1 **Abstract**

2 During practice and competition, golfers are required to use submaximal effort to hit the ball
3 a given distance, i.e. perform a partial shot. While the full golf swing has undergone
4 extensive research, little has addressed partial shots and the biomechanical modifications
5 golfers employ. This study investigates the biomechanical changes between full and partial
6 swings, and determines if the partial swing is a scaled version of the full swing. Using a
7 repeated measures design, thirteen male golfers completed a minimum of 10 swings in the
8 full and partial swing conditions, whilst club, ball, kinematic and kinetic parameters were
9 recorded. Large and statistically significant reductions in body motion (centre of pressure
10 ellipse: 33.0%, $p = 0.004$, $d = 2.26$), combined with moderate reductions in lateral shift
11 (25.5%, $p = 0.004$, $d = 0.33$) and smaller reductions in trunk rotation (arm to vertical at top of
12 backswing: 14.1%, $p = 0.002$, $d = 2.58$) indicate golfers favour larger reductions in proximal
13 measures, combined with diminished reductions as variables moved distally. Furthermore,
14 the partial swing was not found to be a scaled version of the full swing implying a new
15 approach to coaching practices might be considered.

24 **Introduction**

25 In competitive golf, the final shot into the putting green is often termed the ‘approach shot’.
26 This shot determines the distance of the ball from the hole for the first putt. The accuracy of
27 the approach shot will influence the likelihood of success in the following putt (Stökl, Lamb,
28 & Lames, 2011). Golfers will therefore employ course management strategies in an attempt
29 to position the ball in the most advantageous location for distance and approach angle to the
30 hole, with the penultimate shot to the approach. However, researchers, disregarding possible
31 environmental influences, have identified that minor inaccuracies in the contact between the
32 club face and ball will alter ball launch characteristics and result in an unplanned final ball
33 position (Betzler, Monk, Wallace, Otto, & Shan, 2008). Given the final position being
34 unplanned, the ball may be at a distance ‘between clubs’ or shorter than that achievable with
35 a full swing of the most lofted club in the bag. As golfers are limited in number of clubs
36 (n=14) (The R&A, 2016) allowable to be carried, which alter in length and loft (the angle of
37 the club face to the vertical axis), of which each will have a known shot distance. The golfer
38 will need to alter their planned approach shot, through modification of swing, performing a
39 reduced effort swing, termed a partial shot.

40 Partial shots are postulated to be more difficult than full swing shots (Pelz, 2006; James &
41 Rees, 2008; Robertson, Burnet & Gupta, 2014), as outcomes measured using percentage error
42 index (PEI) are significantly worse than those of full swings. Percentage error index is
43 derived from shot distance divided by the error from target reported as a percentage (Pelz,
44 2006). James and Rees (2008) identified a 17% reduction in accuracy for shots between 50-
45 100 yards when compared to those from 100-200 yards during the 2006 PGA tour. Despite
46 the general understanding of this, partial shots in golf are relatively common, between 2012
47 and 2016 the season average for PGA tour professional was 201 approach shots or 3 per
48 round, defined as being less than 100 yards (PGA Tour, 2017). Considering these statistics, a

49 better understanding of partial shots would be advantageous to golfers, as three shots that are
50 significantly less accurate would result in an increase in putts required and higher scores.

51 Surprisingly, the partial swing has received very little attention in the academic literature.
52 Initial investigations addressing distance control (Neal, Abernethy, Moran, & Parker, 1990)
53 and muscle activity (Abernethy, Neal, Moran, & Parker, 1990) during partial swings,
54 highlighted that level of muscular activation did not linearly increase with shot distance
55 (Abernethy et al., 1990) and the temporal sequencing of partial shots were not scaled to full
56 swings (Neal et al., 1990). More recently, researchers have established that the proximal to
57 distal sequencing (PDS) patterns experienced in the full swing (Cheetham, Martin, Mottram,
58 & St Laurent, 2001; Neal, Lumsden, Holland, & Mason, 2007; Tinmark, Hellstrom,
59 Halvorsen, & Thorstensson, 2010), were qualitatively similar for shots from 40m, 55m and
60 70m, however duration of downswing was significantly reduced (Tinmark et al., 2010).

