## 42 **Abstract**

43 Load carriage is seldom completed in isolation, meaning load bearers need to be physically  
44 capable of physical activity after the load carriage task. This study aims to examine changes in  
45 lower limb muscle strength, as measured by torque production across a range of joint angles as  
46 a result of prolonged load carriage. Thirty-four healthy participants underwent two hours of  
47 loaded or unloaded treadmill load carriage, with lower limb muscle function variables assessed  
48 pre and post activity. The loaded group had a mass of (Mean(range)) 76.45 (27.12)kg, stature:  
49 178.56 (17.63)cm, age: 23(6)yrs, and comprised of 13 males and 3 females. While the unloaded  
50 group had a body mass of 73.69(24.19)kg, stature: 178.89(18.49)cm, age: 22(5)yrs and  
51 comprised of 14 males and 4 females. Significant reductions across a range of parameters were  
52 observed. Characterised by reductions at the optimum muscle length for torque output, with all  
53 aspects demonstrating large (knee extension at  $180^{\circ}\cdot s^{-1}$ : 0.51 Standardised SD, knee extension  
54 at  $60^{\circ}\cdot s^{-1}$ : 0.98 standardised SD) or extremely large individual differences (knee flexion at  
55  $180^{\circ}\cdot s^{-1}$ : 2.17 standardised SD). These findings suggest after the completion of the load  
56 carriage task participants are in a significantly reduced physical state, which may have  
57 implications for secondary tasks.

62

## 63 **Introduction**

64

65 The capacity to safely carry external loads is a requirement in many occupational settings,  
66 including the military <sup>1</sup>, firefighting and other emergency services <sup>2</sup>. In these settings there are  
67 frequently secondary tasks which require substantial exertion, such as moving over obstacles  
68 <sup>3</sup>, climbing ladders or evacuating casualties <sup>4</sup>. Furthermore, load carriage is seldom completed  
69 in isolation, meaning upon completion of the load carriage, the load carrier needs to be  
70 physically capable to undergo occupational tasks such as setting up military positions or to  
71 execute attacks involving high intensity activity, such as sprinting or skilful activities, such as  
72 shooting<sup>5</sup>, while emergency services personnel may be required to undertake lifesaving

73 activities. Consequently, this study will assess the impact of prolonged load carriage on the  
74 torque producing capacity of the major muscle groups associated with locomotion.

75

76 Muscular function is accurately assessed by measuring the ability of a muscle or muscle group  
77 to generate force. While electromyography analysis provides a commentary on muscle fibre  
78 recruitment it cannot directly report the change in force produced by the muscle. Isokinetic  
79 dynamometry is commonly used to study changes in the muscles force producing capability<sup>6</sup>  
80 as the findings can be related directly to ability to complete real world tasks, making it a  
81 uniquely relevant tool to study load carriage.

82

83 It has previously been demonstrated that externally carried loads cause a number of acute  
84 changes to lower limb muscle torque output, which are cited as markers for injury risk <sup>7</sup>. These  
85 alterations are characterised by a reduction in ankle plantarflexion and knee extension and  
86 flexion, as measured by peak torque, following a two hour bout of treadmill load carriage task  
87 <sup>7,8</sup>. These findings are important, as it has been previously identified that plantarflexion peak  
88 force output is associated with braking impulse and energy cost and knee peak torque output  
89 has been associated with energy cost <sup>9</sup>. The use of peak torque as a measure of force producing  
90 capacity of the muscle could be viewed as an oversimplification, given that previous research  
91 has shown the timing and muscle length (as measured by joint angle) at which peak torque  
92 occurs can change with movement velocity and fatigue, as such if peak torque shifts from the  
93 optimum position it suggests there is a delay in muscle activation suggesting less economical  
94 gait and a greater injury risk <sup>10,11</sup>. Therefore, it may be useful to support peak torque assessment  
95 with torque measurements at multiple joint angles.

