Abstract

The ability to produce rapid, cost-effective and human-relevant data has the potential to accelerate development of new drug delivery systems. Intraocular drug delivery is an area undergoing rapid expansion due to the increase in sight-threatening diseases linked to increasing age and lifestyle factors. The outer blood-retinal barrier (OBRB) is important in this area of drug delivery, as it separates the eye from the systemic blood flow. This study reports the development of complementary *in vitro* and *in silico* models to study drug transport from silicone oil across the outer blood-retinal barrier. Monolayer cultures of a human retinal pigmented epithelium cell line, ARPE-19, were added to chambers and exposed to a controlled flow to simulate drug clearance across the OBRB. Movement of dextran molecules and release of ibuprofen from silicone oil in this model were measured. Corresponding simulations were developed using COMSOL Multiphysics computational fluid dynamics (CFD) software and validated using independent *in vitro* data sets. Computational simulations were able to predict dextran movement and ibuprofen release, with all of the features of the experimental release profiles being observed in the simulated data. Simulated values for peak concentrations of permeated dextran and ibuprofen released from silicone oil were within 18% of the *in vitro* results. This model could be used as a predictive tool of drug transport across this important tissue.

1 Introduction

The ability to produce models that mimic tissue biology and physiology is crucial in the development of drug delivery systems. Currently, much of the pre-clinical work is conducted in animals, the limitations of which are well-reported and which may be the cause of the 86% of drugs that fail in clinical testing (1). The use of *in vitro* models means that human tissue can be used, minimising species differences as well as ethical concerns. Although lacking the complex environment of a living body, they can be used to generate reliable data on drug transport and toxicology (2-4). Computer science and simulation of pharmacokinetic behaviour is becoming an integral part of pharmaceutical research and development due to the significant reduction in cost and time they can offer. *In silico* tools can, in conjunction with complementary empirical measurements, contribute to the optimisation of novel drug delivery systems, and ever-increasing computing power has allowed more sophisticated models to be developed. The combination of accurate, validated *in vitro* and *in silico* models has the potential to revolutionise the development of drug delivery technologies by providing rapid, reproducible and human-relevant data (5).

Epithelial barriers are particularly important in drug delivery, as one of the primary functions of epithelium is to act as a barrier and certain drugs must cross the barrier to reach the target tissue. Tissues such as skin (6), intestinal (7) and pulmonary epithelium (8) have all been studied in the development of drugs and chemicals, and the complexity of the models of these barriers has improved dramatically in the last few decades, from simple two-dimensional multi-well plate cultures to intricate microfluidic culture chips. Many epithelial barrier models are based on air-liquid interface, such as the ones mentioned above. In the case of fluid-fluid interfaces, many are designed as static culture systems. These static culture systems allow the determination of parameters such as barrier permeability and diffusion coefficients, which are of crucial importance when studying the movement of potential therapeutic treatments across epithelial tissues. They do not, however, provide realistic, time-dependant development of concentration gradients across the model as they do not mimic the many dynamic factors associated with these physiological barriers. With the rapid rise in microfluidic technologies for cell culture that has occurred over recent years, the creation of dynamic *in vitro* models has become more accessible (9).

There are many eye diseases that require treatment with pharmacological agents. In contrast to the front of the eye, where drug delivery can often be achieved by topical application of eye drops and ointments, many eye diseases of the posterior segment of the eye require the delivery of drugs directly into the vitreous. The drugs may be required to treat acute infection or inflammation, or to treat a chronic condition such as age-related macular degeneration or diabetic retinopathy. In the latter case, repeated intravitreal injection or use of drug delivery devices are the preferred methods to achieve therapeutic levels of drug over the extended periods required. Due to the cost and invasive nature associated with repeated intravitreal injection, as well as the potential for sight-threatening complications, much effort has been directed towards developing implants that can deliver drugs over extended periods (10). We have recently developed technology to achieve extended release of drugs from silicone oil tamponades (11, 12). Silicone oils and gases are used to replace the native vitreous humour in the treatment of sight-threatening retinal detachments. They inhibit the

38 flow of aqueous fluids into the subretinal space, exclude inflammatory factors, and support the retina as tears

39 heal (13, 14). Silicone oils are the only medical devices licenced for long-term use as tamponades. Drug

40 release from silicone oil tamponades would release pharmacological adjuncts to the surgical treatment with

41 the aim of reduce complications caused by scarring conditions such as proliferative vitreoretinopathy and

42 proliferative diabetic retinopathy. The ability to predict the release of drugs from such devices, as well as

43 understand factors that influence clearance from the posterior cavity, is crucial if over- and under-dosing is to

44 be avoided.

45 Drugs administered intravitreally, whether via injection or implant, are cleared via two routes, either

46 anteriorly or posteriorly (Figure 1A). Nearly all compounds can be eliminated via the anterior route.

47 Anteriorly, once the drug has diffused across the vitreous, it enters the aqueous of the posterior chamber

48 where it is transported into the anterior chamber and cleared either out through the Schlemm's canal or into

49 the uveal blood flow (15). Alternatively, posterior elimination occurs through permeation across the posterior

50 blood-ocular barriers such as the outer and inner blood-retinal-barrier (BRB). This route requires either

51 adequate passive permeability of agents, which is generally only applicable to very low molecular weight or

52 lipophilic substances, or active transport of molecules by the cells present in the barrier. For this reason,

53 larger or hydrophilic molecules generally have longer half-lives in the vitreous as they are not able to move

54 as freely through the vitreous or pass across the retina (16).