61 Parallel work in drop punt distance control within Australian Rules Football (Ball, 2008;
62 Peacock, Ball, & Taylor, 2017) identified reduction in foot velocity, comparable to club head
63 velocity for golfers, was the determinant of impact parameters associated with reductions in
64 distance. Indicating that the velocity of the implement at contact needed to be manipulated to
65 mitigate the distance requirements of the task (Peacock et al., 2017). Reductions in foot
66 velocity were not proportional to those required in distance, however the nature of the task
67 was proposed as the determining factor as the task did not require the ball to come to rest at
68 the target distance. Rather the ball was aimed at a training mannequin and as such the authors
69 proposed that participants may have altered parameters on the basis of the task, rather than
70 absolute distance control.

71 Importantly, issues arise from these approaches, as the lack of linear relationship to full swing
72 (or maximum distance) is likely to have been driven by the absolute distances used (20m,
73 40m, and 60m; 40m, 55m and 70m; 20m and 60m) by Neal et al. (1990), Tinmark et al.

74 (2010) and Peacock et al. (2017), respectively. Moreover, the effort required for each golfer
75 to hit the desired distance, as measured by the percentage of full swing distance, would likely
76 have been different both across and within ability groups. Alternatively, the applied field of
77 golf coaching promotes a staged reduction in the length of the backswing (Cowle, 2010; Pelz,
78 2006), possibly evidenced by the alterations in downswing duration (Tinmark et al., 2010).
79 This approach has received limited support from empirical research, as elite and amateur
80 golfers have demonstrated significant staged increases in all measures, when participants
81 were instructed to swing easy, medium and hard with a 5 iron (Meister et al., 2011).
82 However, the ambiguous instruction of swing effort provided to the participants limits the
83 comparability between participants.

84 Previous research has identified specific biomechanical parameters associated with
85 maximising club head and ball velocity including; the x-factor (McTeigue, Lamb, &
86 Mottram, 1994), the x-factor stretch (Cheetham et al., 2001), ground reaction forces
87 (Worsfold, Smith, & Dyson, 2007), coefficient of restitution (CoR) of the ball (Chou,
88 Gobush, Liang, & Yang, 1994), weight transfer (Jorgensen, 1994) and centre of pressure
89 range and rate of motion (Ball & Best, 2011). These parameters could provide an inverse
90 theoretical framework from which a scaled reduction of these, in line with the suggested
91 coaching practices (Cowle, 2010; Pelz, 2006), would be present in the partial shot. Recently
92 some support for this theoretical approach was found in the ground reaction force under the
93 lead foot during the swing (McNitt-Gray, Munaretto, Zaferiou, Requejo, & Flashner, 2013).
94 This was characterised by a significant reduction in the magnitude of peak horizontal ground
95 reaction force during the swing, whilst the orientation of the force application did not change
96 during a partial swing (McNitt-Gray et al., 2013).

97 Despite recent findings, neither the kinetic or kinematic contributors used by golfers to
98 achieve partial shots, or how these differ from the full shots, are understood. Furthermore, the

99 limitations associated with use of absolute distance assessment of partial shots (Abernethy et
100 al., 1990; Neal et al., 1990; Tinmark et al., 2010), the qualitative similarities in PDS (Tinmark
101 et al., 2010) and the continued anecdotal coaching approaches to learning partial shots
102 (Cowle, 2010; Pelz, 2006), indicating partial shots may be scaled full shots, suggest further
103 investigation is warranted. Therefore, the purpose of this study was twofold; to assess the
104 biomechanical differences between full and partial golf swings, and to assess if partial shots
105 are scaled from full shots. It was hypothesised that there would be a significant difference in
106 measured biomechanical variables associated with carry distance and the partial swing would
107 be not significantly different in measured biomechanical variables associated with carry
108 distance from a scaled full swing.