96

97 This work aims to use an occupationally relevant model of load carriage<sup>7</sup> to assess the torque  
98 output of the knee flexors and extensors and the ankle plantarflexors and dorsiflexors  
99 throughout the torque curve. It is hypothesised that as a result of load carriage peak torque will  
100 be reduced characterised by a reduction of torque across the range of the movement and by a  
101 shift in the angle of peak torque. This will be the first study to conduct an assessment of torque-  
102 length relationship following load carriage. This method will provide a greater understanding  
103 of the change in muscle behaviour as a result of an occupationally relevant load carriage task.

104

105 **Materials and Methods**

106 **Participants**

107 Voluntary, informed consent was collected from 34 healthy participants. Participants were  
108 matched according to gender, body mass, lower limb strength (all measures), stature, and age.  
109 The loaded group had a mass of (Mean(range)) 76.45(27.12)kg, stature: 178.56(17.63)cm, age:  
110 23(6)yrs, and comprised of 13 males and 3 females. While the unloaded group had a body mass  
111 of 73.69(24.19) kg, stature: 178.89(18.49)cm, age: 22(5)yrs and comprised of 14 males and 4  
112 females (Lower limb strength of both groups are presented in table 1). When assessed via t-  
113 tests no statistically significant differences were observed between groups.

114

115 Ethical approval was attained from the university ethics committee and all procedures were  
116 performed in accordance with the Declaration of Helsinki (2013). To participate in the  
117 laboratory studies the participants were required to meet the following inclusion criteria: 18-  
118 32 years old, be free from musculoskeletal injury and disorders, which may obviously alter  
119 gait, must sufficiently complete a pre-exercise physical activity questionnaire, must be taller  
120 than 163cm and must weigh more than 50kg. These criteria ensured participants reflected  
121 physical characteristics of a military cohort<sup>12</sup>.

122

123

124 **Experimental Design**

125 The study was conducted in a parallel controlled group design with both conditions running  
126 concurrently. Participants walked on a level motorised treadmill (Woodway ELG, Birmingham,  
127 UK)(0% gradient) for 120minutes, at 6.5km·h<sup>-1</sup>, which is a commonly used speed and duration  
128 as it reflects the pace and task duration used in the British Army annual load carriage task<sup>12</sup>.

129

130 Participants consumed water with no restrictions during the treadmill protocol, which reflected  
131 the occupational military setting. The bottle from which the water was drunk was not carried  
132 within the load carriage system.

133

134 (Insert Figure 1 about here)

135

136 The loaded condition consisted of a 32kg external load spread across, webbing (10kg), bergen  
137 (15kg) and a dummy rifle (7kg) (Figure 1), this load was chosen as it reflects the load carriage  
138 system carried during the annual British Army and US Marine Corps load carriage test.

139 However the load is heavier than the load carried by Greek Soldiers (17kg) who carry the load  
140 for a longer distance (21km) during their annual load carriage test. During the task, participants  
141 wore their own walking boots, shirt, and shorts. Participants were advised to wear a polo neck  
142 shirt to avoid the rifle sling rubbing the neck causing skin sores.

143

144 Before and after the treadmill protocol, participants underwent isokinetic and isometric testing.  
145 The test order was the same on each occasion and conducted at approximately the same time  
146 of day (early morning) to control for diurnal variation in the force producing capabilities of the  
147 muscles<sup>13</sup>.

148

### 149 **Lower Limb Strength**

150

151 Isokinetic knee assessment was conducted on the right limb using a Biodex System 3 Pro  
152 (Biodex: New York: USA). The right leg was chosen for all measurement to allow comparison  
153 to previous research<sup>7</sup>. The set up followed BASES guidelines as they were seated in the chair  
154 and secured with straps 5cm above the lateral malleolus, with their hips and knee joints at  
155 approximately 90°, with the inclusion of placing the left leg behind a restraining webbing strap  
156 to limit a countermovement swing. Before testing participants were instructed to undergo the  
157 entire protocol at a submaximal effort (self-perceived 30% effort- confirmed post hoc from a  
158 subsample of five participants) to familiarise the participant with the test protocol.