55 *In vitro* models have often been used to investigate the permeability of drugs and compounds across the

56 retinal pigmented epithelium (RPE) or look to model disease of the outer blood-retinal barrier (OBRB). In

57 order to obtain a physically accurate model of the OBRB, the main anatomical structures (retinal pigment

58 epithelium, Bruch's membrane and choroid), as well as physiological conditions, such as flow, need to be

59 incorporated. Although many of the *in vitro* models of the OBRB that have been reported include the main

60 anatomical structures within the tissue (17-20), few include a flow mechanism to model the blood flow

61 within the choroid and to avoid the formation of an unstirred water layer (21). This flow mechanism is

62 particularly important when investigating the clearance of drugs across the BRB, as it causes systemic

63 removal of drugs. Yeste et al. describe a system which comprises the co-culture of human retinal endothelial

64 cells and ARPE-19 (a widely-used RPE cell line (22, 23)) in a microfluidic culture system (24). This system

65 compartmentalises the cells and they do not, therefore, create a single construct. The transepithelial electrical

66 resistance of each of the cell layers was measured independently; this does not represent the true barrier

67 functionality of the tissue as it investigates each component of the barrier in separate parts. Additionally, no

68 investigations of drug transport across the barrier were conducted. Another microfluidic chip device was

69 reported by Chen et al. who investigated the co-culture of ARPE-19s and human vascular endothelial cells

70 (HUVECs) in a microfluidic model of choroidal angiogenesis (25). Within this model, glucose was

71 transported to the cells within the flow of the media but the movement of the molecules was not studied. The

72 lack of studies regarding *in vitro* modelling of the effects of posterior systemic clearance of drugs in the eye

73 by, for example, incorporating flow, leaves scope for this to be investigated further.

74 The Kirkstall QV600 cell culture chamber is a novel system which has been designed to allow surface
75 cultures of cells which are found in an air-liquid interface environment *in vivo*, for example skin, respiratory
76 epithelium or corneal cells. It can also be modified to co-culture cells at a fluid-fluid interface and expose
77 each surface to independently controlled flow. The availability of published data from studies using this
78 system is limited. The QV600 has been used to study permeability of fluorescein across a cell culture model
79 of gut epithelium (26), demonstrating that the application of flow resulted in increased permeability, as well
80 as increased barrier function of the cells. It has also been used to build a human bronchial or small airway
81 epithelial model, using the combination of the air-liquid interface and flow to improve and accelerate cell
82 differentiation (27). To the best of our knowledge, there are no reports of this chamber being used to build a
83 model of the OBRB. For the purposes of investigating drug permeability across the OBRB, this system
84 provides many of the necessary properties for a representative model, i.e. the ability to mimic clearance by
85 choroidal flow and to incorporate drug delivery devices that work in aqueous and non-aqueous environments
86 (Figure 1B).

87 There have been several studies carried out that specifically use computational techniques to model drug
88 delivery and kinetics in the posterior segment of the eye, including systemic delivery methods, intravitreal
89 injection and ocular implants (28-30). These models all simulate drug delivery within computer built
90 geometries of the eye and although they can provide useful information regarding the drug kinetics in the
91 eye, experimentally these results cannot be validated *in vivo* due to the invasive nature of the techniques that
92 would be required to do so. Much of the work carried out is based on experimental work conducted almost
93 four decades ago by Palestine and Brubaker who investigated the kinetics of fluorescein in the human eye
94 (31). Other published pharmacokinetic data is predominantly from animal models, which brings a series of
95 well-reported problems, including the use of different animal models, differences between animal and human
96 anatomy and vitreous composition, and different experimental setups (32). In order for the sophistication of
97 these models of drug delivery in the eye to be improved, more experimental data is required to provide a
98 greater database for finite element analysis validation. Furthermore, very little data on the release of drugs
99 from silicone oil tamponades is available. For this reason, it could be useful to build predictive models of *in*
100 *vitro* devices used in the development of novel drug delivery devices as they are able to be validated using
101 data from benchtop experiments. Although these models may not provide an approximation of what will
102 occur once the device is administered in the eye, it may make the development process more efficient. In
103 addition, an accurate model of drug transport across the outer blood-retinal barrier may be able to help
104 predict systemic effects from ocular delivery, or design drugs that could be delivered systemically and cross
105 the blood-retinal barrier (33). In this study we used a combinatory approach of *in vitro* and *in silico*
106 modelling to investigate drug transport and clearance through the posterior drug elimination pathway with
107 the aim of producing validated tools for the optimisation of intravitreal drug delivery devices.

Materials and Methods

In vitro model

Materials

Fluorescein isothiocynate conjugated dextran (FD) was purchased from Sigma-Aldrich (FD-4, MW 4kDa) and diluted to 50µg/ml in phosphate-buffered saline (PBS) solution. Ibuprofen (2-(4-Isobutylphenyl)propionic Acid, C13H18O2, MW 206.29) was purchased from Tokyo Chemical Industry UK (I0415)and 1mg/ml was dissolved in technical grade 1000 cSt silicone oil (SIO) obtained from Fluoron GmbH PBS tablets were purchased from Thermo Scientific (Oxoid BR0014G) and used as instructed, 1 tablet per 100ml distilled water. Expanded-polytetrafluoroethylene (ePTFE_M) cell culture membrane inserts were purchased from Merck Millipore (PICM02150, 0.4µm pore size). The microfluidic chambers and associated silicone tubing were QV600 cell culture kits purchased from Kirkstall Ltd (Rotherham, UK) and the peristaltic pump (Parker, PF22X0103) used to generate the fluid flow was also purchased from Kirkstall Ltd. Fluorescence measurements were performed using a microplate reader (FLUOstar OPTIMA, BMG LABTECH). UV measurements were performed in UV transparent, plastic cuvettes (Merck Z605050) using a spectrometer (SPECTROstar nano, BMG LABTECH).