109 **Methods**

110 Participants

111 The study protocol was approved by the Canterbury Christ Church University Ethics
112 Committee and all testing procedures were carried out in accordance with Declaration of
113 Helsinki. Thirteen male participants (40 ± 16 years of age, $1.82\text{m} \pm 0.05\text{m}$ in height, mass
114 $90\text{kg} \pm 20\text{kg}$, UK Council of National Golf Unions (CONGU) handicap of 13 ± 9) took part
115 after providing written, informed consent. Post hoc power assessment of sample size using
116 club head speed as the main determinant of carry distance (Hume, Keogh, & Reid, 2005),
117 computed using G*Power 3 (Faul, Erdfelder, Lang, & Buchner, 2007), demonstrate statistical
118 power greater than 0.95. Inclusion criteria stipulated that they had no current injury that
119 would affect their ability to perform a minimum of 20 golf swings and had played or
120 practiced golf within a year of testing. Prior to testing the participants had retro reflective
121 markers placed on 8 anthropometric sites bilaterally through manual palpation including, the

122 lateral malleolus of the fibula, the acromion process of the scapula, the olecranon process and
123 the ulnar styloid; all markers were placed directly onto the skin.

124 Testing Procedure

125 Following a self-selected duration for warm-up and familiarisation, participants performed a
126 minimum of 10 full golf shots in an indoor testing facility, hitting to their maximum
127 comfortable carry distance, defined as distance travelled from ball strike to calculated first
128 ball ground contact, with a pitching wedge. Full shots were captured first allowing
129 calculation of partial shot target distance in the proceeding condition. Pitching wedge was
130 selected as club face loft is standard (45°), where wedges used with lofts greater than this are
131 inconsistent across individuals due to preference. The pitching wedge was either a men's
132 standard length and lie, provided to participants who used standard sets, or the participants
133 custom fitted pitching wedge. Each shot was aimed towards a target line marked on a wall 5.3
134 m from the driving mat, with a safety net 4.8 m from the driving mat; distances were
135 determined by lab dimensions, participant safety, and minimum distance required for ball
136 tracking (4m).

137 On completion of the 10 full swings, participants were given a self-selected break, no less
138 than 10 minutes, and the 80% target distance for the partial shot was calculated (mean carry
139 distance*0.8). The participant was informed of the new target distance, all distances were
140 verbally reported to the participant in yards as the golfing standard unit. A second period of
141 familiarisation to the target distance was completed; verbal feedback was provided during
142 this familiarisation as either 'good', 'too long' or 'too short'. When the participant reported
143 they had sufficient familiarisation the participant completed a second set of 10 shots to an 80
144 $\pm 5\%$ distance of the full swing distance, as measured by the Flightscope X2 Doppler Ball-
145 Tracking Radar (EDH Ltd, South Africa). Only shots within the accepted margin of error

146 were recorded for further analysis. Verbal feedback, either ‘too long’ or ‘too short’, continued
147 to be used to aid the participant in ranging failed trials.

148 Equipment

149 During each shot two dimensional (2D) kinematic data were collected using a Fastec
150 TS5QM4256 high-speed digital camera (Fastec Imaging Company, USA) operating at 400Hz
151 (focusing range ∞ m, aperture $f/2.8$, shutter speed $2488\mu\text{s}$ and resolution 1536×1536 pixels)
152 centred on the participants’ hands at address, perpendicular to the line of flight of ball. An
153 initial swing capture was recorded and analysed prior to data collection to establish that all
154 markers remained in frame for the full golf swing.

155 During all swings ball flight and club statistics were measured using a Flightscope X2,
156 3.2m behind the target line, ensured by using the ball origin test score of 0° , a roll angle and
157 tilt angle within manufacturer recommendations ($\pm 0.3^\circ$, $9\text{-}12^\circ$ respectively). Pataky (2014)
158 defines the Flightscope as ‘a system with a manufacturer-specified accuracy of approximately
159 99%, achieved through constant during-flight ball monitoring’. Each shot used a Titleist
160 ProV1 golf ball with a metallic dot applied and orientated in the direction of the intended
161 shot. Centre of pressure data was captured using an RS Scan 1m pressure plate (RS Scan
162 International, Belgium) sampling at 100 Hz for 5 seconds using RS Scan version 7 balance
163 software (RS Scan International, Belgium). The pressure plate system was selected to assess
164 the variations in centre of pressure (CoP), as previously it has been shown to be a valid tool
165 for assessing CoP motion associated with balance and performance during static and dynamic
166 movements (Cloak, Nevill, Clarke, Day, & Wyon, 2010; Cloak, Wyon, Nevill, & Day, 2013;
167 Fletcher & Long, 2013; Morrin & Redding, 2013).