159

160 For ankle assessment, participants were seated in the chair and secured with straps. The thigh  
161 supporting attachment was used to ensure a hip angle of approximately 80° and a knee angle  
162 of approximately 170°, again the right limb was used.

163

164 The test protocol consisted of a maximal voluntary isometric knee extension and flexion and  
165 then one set of eight maximal contractions of the knee extensors and flexors at speeds of 60°·s<sup>-1</sup>  
166 and 180°·s<sup>-1</sup>. The ankle test protocol consisted of maximal voluntary isometric plantarflexion  
167 contraction followed by one set of eight maximal contractions of the ankle during dorsi and  
168 plantar flexion at speeds of 60°·s<sup>-1</sup> and 120°·s<sup>-1</sup>. These speeds were chosen to ensure relevant  
169 to previous work in the field<sup>7,8</sup>.

170

171 The tests were conducted in the order of isometric flexion, 30 second rest, isometric extension,  
172 60 second rest, isokinetic knee flexion and extension at  $60^{\circ}\cdot\text{s}^{-1}$ , 30 second rest and isokinetic  
173 knee flexion and extension at  $180^{\circ}\cdot\text{s}^{-1}$ . Ankle testing was conducted in the same order with  
174  $120^{\circ}\cdot\text{s}^{-1}$  being the final measurement. The testing order was chosen as it has been observed that  
175 when participants who have a limited experience of isokinetic dynamometry are tested, higher  
176 reliability scores are observed when lower rotation speeds are used first<sup>14</sup>.

177

178 Maximal voluntary contraction score for isometric contractions were considered the single  
179 highest recorded value. For the isokinetic contractions, visual basic code was used to highlight  
180 the start and end of each repetition, then for each repetition the highest torque value registered  
181 was extracted from each of the eight repetitions on the condition that the target velocity was  
182 attained. The highest five out of eight values were averaged to be presented as the peak torque  
183 score. This method of averaging was chosen as it was frequently observed that participants  
184 took three trials to present accurate and reliable results<sup>10</sup>. However, during data analysis it was  
185 highlighted that a small number of participants achieved higher torques in the first three  
186 repetitions, this method allowed for both events to be accurately portrayed.

187

188 Torque at specific joint angles was extracted at  $5^{\circ}$  intervals including all measurements at  
189 which the participant achieved target velocity. Knee joint angle was defined as the internal  
190 measurement of the knee angle. For example, if the leg is fully extended the angle would be  
191  $180^{\circ}$ , while a seated position would present a joint angle of approximately  $90^{\circ}$ . Joint angles  
192 were derived from the lever position reported by the isokinetic dynamometer, values which  
193 occurred during the target velocity were exported in raw format and were processed in excel.

194

### 195 **Environmental Conditions**

196 Environmental temperature and humidity were monitored (ATP: UK) during all the testing  
197 periods. No statistically significant differences in environmental temperature were observed  
198 during testing (Mean: SD), with a temperature of  $18.7:2.8^{\circ}\text{C}$  and humidity  $50.1:9.4\%$ .

199

### 200 **Statistical Analysis**

201 SPSS for windows version 23 (SPSS, Chicago, USA) and Excel (Microsoft: USA) was used  
202 for statistical analyses. Distribution of the data was assessed using the Shapiro-Wilk test for  
203 normality. Subsequently, differences between groups were assessed using independent group

204 t-tests with an alpha level set at 0.05. Analysis of the change score enabled normalization to  
205 baseline. Before change scores were compared and normalized to body mass the data was log  
206 transformed and plotted to ensure that it did not violate scaling guidelines<sup>15</sup>

207

208 Analysis of the torque at joint angles was examined by three way mixed methods ANOVA of  
209 the change scores once normality was confirmed. Post hoc pairwise analysis was conducted to  
210 confirm the significant differences at individual joint angles. Effect sizes were presented as  
211  $d_{\text{Glass}}$ . The primary measure of individual differences was conducted using standardised  
212 standard deviations<sup>16</sup>. Qualitative thresholds were taken from Smith, Hopkins<sup>17</sup>. Sample size  
213 was calculated using G\*Power<sup>18</sup> using means and standard deviations drawn from the live data  
214 to confirm the study was sufficiently powered. The variable examined was taken from previous  
215 work within our lab and recruitment was stopped when sufficient sample size was met for the  
216 variables of knee extension  $60^{\circ}\text{s}^{-1}$  (n=9 participants per group).

