# Abstract

Multi-band orthogonal frequency-division multiplexing (MB-OFDM) is an important transmission technique for ultra-wideband (UWB) communication. One of the challenges for practical realization of these UWB MB-OFDM systems is the estimation of the channel. In UWB MB-OFDM, the channel can be modelled as sparse, and channel estimation (CE) based on compressed sensing (CS) can be used. However, the existing techniques all require prior knowledge of some channel parameters, which are not known in practice, e.g. the dictionary size, corresponding to the effective duration of the channel impulse response (CIR), and the sparsity of the CIR. Therefore, in this paper, we propose a CSbased channel parameter estimation method to estimate the dictionary size and the sparsity based on a pilot preamble of which the duration is shorter than the total duration of the CIR. Using the resulting parameter estimates, we reconstruct the CIR with the compressive sampling matching pursuit (CoSaMP) method. We show that the proposed algorithm is able to accurately estimate the sparsity and the dictionary size, and can effectively reconstruct the CIR for channels that are either based on a mathematical model or real, measured channels. Moreover, as the algorithm has acceptable complexity, the proposed

method is suitable for practical use.

Keywords: Multi-band orthogonal frequency-division multiplexing (MB-OFDM), ultra-wideband (UWB), parameter estimation, compressive sensing, channel impulse response

# 1. Introduction

Multi-band orthogonal frequency-division multiplexing (MB-OFDM) is a technique that is considered as one of the most promising techniques for ultra wideband (UWB) transmission, thanks to its ability to mitigate the effects of multipath fading and interference, and to achieve a high spectral efficiency at a relatively low cost [1, 2]. One of the issues that needs to be solved in practical UWB MB-OFDM systems comprises the estimation of the channel. To meet this challenge, UWB MB-OFDM adopts a frame-based transmission [3], where

pilot sequences are included in the frame preamble for channel estimation (CE).

<sup>10</sup> However, as the channel impulse response (CIR) in UWB MB-OFDM is very long, long pilot preambles must be used to accurately estimate the channel. As long pilot preambles limit the data throughput, often the pilot preamble is shortened. Because of this shorter preamble, traditional channel estimators, such as least-squares (LS), maximum-likelihood (ML) and minimum mean-squared error (MMSE) estimators [4, 5, 6, 7], fail to accurately estimate the CIR.

In indoor environments, typically the propagation environment is complex, and results in many reflections. At the same time, the resolution of the ultrawideband signal is very high, implying the system can identify many of the multipath components. As a consequence, the channel impulse response will <sup>20</sup> typically be very long. However, measurements of the UWB indoor channel show that the multipath components are strongly clustered, implying the channel impulse response, although being widely dispersed in time, only contains a limited number of non-zero contributions, i.e. the channel can be modelled as sparse. For example, [8, 9] demonstrate that indoor channel models consid-<sup>25</sup> ered for the IEEE 802.15.4a standard [10] are sparse. Moreover, this sparsity is shown to be enlarged when the signal resolution increases [9]. Also the different channel models for the IEEE 802.15.3a standard [11] can be described with a limited number of non-zero channel taps. Besides the theoretical channel models considered in the literature, we also performed a measurement campaign in

- <sup>30</sup> a laboratory environment, and show in this paper that the resulting channel is sparse. Consequently, we can use compressive sensing (CS) methods [12, 13] to reconstruct the CIR and achieve channel estimation. Recently, several CE algorithms based on CS for UWB communication have been developed [8, 14, 15, 16]. In [8], the applicability of CS for UWB channel estimation is investigated, and
- the authors employ standard Matching Pursuit (MP) algorithms for CS, such as subspace pursuit (SP) [17], orthogonal matching pursuit (OMP) [18] and compressive sampling matching pursuit (CoSaMP) [19], to accurately reconstruct the CIR. In [14], the authors propose four practical dictionaries to increase the sparsity of UWB signals, so that the UWB signals can be reconstructed more
- <sup>40</sup> efficiently. In [15], another CS technique, i.e. the Bayesian CS (BCS) algorithm [20], is employed to reconstruct UWB signals and obtain CE. Although the BCS algorithm achieves a better performance than the MP algorithms, it requires intensive computations, raising a barrier for practical implementation. In [16], a CS dictionary, called eigen-dictionary, is proposed, exploiting the sta-
- tistical sparsity of UWB signals where the channel structure exhibits several clusters of significant channel coefficients. Based on this structure, two novel BCS algorithms are proposed to efficiently reconstruct UWB CIR. Common to all these CS-based CE algorithms is that they require prior knowledge of the parameters of the underlying CIR model, which is not available in prac-
- <sup>50</sup> tice. Without the knowledge of these parameters, the CIR can not be estimated accurately, deteriorating the performance of UWB MB-OFDM systems.