168

169

170

171 Processing and data extraction

172 Swing kinematics and kinetics were used to compare the techniques used by golfers to
173 perform both full and partial golf shots. The three swing events were; Address, which was the
174 last frame before the initiation of movement of the club in a clockwise direction; Top of the
175 backswing, which was the last frame before motion of the downswing, as indicated by the
176 first movement of the club in the opposite direction to the backswing; and Ball Contact,
177 which was defined as the frame at which the club first made contact with the ball. From these
178 measures backswing duration was the time between the address frame and the top of the
179 backswing, the downswing duration was the time between the top of the backswing and ball
180 contact and the total swing duration was the time between address and ball contact frames.
181 The kinematic variables were the lead forearm angle to vertical at the top of the backswing
182 (AV), the lead wrist angle at the top of the backswing - defined as the angle between the
183 forearm and the shaft of the club, and stance width - defined as the distance between
184 retroreflective markers placed on the left and right lateral malleolus of the fibula. The kinetic
185 variables were the centre of pressure excursion (CoPE) - defined as the total distance that the
186 centre of pressure travelled throughout the duration of the golf swing, the range of the centre
187 of pressure in the anteroposterior direction (CoPy) and the range of the centre of pressure in
188 the mediolateral direction (CoPx) between the start and the end of the swing. Finally, the
189 ellipse area (CoP Ellipse), a combined measure indicating the total motion of the centre of
190 pressure during the swing, is considered indicative of the overall weight transfer during the
191 swing was calculated. Thus, providing a single indicator of weight transfer motion during the
192 swing for coaching application. Extraction of the kinetic data at relevant swing events was
193 performed using the vertical force trace on the RSScan software and the method employed by
194 Worsfold et al. (2007).

195

196 Flightscope® X2 measurements were club head velocity (CHV) (m/s), shot accuracy as
197 measured as lateral displacement of the ball to the target line (m), Ball velocity (m/s) and
198 carry distance of the ball (m), all of which were reported by the Flightscope® X2 software.
199 Performance Error Index (PEI) was also calculated by dividing the mediolateral error of the
200 shot (m) by the carry distance that golf shot achieved (Pelz, 2006), which allows comparison
201 of error to be drawn between golfers who can hit to different shot distances with the same
202 club. Initial analysis was undertaken to determine if golfing ability, as measured by handicap,
203 was an influencing factor. The participant group was split into low (n= 6; handicap 4.8±5.4)
204 and high (n=7; handicap 19.3±3.7), cut off set at 12, upon which independent samples t-tests,
205 with a Holm's sequential Bonferroni correction, were conducted on all variables. No variable
206 displayed statistical significance ($p>0.05$) between the low handicap and high handicap
207 groups, in either full or partial shots. Therefore, all golfers were grouped for the statistical
208 analysis.

209

210 Statistical Analysis

211 Prior to statistical analysis parametric assumptions were tested using a Shapiro-Wilk test, any
212 variables violating parametric assumptions were compared using a Wilcoxon signed rank test,
213 while paired sample t-tests were used for those that did not. To minimise the chance of type
214 one errors Holm's sequential Bonferroni correction was applied. Effect sizes (Cohen's D)
215 were calculated for all statistically significant findings using an online calculator (Lenhard &
216 Lenhard, 2016), which were evaluated as small, medium or large effects based on the values
217 of 0.2, 0.5 or 0.8 respectively (Cohen, 1988). Two rounds of statistical tests were completed
218 on the data firstly comparing partial shot (PS_m) to the full shot (FS), to identify whether the

219 full and partial shots are different. A secondary analysis to determine if the partial shot (PS_m)
220 was a scaled version of the full swing by calculating a theoretical 80% (PS_t) value for the full
221 swing ($\text{variable} \times 0.8$). Not all variables were included in the secondary analysis, only those
222 expected to change to reduce carry distance based on Cheetham (2014). The level of
223 statistical significance was set at $p \leq 0.05$ for all tests. The statistical analysis was performed
224 with SPSS version 24.0 (SPSS Inc., Chicago, IL, USA).