Methods

Cell culture

ARPE-19 cells (ATCC® Number: CRL-2302™) between passage 23-30 were cultured in Dulbecco's Modified Eagle Medium/Ham's Nutrient Mixture F-12 Formulation (1:1 mix) with L-Glutamine, 15mM HEPES and sodium bicarbonate (DMEM-F12) (Sigma, D8437) supplemented with 10% fetal bovine serum (FBS) (BioSera, S1900) and 1% Penicillin/Streptomycin (Sigma, P0781). Following seeding, cells were maintained in 2% serum. Cells were seeded on ammonia plasma-treated ePTFE_M cell culture insert membranes, (NH3_ePTFE_M). These are ePTFE membranes that have been subjected to a proprietary treatment by the manufacturer, designated ePTFE_M, and ammonia gas plasma treated to improve the hydrophilicity of the membrane as described previously (34, 35) designated NH3_ePTFE_M. Following seeding cells were cultured for 10 days at 37˚C in a humidified incubator with 5% CO_2.

Determination of apparent permeability coefficient

Permeability experiments were performed in a classic two-compartment, zero-flow, model system. NH3_ePTFE_M cell culture inserts were placed in a 24 well plate and 400µl of tracer molecule (50µg/ml FITC-dextran) (MW: 4 kDa) solution was added to the donor compartment with 600µl of PBS solution in the receptor compartment. In static conditions, transmembrane flux (J_d) is predominantly determined by diffusive forces and can thus be calculated using the permeability (P_s) and concentration gradient (ΔC):

$J_d = P_s \, \Delta C$

143   At time intervals of 1, 3, 8 and 24hr, 50µl samples were taken from the receptor compartment and replaced

144   with fresh PBS solution. Samples were stored at 4^0C and protected from light until the time points had been

145   completed and the fluorescence intensity of the samples was read in a microplate reader at λ_{ex}(excitation

146   wavelength): 485nm, λ_{em} (emission wavelength): 535nm. Flux was determined from the slope of the linear

147   portion of the curve. Calibration curves ($R^2 \geq 0.997$) for each molecule were made using a serial dilution of

148   50µg/ml dextran solution. Average measurements for blank (0µg/ml of dextran) were subtracted from the

149   standards and the unknown samples. Concentrations of the unknown samples were determined from the

150   calibration curves and each sample was repeated in triplicate (n=3).

151   **Measurement of drug release**

152   An experimental concentration of 1mg of ibuprofen (ibu) in 1ml of 1000c.st Silicone oil (Fluoron GmbH)

153   was used. The ibu-SiO was stirred for 72 hours in a sealed flask and then filtered in a Class II biological

154   safety hood to sterilise. In a 24-well plate, 1mL of ibu-SiO was syringed on top of 500µl of PBS. At defined

155   time points, 100µl samples were taken from the PBS, transferred to UV transparent cuvettes (UVette,

156   Eppendorf) and the time-dependent increase in ibuprofen concentration measured by UV-Vis spectroscopy

157   (n=3).

158   **Determination of Diffusion coefficients**

159   The diffusion coefficients (D) were calculated using the Stokes-Einstein equation, using the solvent

160   viscosity, either DMEM-F12, PBS, water or SiO (µ), the apparent radius (r) of either the dextran or

161   ibuprofen molecule (36), temperature (T) and Boltzmann constant (k):

162    $D = kT/6\pi\mu r$

163   **Drug clearance study**

164   The Kirkstall QV600 system was arranged in a single-pass series fluid circuit using a peristaltic pump to

165   control the fluid flow inlet rate (Figure 1C). Either acellular or cell-seeded cell culture inserts containing

166   400µl of tracer solution were inserted into the QV600 chamber to allow flow across the receptor side of the

167   membrane. The cell culture inserts have a smaller diameter than the QV600 chamber. In order to create a

168   seal between the donor and receptor compartments, a silicone O-ring was placed around the exterior wall of

169   the insert before it was placed in the chamber. The system was incubated at 37^0C and phosphate buffered

170   saline solution was perfused through the receptor chamber at a constant flow rate for 24 hours (8 hours for

171   2ml/min experiments). The flow rates used were 20µl/min, 200µl/min, 400µl/min.

172   FITC-conjugated dextran (4kDa) was dissolved in DMEM-F-12 supplemented with 10% foetal calf serum to

173   50µg/ml in the donor chamber. The systems were set up and perfused for 1hr, after which the flow was

174   stopped and the tubes were clamped. The solution in the receptor chamber was completely removed and

175   homogenised, and 50µl samples were taken. The systems were cleaned and reset and this was repeated for

176   increasing periods of time (1hr time increments). The fluorescence intensity of the samples was read in a

177 microplate reader at λ_{ex}: 485nm, λ_{em}: 535nm. Concentration of the unknown samples was determined from

178 the calibration curves and each sample was repeated in triplicate (n=3).

Measurement of ibuprofen release from silicone oil under flow conditions

180 The QV600 chamber and peristaltic pump were assembled as previously described. The system was primed

181 with 30mL of sterile PBS. 2mL of 1mg/mL ibu-SiO was added directly on top of the PBS. The system was

182 incubated at 37^0C and PBS was perfused through the receptor chamber at a constant flow rate for 24 hours (8

183 hours for 2ml/min experiments). The flow rates used were 20µl/min, 200µl/min and 2ml/min. At set time

184 intervals, the ports were clamped shut and the volume of PBS beneath the ibu-SiO removed using a 25 gauge

185 needle. A 25G needle allows the PBS to be removed but the viscosity of the oil prevents its withdrawal

186 through the needle. The solution was homogenised and 50µL samples taken. UV-Vis was used to determine

187 the ibuprofen concentration in the samples as previously described.