In this paper, we extend the CoSaMP algorithm from [19], which combines low complexity and good CE performance, to autonomously estimate the required channel parameters. The CoSaMP algorithm requires the knowledge about the dictionary size, of which the optimal value is strongly correlated to the effective CIR duration, i.e. the duration of the part of the CIR containing

the dominant channel components, and the sparsity of the channel, i.e. the number of non-zero channel taps. Optimally, the dictionary size and sparsity must be estimated jointly. Several classical algorithms exist to achieve this joint

- estimation, e.g. the simplex algorithm [21]. However, the computational burden of these algorithms is very high, and therefore limit the applicability of these joint estimators. Therefore, as main novelty, we propose in this paper an algorithm that has low complexity compared to the above-mentioned joint estimation algorithm. To this end, we first show that, although the dictionary
- size and sparsity are correlated, the optimal value of the dictionary size becomes essentially independent of the sparsity if the sparsity is sufficiently large. Based on this observation, we propose a two-step approach, where in the first phase, the optimal dictionary size is estimated, while in the second phase, the optimal value of the sparsity is obtained. In both phases, the algorithm adap-
- tively searches for the optimal value of the parameter, using the pilot sequence included in the preamble. We show that the proposed adaptive CS-based parameter estimation algorithm not only can be applied to channels simulated based on a mathematical model, but also is able to exactly reconstruct the CIR measured in realistic scenarios. Although the proposed algorithm is sub-optimal
- <sup>75</sup> in the sense that the mean-squared error of the resulting channel estimation is slightly higher than for the case where the simplex method is used, the resulting complexity is much smaller than with the simplex method, e.g. for short pilot preambles, the complexity of the proposed algorithm is 10 times lower than with the simplex method, and the difference in complexity increases when the length
- of the preamble increases. Further, we compare the performance of the proposed algorithm with state-of-the-art algorithms, and demonstrate that the proposed algorithm performs well, even if the pilot preamble is considerably shortened.

The rest of the paper is organized as follows. In Section 2, we introduce the channel model used for MB-OFDM systems and describe the measurement setup <sup>85</sup> used to obtain the sparse measured channel. In Section 3, we briefly explain how CS is applied to the estimation of sparse channels, and we discuss the influence of the dictionary size and sparsity on channel reconstruction. The algorithm to

estimate the dictionary size and the sparsity is introduced in Section 4. Further, we evaluate the complexity of the proposed algorithm in this section. In Section

<sup>90</sup> 5, we evaluate the performance of the proposed algorithm and compare its performance with that of state-of-the-art algorithms. Finally, the conclusions are given in Section 6.

# 2. Sparse Channel

In this section, first we briefly introduce the CM for the IEEE 802.15.3a standard [11], suitable for UWB MB-OFDM systems that was used to generate the simulated channels, and then we describe the measurement setup that was used to obtain sparse measured channels to test our algorithm in realistic scenarios.

#### 2.1. Channel Model

The channel impulse response considered for the IEEE 802.15.3a standard [11] consists of a tapped-delay line model containing L clusters of K multipath components:

$$h(t) = X \sum_{l=1}^{L} \sum_{k=1}^{K} \alpha_{k,l} \delta(t - T_l - \tau_{k,l}), \qquad (1)$$

where  $\alpha_{k,l}$  are the multipath gain coefficients,  $T_l$  is the delay of the *l*-th cluster,  $\tau_{k,l}$  is the delay of the *k*-th multipath component relative to the *l*-th cluster arrival time  $T_l$  and the prefactor X corresponds to the log-normal shadowing. The delays  $T_l$  and  $\tau_{k,l}$  follow an exponential distribution with cluster arrival rate  $\Lambda$  and ray arrival rate  $\lambda$ , respectively:

$$P(T_l|T_{l-1}) = \Lambda \exp[-\Lambda(T_l - T_{l-1})]$$
<sup>(2)</sup>

$$P(\tau_{k,l}|\tau_{k-1,l}) = \lambda \exp[-\lambda(\tau_{k,l} - \tau_{k-1,l})].$$
(3)

