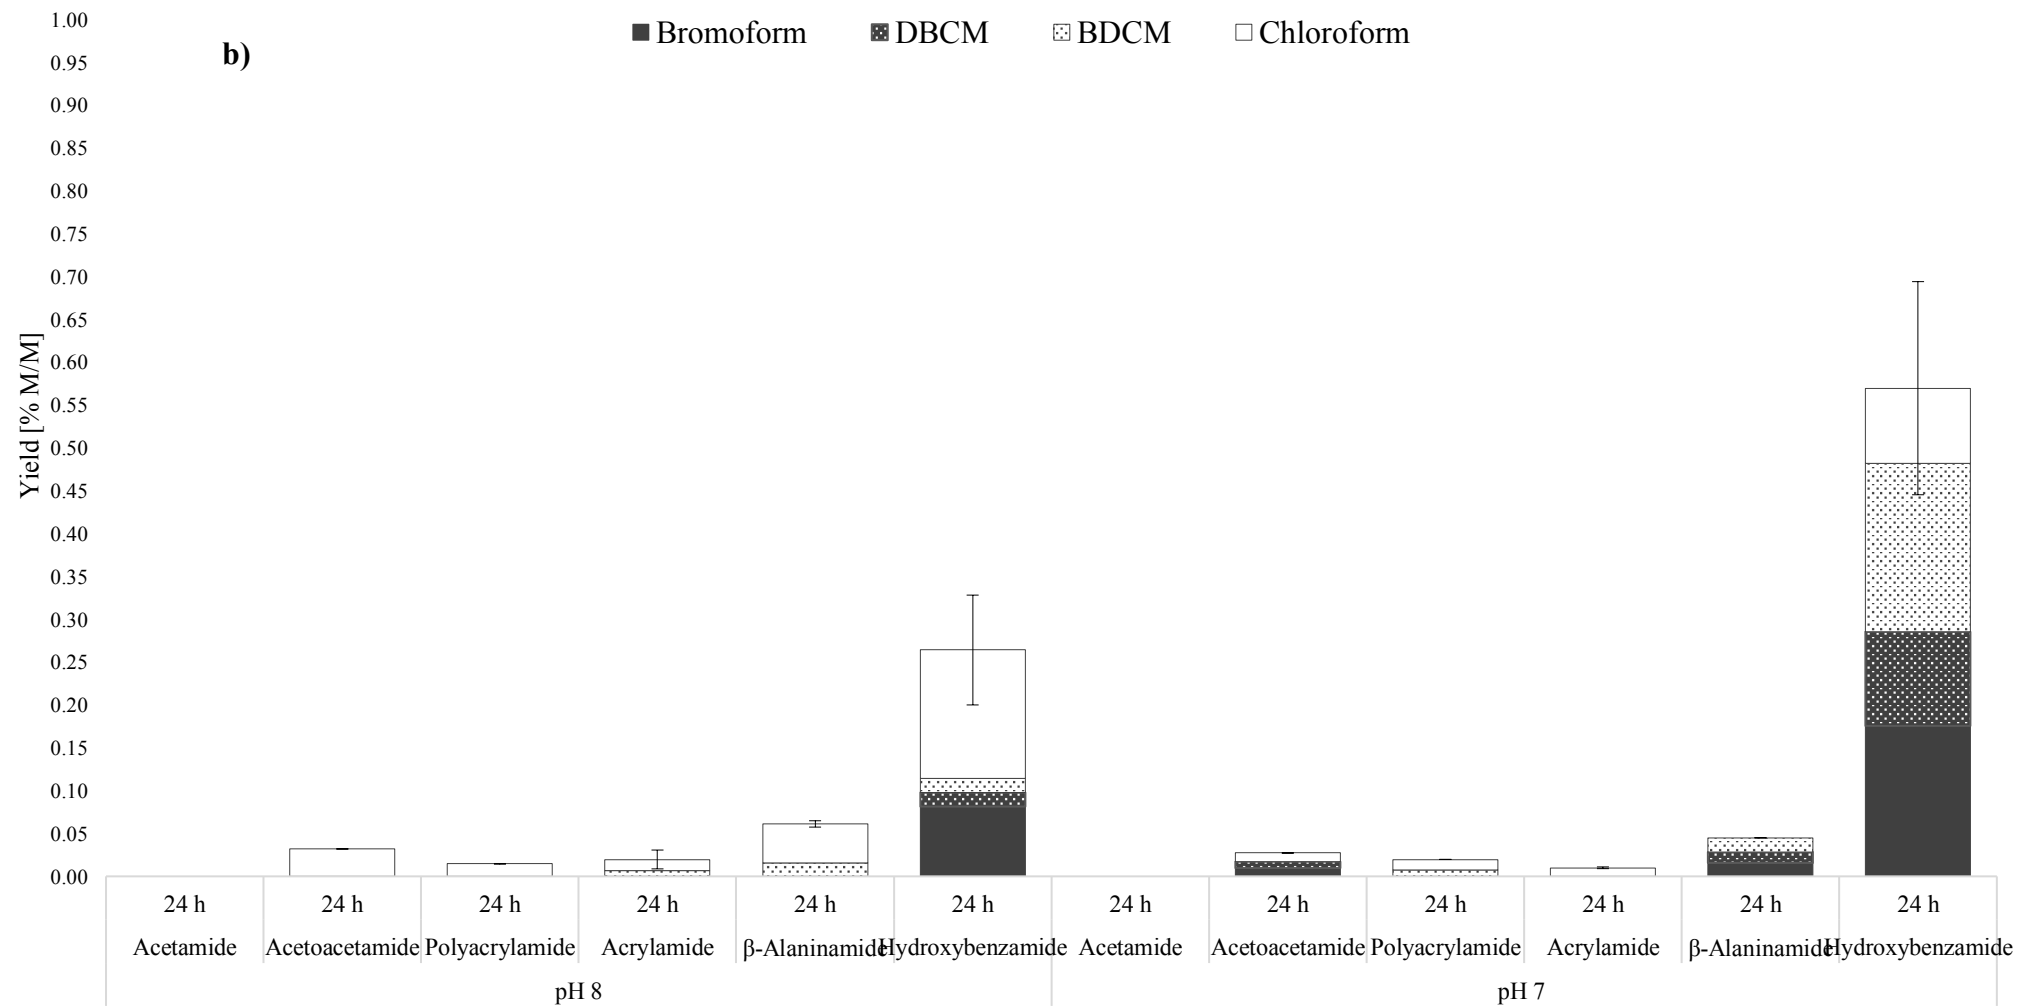

Fig. 4. THMs formation upon **a)** chlorination and **b)** chloramination with bromide addition. Error bars represent the range of duplicate experiments.

(Initial conditions: Amides conc. = 10 μ M, $\text{Cl}_2/\text{NH}_2\text{Cl}$ dose = 20 M/M, and bromide = 100 μ g/L).