225

226 **Results**

227 *Full Swing versus Partial Swing*

228 All data are reported as mean \pm standard error (SE). The analysis of the Flightscope data for
229 carry distance showed that during the partial shot session all golfers managed to hit within the
230 required target distance and margin of error ($80\% \pm 5\%$). The analysis of the kinematic data
231 showed that AV significantly reduced between the full and partial shots ($z = -3.059, p =$
232 $0.002, d = -2.58$), whereas wrist angle was found not to be significantly different between the
233 two swing conditions. Lateral shift ($t(10) = 3.667, p = 0.030, d = -0.33$) and stance width
234 ($t(11) = 3.785, p = 0.024, d = -0.54$) also displayed significant changes between the full swing
235 and the partial swing (table 1).

236

237 TABLE 1 NEAR HERE

238

239

240 Figure 1 shows the analysis of the pressure excursions, significant differences were found in
241 the CoPE (FS: 0.858 ± 0.047 m, PS_m : 0.654 ± 0.054 m; $t(11) = 6.591, p < 0.001, d = 1.17$)

242 and CoPx (FS: 0.349 ± 0.025 m, PS_m: 0.305 ± 0.029 m; $t(12) = 3.944$, $p = 0.021$, $d = 0.46$),
243 both of which were significantly lower during the partial shot compared to the full shot
244 condition. This translated into the CoP Ellipse also exhibiting significantly lower area in the
245 PS_m ($z = -2.903$, $p = 0.004$, $d = 2.26$) (table 1).

246

247 FIGURE 1 NEAR HERE

248

249 The lateral distance of the shot to the target line was found not to be significantly different
250 between full (4.73 ± 0.41 m) and partial (4.05 ± 0.53 m) shots, as was PEI (FS: $4.35 \pm 0.04\%$,
251 PS_m: $4.51 \pm 0.70\%$, $p > 0.05$). Both CHV ($t(12) = 19.918$, $p < 0.001$, $d = 1.94$) and ball
252 velocity ($t(12) = 21.083$, $p < 0.001$, $d = 1.47$) significantly reduced between the full and
253 partial shots. Further significances were found in the flight time ($t(12) = 19.716$, $p < 0.001$, d
254 $= 1.98$) and peak height ($t(12) = 17.051$, $p < 0.001$, $d = 2.20$). All Flightscope measures are
255 displayed in table 2.

256

257 TABLE 2 NEAR HERE

258

259

260 Partial Swing versus Theoretical Swing

261 The kinematic variables found that wrist angle at top of back swing ($t(10) = 4.920$, $p = 0.001$,
262 $d = 0.96$) and AV ($z = 2.118$, $p = 0.034$, $d = 1.31$) was significantly higher for the measured
263 partial shot. This was also true for the temporal swing variables, with swing duration (PS_m:

264 1.09 ± 0.04 s, $PS_t: 0.88 \pm 0.04$ s; $t(10) = 11.597$, $p < 0.001$, $d = 1.44$), back swing duration
265 ($PS_m: 0.78 \pm 0.04$ s, $PS_t: 0.65 \pm 0.04$ s; $t(10) = 10.075$, $p < 0.001$, $d = 1.08$) and downswing
266 duration ($PS_m: 0.31 \pm 0.01$ s, $PS_t: 0.24 \pm 0.01$ s; $t(10) = 16.362$, $p < 0.001$, $d = 2.33$) all being
267 significantly longer for the measured partial swing (figure 2). Centre of pressure measures
268 displayed no significant difference between measured and theoretical partial swings, although
269 CoP Ellipse ($p = 0.084$) and CoPx ($p = 0.067$) neared significance.