Computer Model

Geometry of the QV600 chamber and grid generation

190 Figure 2 shows the 2-dimensional geometrical models used. Key dimensions are based on dimensions as

191 stated by the technical drawing from the QV600 chamber. Differences in the donor compartment domain

192 take into account the differences in geometry between the cell culture inserts (Figure 2A-D) and the silicone

193 oil tamponade (Figure 2E,F). The cell culture inserts have a smaller diameter than the chamber therefore the

194 width of this domain is reduced. Additionally, the geometry used in the dextran transport studies included a

195 third domain representative of the ePTFE/cell membrane. The dimensions of this domain were altered

196 dependent on the inclusion of a representative cell monolayer.

197 The mesh was generated using the commercial software, COMSOL Multiphysics. For the single phase,

198 dextran transport studies, the mesh comprised free triangular elements with boundary layers at the no slip

199 walls. The total number of elements in the mesh was 38267. For the ibuprofen release studies the mesh

200 consisted of 2258 free triangular elements in a moving mesh system to model the flow of two immiscible

201 liquids.

Governing equations

203 The incompressible Navier-Stokes equations along with a species transport equation were solved in order to

204 obtain the velocity and concentration fields across the models.

205 Momentum equation:

$$\rho \left(\frac{\partial \boldsymbol{u}}{\partial t} + \boldsymbol{u}.\nabla \boldsymbol{u} \right) = -\nabla p + \nabla.\mathbf{T} + \mathbf{f}$$

207 The left-hand side of the equation describes the product of the density of the fluid, ρ, and the acceleration

208 that is experienced by the particles within the fluid where $\boldsymbol{u}$ is the velocity vector. The right-hand side of the

209 equation incorporates the forces which are responsible for the particle acceleration, the pressure ~~gradient~~, p;

210 the viscous shear stresses, **T**; and volume forces, **f**, which is equal to the product of the gravity constant, g,

211 and the density of the fluid.

212 Continuity equation:

213 $$\nabla.\boldsymbol{u} = 0$$

214 Species transport equation:

215 $$\frac{\partial c_i}{\partial t} + \nabla.(-D\nabla c_i) + \boldsymbol{u}.\nabla c_i = 0$$

216 This equation~~o~~ solves the mass conservation equation for the concentration of one or more chemical species,

217 c_i. T ~~*D* is~~ the diffusion coefficient, D, which was determined from the *in vitro* studies ~~and *u* is the velocity vector~~, is specific to each species.

218 These are presented in table 1. ~~.~~ As the drugs used in this study are not reacting with the cells and the cell

219 layer acts only as a barrier, the right hand side of the equation is zero.

220 Two models were investigated in this study. One to study the passage of dextran molecules across the

221 NH3_ePTFE_M membrane and one to study the release of ibuprofen from silicone oil. These two models are

222 described separately:

Dextran Transport Model

224 The model itself consists of two parts, a laminar flow interface to compute the velocity flow and pressure

225 fields of the single-phase fluid flow and a transport of diluted species interface which is able to calculate the

226 concentration field of a dilute solute in a solvent, i.e. the fluorescently labelled dextrans diluted in culture

227 medium. The model was run to simulate both the absence and presence of cells using alterations in both the

228 geometry and permeability boundary conditions that are described below.

229 An additional physics node was included to model the transport of FD through the membrane into basolateral

230 medium flow. This model accounts for the dissipation of kinetic energy experienced by the fluid moving

231 through a porous matrix, through means of viscous shear. This node was only applicable to the membrane

232 part of the model and were therefore only applied to that domain. The NH3_ePTFE_M membrane was

233 modelled as a porous matrix material with a porosity of 0.3, as specified by the manufacturer.

Boundary Conditions

235 A no slip boundary condition was applied to the walls ~~borders~~ of the geometry. The inlet was applied to the

236 left-hand wall of the inlet tube. A range of inlet flow rates was investigated to coincide with the flow rates

237 used in the *in vitro* experiments: 20µL/min, 200µL/min, 400µL/min, and 2mL/min. The outlet was applied to

238 the right-hand wall of the outlet tube. The outlet condition was a pressure condition, closer to a zero

239 boundary condition which improves convergence, represented by a function combining density and gravity.

240 In addition to the wall, inlet and outlet conditions, a volume force was applied to the entire geometry to
241 include the effects of gravity on each domain.

242 Two transport of diluted species nodes were used in the transport of dextran simulations. One for the donor
243 and receptor domains and one for the membrane domain. This separate node for the membrane domain
244 allowed the difference in diffusion in that domain to be accounted for.

245 For the donor and receptor domains, a no flux boundary condition was applied to the exterior boundaries of
246 the geometry on the same edges as the no slip conditions for laminar flow. An outflow condition was applied
247 to the outlet to account for transport of FD out of the domain by the fluid motion. At the boundaries where
248 the two domains meet the membrane domain, a pointwise constraint was applied to compute the transfer of
249 mass across the membrane out of the donor domain into the receptor domain. The pointwise constraint was a
250 function of the two concentrations at the boundaries which were defined by the diffusive and convective
251 movements of the FD through the domains. The flux across the boundaries was computed based on the
252 concentration of FD and the diffusion coefficient for each domain.