217

## 218 **Results**

### 219 **Adverse Events**

220 No participants experienced any major injury as a result of this study. However, six participants  
221 experienced blisters on their feet as a result of the load carriage protocol and three participants  
222 noted hotspots due to the load carriage equipment rubbing on their shoulders and hips.  
223 Grannuflex (a hydrocolloid, moisture retentive wound dressing) and zink-oxide tape were  
224 provided to the participants during and after the study, and the participants were advised to  
225 wear polo neck shirts. Participants reported that these were very useful in mitigating the skin  
226 sores.

227

### 228 **Sample Size Profile**

229 Three participants failed to complete the load carriage task, these consisted of two females and  
230 one male. All three participants stated the reason for withdrawal was excessive pain across their  
231 shoulders as a result of the load.

232

### 233 **Lower limb Muscle Strength**

234

235 (Insert Figure 2 about here)

236

237 Figure 2 presents significant differences in the knee flexors at  $180^{\circ}\cdot s^{-1}$  were observed between  
238  $95^{\circ}$ - $125^{\circ}$ , while knee extensors demonstrate reductions between  $95^{\circ}$ - $105^{\circ}$  at  $60^{\circ}\cdot s^{-1}$  and  $95^{\circ}$ -  
239  $125^{\circ}$  at  $180^{\circ}\cdot s^{-1}$ .

240

241 Seventeen participants completed the unloaded protocol and 16 completed the loaded protocol,  
242 however some participants (n presented in table 1) were not able to achieve the target velocity  
243 so were excluded from the analysis. Large effect sizes were observed for all significant  
244 variables.

245

246 (Insert Table 1 about here)

247

248

249 (Insert Table 2 about here)

250

251

252 A statistically significant change was observed in the angle of peak torque in the knee flexors  
253 at  $60^{\circ}\cdot s^{-1}$  (Table 2), despite no change in torque at individual joint angles or peak torque  
254 magnitude.

255

256 (Insert table 3 about here)

257 Table 3 presents individual differences observed for knee flexion.

258

## 259 **Discussion**

260 This is the first study to demonstrate an overall reduction in torque across multiple joint angles  
261 in both the knee extensors and flexors, as a result of two hours of treadmill load carriage (fig.2).

262 This can be further characterised by a reduction in peak torque and a statistically significant  
263 shift in the position of peak torque from a number of variables in the knee but none in the ankle,  
264 suggesting that load carriage instigates a reduction in torque output, while table 3 explains that  
265 individual differences were observed in these findings. As such it is possible to accept the  
266 hypothesis that peak torque is reduced in the knee extensors and flexors and ankle  
267 plantarflexors as a result of two hours of load carriage. This can be defined by changes in the  
268 position of peak torque and the profile of the curve from multiple triangulatory measurements.

269

## 270 **Peak Torque**

271 Reductions in peak torque (table 1) were observed for most measures of knee flexion and knee  
272 extension for both isometric and isokinetic contractions supported by large effect sizes, the  
273 observed changes across a range of velocities and contraction types provides strong  
274 triangulatory support for the changes. Furthermore, while reductions of peak torque between  
275 9% and 15.1% in the load carriage group were observed for knee flexion in alignment with  
276 previous work<sup>19</sup>, and increases from baseline were observed for the unloaded group, which  
277 suggests greater decrements than previously documented.