270

271 FIGURE 2 NEAR HERE

272

273 Analyses of the Flightscope variables indicated that both CHV ($t(12) = 5.898$, $p < 0.001$, $d =$
274 0.58) and ball velocity ($t(12) = 14.286$, $p < 0.001$, $d = 0.56$), were significantly higher for the
275 measured partial shot when compared to the theoretical partial shot value. This was also true
276 for the flight time ($t(12) = 5.693$, $p < 0.001$, $d = 0.69$), but the peak shot height ($t(12) = -$
277 6.562 , $p < 0.001$, $d = 0.75$) was significantly lower than the theoretical partial shot (table 1).

278

279

280

281 **Discussion and Implications**

282 Theoretically, the reduced carry distance required of the partial shot, would mean that the
283 expectation for significant differences in measured biomechanical and temporal variables to
284 those of a full swing could be expected. Results, specifically statistically significant
285 differences across measures of kinematic, kinetic, club and ball parameters between whole
286 and partial shots, corroborate this proposition and allow the acceptance of the primary

287 hypothesis. Statistically significant and large decreases in the CoP ellipse, by 33.0% ($z = -$
288 $2.903, p = 0.004, d = 2.26$) and the CoPe, by 23.7% ($t(12) = 6.591, p < 0.001, d = 1.16$) and
289 smaller, yet still significant declines, in the lateral shift (14.3%) and CoPx (12.5%) measures
290 for the PSm were characteristic of partial swings. The reduction of the CoPx range provides
291 corroborative support to reductions in magnitude of peak lateral forces identified by McNitt-
292 Gray et al. (2013). As lateral motion of the CoP (calculated from the vertical force) will have
293 been caused by a net lateral force being applied to the system, therefore the reduced CoPx
294 will have been a result of a reduced lateral force, as identified by McNitt-Gray et al. (2013).
295 Resultantly, it appears that strategies employed by participants in performing partial shots are
296 associated with a reduction in the magnitude of centre of pressure motion, caused by reduced
297 force application. Furthermore, when these reductions are considered in light of previous
298 work focused on maximising club head velocity (Ball & Best, 2007; Ball & Best, 2011), it
299 appears that participants are intuitively reducing parameters normally maximised for gaining
300 distance. Therefore, the reductions in the motion of the CoP are fundamental in controlling
301 partial shot distance. Meaning that from a coaching perspective, with specific reference to the
302 weight transfer (CoPx), golfers reduce their lateral motion and so advice should focus on
303 limiting the natural weight transfer of the golf swing when practising partial shots.

304

305 Examination of swing kinematics provide further insight into the strategies employed by
306 golfers when playing partial shots. The AV angle, a basic two-dimensional indication of the
307 rotation in the upper torso, continued the pattern of reduced motion exhibited in the centre of
308 pressure. The AV was significantly lower for the PSm ($135.68 \pm 7.33^\circ$) than the full swing
309 ($157.91 \pm 7.38^\circ$), inferring that torso rotation was reduced during the partial shot. No
310 significant differences were observed in the wrist cock angle at the top of the back swing, but
311 there was a significant change at ball impact (FS: $180.66 \pm 2.64^\circ$, PSm: $178.17 \pm 2.57^\circ, d =$

312 2.26). This suggests that the participants used a shortened backswing and may have been
313 trying to actively prevent the natural release of the club through impact, in an attempt to limit
314 club head velocity and therefore better control partial shot distance (Jorgensen, 1994). The
315 change in the wrist angle at impact was not an artefact of alterations in swing set up, as no
316 changes in the wrist angle were detected at address. Interestingly a statistically significant
317 reduction in stance width was identified at address, as golfers narrowed their stance when
318 performing the partial shot ($t(11) = 3.785, p < 0.05, d = 1.37$). The reduction in the stance
319 width will have consequences for other areas of the swing, in that the golfer will need either
320 to increase the knee bend or hip lean to maintain stance height, or perform the swing in an
321 increased upright position.