253 The second transport of diluted species node applied similar boundary conditions as above but across the
254 membrane domain, therefore accounting for the difference in diffusion. A no flux condition was applied on
255 the exterior wall boundaries of the membrane. The same function for the pointwise constraint was applied to
256 the boundaries which were shared with the other two domains. The dimensions of the membrane domain
257 were altered depending on whether the presence of the cells was being modelled or not. In the presence of
258 cells, the membrane domain was 70μm in height and the appropriate diffusion coefficient of the domain was
259 used, as described in table 1**Error! Reference source not found.**. In the absence of the cells, the domain
260 was reduced to 50μm and the diffusion coefficient was altered to account for their absence.

261 **Ibuprofen Release Model**

262 The second model explored ibuprofen release from SiO. With the differences that the ibuprofen release
263 studies require, the model was altered to simulate the interaction of two immiscible fluid phases: the aqueous
264 PBS phase and the 1000 c.st silicone oil phase. This model also removes the membrane domain as the
265 movement of drug was directly from the oil into PBS.

266 To model the two-phase nature of the model, an additional moving mesh mechanism was used. The laminar
267 flow moving mesh physics node in COMSOL solves the same equations for velocity and pressure fields but
268 also tracks the movement of the interface between two immiscible fluids by allowing deformation of the
269 mesh during the solution.

270 A free mesh deformation was prescribed to the domains either side of the interface. To the inlet and outlet
271 tubes of the geometry were prescribed a fixed mesh as only one of the fluid phases moved through these
272 regions. The mesh is also prescribed zero displacement at the exterior boundary walls to prevent collapsing
273 of the solid wall boundaries. Those walls which were in contact with the fluid-fluid interface were prescribed

274 free deformation of the mesh parallel to the exterior wall boundaries but with zero perpendicular
275 displacement, again to prevent collapse of the solid exterior walls.

276 The additional equation solved for in the laminar flow, moving mesh interface was the Navier slip equation.
277 This condition was applied to the boundaries which were in contact with the fluid-fluid interface and is
278 appropriate for the two-phase flow model. This condition adds a frictional force, $\boldsymbol{F_{fr}}$, at a stationary wall
279 which allows the interface to move against the wall.

280

281 $$\boldsymbol{F_{fr}} = -\frac{\mu}{\beta}\boldsymbol{u}$$

282 Where β is the slip length, which was a function of the element size of the mesh, μ is viscosity and $\boldsymbol{u}$ is the
283 velocity vector. The fluid-fluid interface node also takes into account the interfacial tension of the two fluids,
284 $\sigma = 50$mN/m (37), and the contact angle between the wall and the fluids, $\theta_w = 1.3$ rad (38).

285 Due to the nature of the two-phase model, a stationary solution for the velocity field could not be solved
286 because of the movement at the interface, therefore a time-dependent solution was obtained over 9 seconds,
287 at which point the flow stabilised. This ~~steady-state solution~~stabilised flow was used as the velocity field
288 input for the transport of diluted species solutions.

289 The solution for the transport is simpler for the release of ibuprofen because the concentration species only
290 moves through two domains and not th~~erough a~~ fluid matrix domain therefore the movement is purely
291 diffusion and convection in the two different fluids. An additional expression for the partition coefficient is
292 included in the mass transport between the two phases.

293 **Boundary Conditions**

294 A no-slip condition was applied to the exterior boundary walls as with the previous model studies. The walls
295 in contact with the fluid-fluid interface were assigned a Navier slip condition. This condition allows the
296 fluid-fluid interface to move along the wall. Additionally, the top boundary of the oil phase, parallel to the
297 fluid-fluid interface, was assigned a slip condition. This slip condition allows the deformation of the mesh to
298 continue throughout the phase whilst still applying a no penetration condition, meaning the model allows the
299 movement of the mesh without fluid leaving that domain.

300 The inlet and outlet conditions were as previously describes and the same flow rates were investigated as
301 with the dextran transport studies: 20µL/min, 200µL/min, 400µL/min and 2mL/min. A volume force was
302 also implemented across the entire geometry to account for gravity in the system.

303 Two transport of diluted species nodes were used to investigate the release of ibuprofen from the silicone oil:
304 one for the oil phase and one for the aqueous phase. The appropriate diffusion coefficients as described in
305 table 1**Error! Reference source not found.** were applied to each fluid domain and a pointwise constraint

306 was applied at the fluid-fluid interface. This pointwise constraint takes into account the concentration at the

307 interfaces and solves for the mass flux across that boundary using a function of the concentration gradient

308 and the partition coefficient. The accepted error between the computer models and experimental data was set

309 by two boundaries, <10% = good agreement and <20% = acceptable agreement.

310 **Material properties**

311 1000 c.st silicone oil is often used by surgeons because its viscosity makes it easily injectable, a motivation

312 for its use in this study. SiO has a lower density than water, and therefore floats on it but has a higher

313 viscosity. These properties are shown in Table 2. Rheological evaluation of water, PBS and silicone oil was

314 done using a Rheosense Inc µVISC rheometer (Rheosense Inc., USA) with a 100N load cell. The results

315 showed negligible differences between water and PBS in terms of viscosity and density, therefore water was

316 used as the aqueous fluid of interest in the computer model. A handheld density meter (Anton Parr) was used

317 to measure the density of the fluids at 37°C.

318 **Results and Discussion**

319 **Grid Independence Studies**

320 To demonstrate grid independence, simulations were run with varying degrees of mesh refinement (dextran

321 model between 18,000 and 108,814 elements, ibuprofen model between 300 and 4000 elements). The

322 velocity at two points in the geometry was measured (Figure 2A, 2E) and compared as the mesh was refined.

323 The number of elements used in each model was justified by using the mesh refined to within 5% agreement

324 between both points and the highest resolved mesh (Figure 2G, H). This was decided on to reduce the

325 computational time without compromising on accuracy and was chosen as acceptable error limit. For the

326 dextran model, this was 38267 elements. For the ibuprofen model, this was 2258 elements.