278

279 When the joint angle of torque was assessed and presented in table 2, this study observed that  
280 peak torque occurred at a larger angle in the load carriage group compared to unloaded control  
281 at both baseline and for change scores, for both knee flexion ( $p=0.03$ ) and extension at  $60^\circ \cdot s^{-1}$   
282 ( $p=0.008$ ) with a trend for knee extension at  $180^\circ \cdot s^{-1}$  ( $p=0.08$ ). These results suggest that while  
283 peak torque is reduced during load carriage, the working muscle also requires a greater distance  
284 to achieve peak torque suggesting a shift from optimal muscle length. It is noteworthy that the  
285 angle of peak torque changed in knee flexion at  $60^\circ \cdot s^{-1}$ , while no differences were observed in  
286 peak torque or the torque profile curve, highlighting a change in torque producing capacity  
287 which would have been missed by peak torque testing. Due to reduced specificity of isokinetic  
288 dynamometry it is unclear what impact this shift in angle of peak torque will have on the  
289 participant's locomotive ability.

290

291 Significant reductions in ankle plantarflexor peak torque across all parameters were observed  
292 as a result of the load carriage in agreement with previous work<sup>8</sup>, which were supported by  
293 moderate to large effect sizes (Table 1). As previous work has shown that the ankle  
294 plantarflexors provide propulsive force to propel the body forwards during locomotion<sup>20</sup>, it is  
295 likely that this reduction in muscle strength will increase the energy cost of the task. Moreover,  
296 a number of muscles such as the peroneus longus that are involved in plantarflexion have  
297 secondary roles providing mediolateral support for the ankle protecting against ankle inversion  
298 injury. However, further research is required to examine this in more depth.

299

## 300 **Torque angle relationship**

301 The examination of knee extension and flexion at multiple joint angles is novel to load carriage  
302 study. It is clear that the faster joint movements displayed reduced torque output over a larger

303 proportion of the joint angle (Fig.2). In all instances, the peak torque values occurred during  
304 the optimal muscle length for force, displayed by a flattening of the curve around its peak of  
305 the loaded post-test measurements. It is notable that these are muscle lengths (95°-125°) which  
306 do not occur during load carriage. So when the muscle is at lengths which are reflective of  
307 locomotion (130°-180°<sup>21</sup>) there appears to be no significant change between loaded and  
308 unloaded groups. These findings suggest that while changes in torque and peak torque can be  
309 observed by isokinetic dynamometry of the whole muscle action, it is unclear whether this loss  
310 will have a pronounced effect on the muscle's ability to produce force at muscle lengths relevant  
311 to walking with or without external load.

312

313 This study assessed lower limb strength as a result of a two hour occupational load carriage  
314 task to highlight that the reduction in peak torque (Table 1), change in the torque profile (Fig2)  
315 and that the position of peak torque shift as a result of load carriage (Table 2). These findings  
316 suggest a delay in muscle fibre recruitment, potentiating the body's ability to mitigate the effect  
317 of the load suggesting the participant may be exposed to greater injury risk and reduced  
318 movement economy. Interestingly, large inter individual responses were observed for most  
319 isokinetic dynamometry testing with large standard deviation. This suggests that there is merit  
320 in future research examining the profile of the torque curve, both in an experimental design  
321 study supporting load carriage and in a clinical setting. These findings suggest that the load  
322 carrier may be exposed to reduced ability to produce force in the low limb suggesting they are  
323 less able to move economically and are exposed to increased injury risk. Further studies  
324 examining impact forces are required to confirm this.

### 325 **Limitations**

326 This study highlights the benefit of assessing knee torque output at specific joint angles.  
327 However, it was not possible to evaluate ankle torque output in the same manner due to the  
328 limited range of movement of the ankle joint. Future work could be conducted at a lower  
329 velocity and would increase the range of movement for which the participants are at the target  
330 velocity.

331

### 332 **Perspectives**

333 This paper analyses torque output of the knee extensors and flexors at multiple joint angles  
334 which highlighted that reductions in torque output occur at muscle lengths not typically used  
335 during locomotion. This suggests that the change in output is likely to be greater than

336 previously thought. Future research should focus on analysis of torque at specific joint angles,  
337 to provide comprehensive assessment of the muscle action. In an applied setting, load carriage  
338 instigates significant alteration to lower limb strength which could influence injury risk through  
339 changes in impact forces and energy cost of the task to the participants.