322 Assessment of the club and ball parameters suggest which of the approaches golfers employ
323 in line with the reduced stance width. Specifically, an increase in the club shaft angle was
324 observed at impact in the PS_m condition, suggesting that the golfer stood in an increased
325 upright position. Theoretically, this would have caused the heel of the club to be lifted,
326 opening the face of the club at impact and increasing the likelihood of the toe of the club
327 impacting the ground first causing an off centre strike. It would, therefore, be expected that
328 the lateral accuracy of the shot would have been compromised in the PS_m condition, as
329 previously indicated (Abernethy et al., 1990; James & Rees, 2008; Pelz, 2006). However,
330 measures of accuracy (both relative and absolute) did not demonstrate a statistically
331 significant difference between full shots and PS_m, likely due to the increase in club shaft
332 angle being insufficient to demonstrate significance after application of Holm's Sequential
333 Bonferroni correction ($t(12) = -2.312, p = 0.197, d = 0.79$). The main significant findings,
334 with regard to ball motion and shot outcome, were a reduction in ball and club head velocity
335 during the PS_m condition. This had anticipated implications for other variables, namely the
336 statistically significant reductions in flight time and peak height of the shot, given that these

337 depend predominantly on ball velocity, spin rate and launch angle, the final two displaying no
338 significant change between full swing and PS_m ,

339

340 FIGURE 3 NEAR HERE

341

342 Findings in combination suggest an interesting pattern when percentage change from the full
343 swing is considered (figure 3). It is clear that the magnitudes of reduction from full swing to
344 partial swing become less as the location of variables move distally, from a 33.0% reduction
345 in the CoP ellipse to a 1.4% reduction at the wrists. It, therefore, can be proposed that
346 participants prefer a proximal to distal reduction in segment contribution, with greater
347 emphasis on the reduction of the more proximal aspects of the swing such as the hub and
348 trunk motion, as opposed to the more distal aspects, such as lower arms and wrists. This
349 aligns with the PDS findings noted previously (Cheetham et al., 2001; Neal et al., 2007;
350 Tinmark et al., 2010) as reduced foundational movements of the proximal segments
351 automatically decrease the interaction torques available to produce end point velocity, in this
352 instance the velocity of the club head (Putnam, 1993; Hirahima, Kudo, & Ohtsuki, 2003;
353 Hirashima, Kudo, Watarai, & Ohtsuki, 2007). In this way, participants reduce club head
354 velocity at impact by manipulating the larger body segments i.e. the legs and hips, rather than
355 attempting to interfere with the smaller body segments (arms and wrists) that are better suited
356 to fine motor alterations.

357 Initial analysis indicates that the partial swing is significantly different from the full swing
358 and that the alterations that characterise a partial swing are not consistent across all variables.
359 This speaks directly to the rejection of the secondary hypothesis, routed in applied practice
360 (Cowle, 2010; Pelz, 2006), that the partial swing is a scaled version of the full. Following

361 calculation of a theoretical 80% partial shot (PS_t), statistical analysis highlighted a number of
362 interesting findings. The ball speed and club head speed were significantly greater for the
363 measured partial shot (PS_m), furthermore reduction in both variables was not uniform (club
364 head speed: 15.8%, ball speed: 14.9%). This would be indicative of a less efficient transfer of
365 energy from club head to the ball, possibly caused by the increased vertical club shaft angle
366 at ball contact. The direction of this change was unexpected as it has previously been
367 identified that the CoR of a golf ball increases as club head speed reduces (Hill, 2010;
368 Penner, 2002) and so the club head speed would have been expected to be less than the
369 theoretical 80% calculated. Conversely, it appears that greater than 80% of full club head
370 speed is required to propel the ball to 80% distance. This finds support from Peacock et al.
371 (2017), who identified a similar outcome when assessing submaximal kicks in Australian
372 Rules Footballers. However, this finding should be treated cautiously, as the carry distance
373 calculated by the Flightscope software is based on point to point displacement, rather than the
374 full path of the ball flight, and so any fade or draw motion in the trajectory will not have been
375 incorporated. This explanation is supported by a significantly longer measured flight time
376 compared to theoretical (PS_m : 4.55 ± 0.12 s, PS_t : 4.29 ± 0.09 s, $p < 0.001$, $d = 0.70$), as
377 increased flight time with a significantly lower than theoretically calculated peak height
378 would suggest that the ball did not travel in a straight line. It could, therefore, be proposed
379 that golfers alter not only the force applied within the shot, but also the flightpath of the ball,
380 known as strategic shot selection (Langdown, Bridge, & Li, 2012).