327 **Dextran Transport Studies**

328 The predicted velocity profiles within the Kirkstall QV600 for flow rates 20, 200 and 400µL/min the

329 velocity fields produce similar patterns (Figure 3). A parabolic flow out from the inlet tube and in to the

330 outlet tube with considerably lower velocities in the main well of the chamber. Each flow rate shows areas of

331 recirculating flow trapped in the corners of the receptor compartment on the inlet side which increase in size

332 as the inlet flow rate is increased. The streamlines show that at the lowest flow rate, 20µL/min, the flow in

333 the main chamber has little effect on the velocity field in the donor compartment of the chamber. As the flow

334 rate increases, the flow profile of the donor compartment becomes more uniform as fluid from the main well

335 penetrates through the membrane and causes fluid flow in the donor compartment. This phenomenon is most

336 obvious at the highest flow rate, 2ml/min. In the donor compartment of this simulation, a complex flow

337 regime is observed. The velocities in the main well of the chamber are also considerably higher than in

338 comparison with lower inlet flow rates. Another feature of this high flow rate is the development of a

339 dominating stream of fluid from the inlet tube to the outlet port and large area of recirculating fluid beneath

340 this stream which occurs in the majority of the chamber volume. Previous studies have reported the flow rate

341 within the choriocapillaris *in vivo* to be 9.45mL/hr or 160μL/min (39) and disruptions or alterations in the

342 flow have been attributed to problems with homeostasis within the RPE (40, 41). Here we wanted to

343 investigate a range of flow rates, including one which was biologically relevant, in order to prove the

344 reliability of the computer model. For this reason, flow rates which were experimentally achievable were

345 used. Although 2mL/min was tested in the computer model and produced interesting flow patterns, this flow

346 rate was found to be too high to maintain the survival of the ARPE-19 cells, therefore no further studies were

347 conducted using 2mL/min.

348 To validate the numerical model, the results for concentration of dextran on the receptor compartment side of

349 the membrane were compared with experimental data. Permeability and diffusion coefficients were

350 determined in simple static experiments and implemented in the numerical model. The resulting coefficients

351 (table 1) were comparable with those seen in a similar experiment by Mannermaa et al. (19). In that study,

352 the authors compared the transport of drugs through a static, ARPE-19-based model and bovine RPE tissue,

353 finding similar transport trends. The simulation shows the concentration gradient of dextran in the donor

354 compartment to decrease with increasing flow rate after 24 hours. As expected, dextran is less readily cleared

355 across the barrier when the presence of cells is included in the simulation (Figure 4). The results of the model

356 were then validated using data from complementary *in vitro* experiments. The numerical model shows

357 agreement with the *in vitro* data in both the acellular and cell seeded experiments (Figure 5). At the higher

358 flow rates, the simulated results are able to mirror the change in release exhibited *in vitro* which shows a

359 shift to a burst release response followed by an exponential decay in concentration over time and there

360 appears to be no correlation between flow rate and simulation accuracy (42). The simulation of dextran

361 transport was able to predict the maximum concentration (C_{max}) observed in that chamber to within 5% of the

362 acellular experimental data. The introduction of cells to the system increased the error observed in C_{max} but

363 still to within 18% of the experimental data. Similar studies which simulated permeability of different

364 molecular weight FITC-dextrans in a static set-up and across collagen or agarose gel, showed an increase in

365 error (between approximately 4% and 46%) between their simulated and experimental results with increasing

366 molecular weight (43). Here, we have only presented data for the transport of 4kDa FITC-dextran; other

367 sizes were also investigated (40kDa and 70kDa FITC-dextran) with 4kDa and 40kDa producing similar

368 errors, but 70kDa showed increased error in comparison. The simulation does not take into consideration the

369 biological effects of culturing cells under flow might have on the barrier functionality of the ARPE-19 cell

370 monolayer. There are studies which have investigated biological effects on epithelial tissues in computer

371 simulations, for example modelling inflammatory effects on intestinal epithelium in necrotising enterocolitis

372 (44), and investigating links between epithelial morphogenesis and cancer mutations (45). A combination of

373 computational fluid dynamics modelling such as in this study and a more computational biology approach to

374 investigate cell dependent changes in transport and clearance of molecules could further improve the

375 agreement between the experimental and simulated data in cell seeded simulations.

376 **Ibuprofen Release Studies**

Tracking the fluid-fluid interface is of importance when considering the concentration distribution of drugs across the two fluids. An adaptive mesh was used to simulate the interaction between the silicone oil phase and the aqueous PBS phase. Based on the interfacial tension and wall contact angle of the two fluids, the simulation shows that a meniscus is formed between the two phases over time until a steady state is reached at approximately 1.4 seconds (Figure 6).

In the two phase system (oil and aqueous), the simulation shows two distinct flow fields within each phase (Figure 7). The flow field in the oil phase, however, does appear to be influenced by the flow rate of the aqueous phase. The flow fields formed at 20µL/min, 200µL/min and 400µL/min show similarities to those formed in the single phase, membrane system. At 20µL/min, however, the low flow rate inlet stream within the aqueous phase appears to bounce off the oil phase and creates a ripple within the primary flow stream. The interaction between the main flow stream and the oil phase also creates two recirculating streams within the oil domain itself. This phenomenon is observed for each of the flow rates studied with the split in the two streams shifting towards the inlet as the inlet flow rate increased. Unlike the 2mL/min flow field in the single phase system, the 2mL/min flow profile for the two phase model did not develop large regions of recirculating flow and maintained a single dominating fluid stream from inlet to outlet.

The concentration fields within the oil domain showed little difference as the flow rate increased other than to shift the centre of diffusion either towards the inlet at 2mL/min. For each flow rate the ibuprofen was never completely cleared from the oil domain by the final 72 hour time point. The simulation predicted that a small region of oil at the top of the domain, in contact with the exterior wall of the chamber through to the centre of the domain, maintained a low concentration of ibuprofen.

To model the release of ibuprofen from SiO, the physics controls of the computer model was redesigned to allow the interaction of two immiscible fluid phases within the QV600 chamber. For this ibu-SiO model, the moving mesh method was applied. COMSOL Multiphysics report that this method provides the best results when tracking the interface between the phases is of importance and also allows mass transport across the interface which is difficult to implement using other methods (46). At 20µL/min, the flow entering the main chamber bounces of the bottom of the meniscus formed by the oil phase and creates a ripple in the main stream of flow. The interaction of the main stream of flow with the oil domain also creates very low velocity recirculating flow patterns within the oil which are separate to the main flow stream. The movement within the oil could be expected to have implications on the distribution of ibuprofen within the oil phase but it appears that, because the velocities are so low, the diffusion of the ibuprofen from the oil still occurs symmetrically out from the centre of the domain. As the inlet velocity increases, more asymmetrical diffusion patterns appear, but the recirculation velocities within the oil remain very low in comparison with the velocity observed in the main stream of flow, and so the distribution of ibuprofen in the oil domain appears to be controlled by the concentration gradient between the two phases. This in turn is controlled by the convection of ibuprofen away from the interface by the fluid flow. The flow profiles in the aqueous phase of the two phase model were not comparable with those seen in the dextran transport model. In that model, the membrane was modelled as a fluid matrix domain whereby the fluid can move through the domain at a

414 retarded rate based on the porosity and permeability of the membrane. For this reason only a small
415 percentage of fluid actually passes through the membrane and interacts with the donor domain. The majority
416 of the flowing fluid sees this as a walled domain and so this reduces the height of the chamber which is the
417 reason for recirculating flows to develop instabilities. In the two-phase, oil/PBS model, the force of the
418 aqueous flow is partially absorbed by the oil which causes the recirculation within the oil but also reduces
419 the velocity of the aqueous flow in comparison with the single phase model. This reduction in velocity also
420 removes the secondary recirculating streams which occur in the single phase model.

421 As with the dextran transport simulations, to validate the computer model of the ibu-SiO device within the
422 QV600 chamber quantitatively, the concentration of ibuprofen in the receptor domain was measured over
423 time. The accuracy to which the model was able to predict the concentration of ibuprofen varied with the
424 inlet flow rate. There is strong agreement in the trends between the experimental and simulated data (Figure
425 8), with the simulation able to predict the concentration of the ibuprofen in the receptor chamber over 24
426 hours. There are small discrepancies in the values of the C_{max} at each flow rate, but the simulation is able to
427 predict the total exposure of the ibuprofen in the bottom chamber to within 10%. At the highest flow rate,
428 which is unrealistic in comparison with the *in vivo* environment, the C_{max} was underestimated by the
429 simulation, although the values for concentration under these conditions were at the very lower measurement
430 limit of the UV-Vis spectrophotometer. Furthermore, the differences in absolute value of C_{max} were
431 negligible in comparison to the 1mg/mL initial concentration present in the SiO.

432 Computational models, such as the ones incorporating fluid dynamics, present the advantage of accurately
433 describing the system behaviours when its constitutive parameters are varied. Unlike the traditional,
434 benchtop experiments, after thorough validation and benchmarking, these models can be used to describe
435 complex systems in a fast, inexpensive, accurate and reliable manner. Moreover, a vast parameter field can
436 be tested and considered, enabling the analysis and comparison of different physical processes such as fluid
437 flow or drug transport and diffusion.

438 The fluid flow set up used in this study was designed to emulate the mechanism of elimination of molecules
439 via convectional clearance analogous to the systemic circulation present in choroidal tissue *in vivo*. To
440 validate the computer model, comparisons of the average concentration in the receptor compartment of the
441 Kirkstall QV600 chamber were made between predicted and experimental data. It is important to note that
442 previous studies have used computer models to study drug delivery and distribution in the posterior segment
443 of the eye (29, 47, 48); these studies, however, are mostly theoretical or based on experimental data
444 published by Palestine and Brubaker which investigated the pharmacokinetics of fluorescein in the vitreous
445 of humans (31). Our study looked to create an *in silico* model which could predict drug distributions in an *in*
446 *vitro* model which could be used in the development of a novel ibu-SiO drug delivery device.

447 As robust and mathematically stringent as computer models may be, they will never be able to provide a
448 fully accurate representation of a biological environment due to the variability and continually dynamic
449 environment of nature. What they are able to do is provide predictions of results across a vast number of

parameters in a fast and inexpensive manner. In terms of developing drug delivery devices such as the ibu-SiO described here, it allows variations in conditions such as initial concentration, drug permeability and material properties and produces estimations which can narrow the range of expensive and time consuming experimental work that would otherwise need to be conducted. Ultimately it would be of interest to apply the knowledge and understanding of drug release from SiO gained from these complementary *in silico* and *in vitro* models to build a computational model of the eye which could help us predict how this system might work *in vivo* in a human eye.

Conclusion

The ability to model drug transport across epithelial tissues such as the blood-retinal barrier could lead to the development of more effective treatments. The data presented here demonstrate the ability of *in silico* models to predict *in vitro* behaviour in complex environments. When used together, these complementary *in vitro* and *in silico* models could help make the design of drug delivery devices more efficient, as well as having potential benefits to the drug discovery community. Ophthalmologists and other researchers should be cautious when interpreting data from any model. No model will fully recapitulate the complex environment of the human eye, but more sophisticated designs that can reproduce features such as choroidal flow can help move experimental data closer to clinical behaviour.