381 Departing from the ball flight and outcome variables, the temporal and kinematic differences
382 between the PS_m and PS_t exhibited further interesting variations. The total swing, back swing
383 and down swing durations were all significantly longer for the PS_m condition when compared
384 with the calculated PS_t . Furthermore, this duration of various segments of the swing
385 demonstrated no statistically significant change from the full swing. This is in direct

386 contradiction to previous work (Tinmark et al., 2010) that indicated a shorter downswing
387 duration for full swings, although this could have been a direct result of the lower distances
388 examined previously. However, previous findings were potentially limited, as clubs used for
389 the full swing differed to those for the partial swings, and so recommendations from these
390 findings would be to make swing duration comparisons only within club.

391 Contrasting to the findings between the full and PS_m conditions, the kinematic and kinetic
392 assessment yielded only a single significant difference between PS_m and PS_s. Lead arm
393 angle to the vertical was significantly higher in the PS_m condition, indicating that trunk
394 rotation was higher than predicted. Two of the centre of pressure variables approached
395 significance, CoP ellipse ($p = 0.084$) and CoPx ($p = 0.064$), with the former reducing much
396 more than expected (33.0%) from the full swing. These findings indicate that as initially
397 suggested, golfers moderate a range of biomechanical variables of their full swing during the
398 completion of partial swing shots. However, the percentage reduction in contribution across
399 variables is not uniform; therefore, no claim of the partial swing being a scaled version of the
400 full swing can be made and the second hypothesis must be rejected.

401 **Limitations**

402 This work is not without its limitations, as the golf swing is a 3D multi-planar movement,
403 therefore, the use of a single camera in this study reduces the accuracy of the joint angle
404 measures, due to out-of-plane movements. However, the exploratory nature of the study
405 served to, beyond the central aim of the study, determine if further study, including 3D
406 analysis, is warranted. Furthermore, and more importantly, the two dimensional assessment,
407 used widely by golf coaches, provides a far more applied approach and applicability of these
408 measures.

409 The protocol could also have been identified as a limiting factor, however the nature of the
410 investigation, trying to determine if there are specific techniques, made the order of testing
411 and the use of participant specific pitching wedges fundamental to the process. As the
412 proportional distances under investigation required full swing distance to be measured first,
413 before proportional distances could be calculated. While the use of participant specific
414 pitching wedges stopped alteration of technique due to change in equipment and was
415 maintained between testing conditions. Therefore, any alterations would be consistent across
416 conditions and unlikely to cause biomechanical changes associated with the partial shot.

417

418 **Conclusion**

419 Participants demonstrated that performance of partial shots required reduction in centre of
420 pressure motion, lateral shift, trunk rotation and stance width, however the magnitude of
421 these reductions were not uniform across all measured variables. The main hypothesis that
422 partial shots are different from full shots can be accepted. However, the secondary hypothesis
423 that partial shots are scaled full shots, was not supported. Indeed, when performing partial
424 shots participants did not use the same technique that they use for full shots; suggesting that
425 golf coaches may consider dedicating time to training the partial shot as a separate golf skill
426 although, veracity of this proposition would benefit from assessment of partial shots using
427 three-dimensional kinematics. Further, golfers favoured the reduction of movements of the
428 larger body segments i.e. the legs and hips, over the reduction of smaller body segments such
429 as the arms and the wrists to reduce club head speed at impact and therefore shot carry
430 distance. In this way, the swing maintains a proximal to distal pattern, being initiated by
431 larger reductions in proximal segment contribution, causing a diminishing reduction in the
432 more distal measures, although these were not proportional to the initial reduction. Finally,

433 the accuracy of partial shots is not changed when compared to full swing shots; however, the
434 variability of the measures indicates that golfers across the spectrum of golf handicaps can
435 have issues with the performance of partial shots. Future work should attempt to identify
436 optimal movement patterns that golfers can employ to improve relative accuracy in terms of
437 partial shots and kinetic and kinematic differences between golfers with low and high PEI
438 values for partial shots.