Author Contributions

AED carried out lab work, computational modelling, data analysis and drafted the manuscript. RLW participated in the design of the study critically revised the manuscript. . GL performed data analysis and critically revised the manuscript. SRP participated in computer model design, data analysis and critically revised manuscript. VRK conceived the study, designed the study, coordinated the study and helped draft manuscript. All authors gave final approval for publication and agree to be accountable for the work performed therein.

622   Input geometry, red dots indicate points 1 and 2 for grid independence study, and (F) mesh generated for

623   Kirkstall QV600 chamber used in ibuprofen release simulations. This mesh comprised 2,258 free triangular.

624   (G) Percentage difference in velocity at two points in the centre of the chamber compared with the finest

625   mesh for dextran transport (finest mesh: 108,814 elements). (H) Percentage difference in velocity at two

626   points in the centre of the chamber compared with the finest mesh ibuprofen release (finest mesh: 3481

627   elements). An acceptable mesh density was deemed to produce <5% error.

628   **Figure 3: Steady-state velocity fields for different inlet flow rates used in the Kirkstall QV600 chamber**

629   **geometry for dextran transport studies.** Inlet flow rates: (A) 20μL/min, (B) 200μL/min, (C) 400μL/min

630   and (D) 2mL/min. Colour scale bar indicates velocity (m/s). Streamlines show velocity field. Each flow rate

631   shows areas of recirculating flow trapped in the corners of the receptor compartment on the inlet side which

632   increase in size as the inlet flow rate is increased. The flow profile of the donor compartment becomes more

633   uniform with increased flow rate.

634   **Figure 4: Concentration fields for different inlet flow rates used in the Kirkstall QV600 chamber**

635   **geometry for dextran transport studies across acellular and seeded membranes at 1 hour**. Colour scale

636   bar indicates concentration (mol/m^3). As expected, the drug is cleared from the donor chamber more rapidly

637   as flow rate increases, but is impeded by the presence of cells.

638   **Figure 5: Experimental vs simulated average concentration profiles in the receptor compartment of**

639   **the Kirkstall QV600 chamber for dextran transport studies across acellular and seeded membranes.**

640   Experimental data presented as mean concentration $\pm$ 1 SD, n = 3. There is good agreement with respect to

641   the concentration at all flow rates, including the change of behaviours from burst release to exponential

642   decay, with differences within 5% for acellular and 18% for cellular experiments.

643   **Figure 6: Deformation of the mesh.** A steady-state solution is reached indicated by the meniscus formation

644   at fluid-fluid interface boundary of the two phases (green boundary).

645 **Figure 7: Stead-state velocity (A) and concentration at 1 hour (B) fields for different inlet flow rates**

646 **used in the Kirkstall QV600 chamber geometry for ibuprofen release studies**. Inlet flow rates:

647 20μL/min, 200μL/min and 2mL/min. (A) Colour scale bar indicates velocity (m/s), streamlines show

648 velocity field. (B) Colour scale bar indicates concentration (mol/m^3). The velocity simulation shows two

649 distinct flow fields within each phase, with velocity within the oil phase being influenced by the flow in the

650 fluid phase. This is accompanied by concentration contours that indicates that the fluid phase is influencing

651 the concentration gradient in the oil phase.

652 **Figure 8: Experimental vs simulated average concentration profiles of ibuprofen in receptor**

653 **compartment of Kirkstall QV600 chamber**. Experimental data presented as mean concentration ± 1 SD, n

654 = 3. There is good agreement with respect to the concentration at all flow rates, including the change of

655 behaviours from burst release to exponential decay, with differences within 10%.

656

657

658 **Tables**

659 Table 1 - Input parameters for dextran transport studies

Parameter	Value
Diffusion coefficient of FD in water	2.39 x10^{-11} m^2/s
Diffusion coefficient of FD across ePTFE	1.2x10^{-6} m^2/s
Diffusion coefficient of FD across ePTFE ARPE-19 complex	1.1x10^{-7} m^2/s
Initial concentration of FD in donor domain	50 µg/mL
Initial concentration of FD in membrane domain	0 µg/mL
Initial concentration of FD in receptor domain	0 µg/mL
Flow rate	20,200,400,2000 µL/min
Permeability coefficient of ePTFE	1.4x10^{-5} cm/s
Permeability coefficient of ePTFE ARPE-19 complex	8.8x10^{-6} cm/s
Porosity of ePTFE membrane	0.3 (from manufacturer)
Density of water at 37°C	994.12 kg/m^3
Dynamic viscosity of water at 37°C	0.691 mPa.s

660

661 Table 2 - Input parameters for ibuprofen release studies

Parameter	Value
Diffusion coefficient of ibuprofen in 1000c.st silicone oil	3.35 x10^{-11} m^2/s
Diffusion coefficient of ibuprofen in water	2.27 x10^{-13} m^2/s
Partition coefficient of ibuprofen	2.2 (49)
Initial concentration of ibuprofen in oil phase	1 mg/mL
Initial concentration of ibuprofen in aqueous phase	0 µg/mL
Flow rate	20, 200, 2000 µL/min
Interfacial tension 1000c.st silicone oil/PBS	50 mN/m (37)
Wall contact angle of fluid interface	1.3 rad (38)
Density of water at 37°C	994.12 kg/m^3
Dynamic viscosity of water at 37°C	0.691 mPa.s
Density of silicone oil at 37°C	967 kg/m^3
Dynamic viscosity of silicone oil at 37°C	790 mPa.s