We select  $\tau_{0,l} = 0$ . The multipath gain coefficient  $\alpha_{k,l}$  in (1) can be decomposed as follows:

$$\alpha_{k,l} = p_{k,l} \zeta_l \beta_{k,l},\tag{4}$$

Parameters	CM1	CM2	CM3	CM4
Λ	0.0233	0.4	0.0667	0.0667
$\lambda$	2.5	0.5	2.1	2.1
Г	7.1	5.5	14.00	24.00
$\gamma$	4.3	6.7	7.9	12
$\sigma_1 (dB)$	3.3941	3.3941	3.3941	3.3941
$\sigma_2 (dB)$	3.3941	3.3941	3.3941	3.3941
$\sigma_x (\mathrm{dB})$	3	3	3	3

Table 1: Parameters of the Four Channel Models (CMs) from [11]

where  $p_{k,l}$  equiprobably takes the values  $\pm 1$  to account for signal inversions due to reflections,  $\zeta_l$  represents the fading associated with the *l*-th cluster, and  $\beta_{k,l}$ corresponds to the fading associated with the *k*-th ray of the *l*-th cluster. This fading coefficient  $\zeta_l \beta_{k,l}$  follows a log-normal distribution:

$$20\log_{10}(\zeta_l\beta_{k,l}) \sim N(\mu_{k,l}, \sigma_1^2 + \sigma_2^2), \tag{5}$$

where  $\sigma_1$  is the standard deviation from the cluster log-normal fading term  $\zeta_l$  and  $\sigma_2$  is the standard deviation from the ray log-normal fading term  $\beta_{k,l}$ . Further, defining the cluster decay factor  $\Gamma$  and ray decay factor  $\gamma$ , the mean  $\mu_{k,l}$  can be written as:

$$\mu_{k,l} = \frac{10\ln(\Omega_0 - 10T_l/\Gamma - 10\tau_{k,l}/\gamma)}{\ln(10)} - \frac{(\sigma_1^2 + \sigma_2^2)\ln(10)}{20},\tag{6}$$

where  $\Omega_0$  is the average energy of the first path of the first cluster. Finally, the log-normal shadowing factor X of the total multipath power from (1) has the distribution:

$$20\log_{10}(X) \sim N(0, \sigma_x^2),\tag{7}$$

where  $\sigma_x$  is the standard deviation of the log-normal shadowing of the total multipath power.

The parameters of the four channel models presented in [11] are listed in Table I. These four models consider communication among UWB devices located within a range of less than 10 m. Specifically, CM1 and CM2 model

- the line-of-sight (LOS) and non-LOS (NLOS) channel environments, for ranges smaller than 4 m. For larger ranges, the NLOS models CM3 and CM4 are used, with emphasis on the strong delay dispersion  $\Gamma$  from CM4 [2]. In this paper, we consider discrete-time channel models derived from the above continuoustime models. Following the IEEE 802.15.3a standard [11], the discrete-time
- CIR  $\mathbf{h} = [h(0), h(1), \dots, h(L_{taps} 1)]$  can be obtained by oversampling the continuous-time CIR h(t), followed by an anti-aliasing filtering, down conversion and decimation. As an example, we show in Figure 1(a) the discrete-time domain CIR for a realization of CM1 with tap spacing t = 1/6 ns, together with a close-up of the 180 first taps. As can be observed, the number of dominant
- taps, having a non-negligible amplitude, is quite small, i.e. most taps have a (close to) zero amplitude. Further, the dominant taps are confined in the first part of the CIR, i.e. the tail contains only close-to-zero taps. Hence, the effective duration of the CIR, corresponding to this dominant, first part of the CIR, is much smaller than the total duration of the CIR. Similar results are obtained with the other three channel models. Therefore, the channel can be considered as sparse in the time domain, indicating that compressive sensing methods to

#### 2.2. Measured Channel

reconstruct the CIR can be employed.

- The experiments to measure the sparse channels were carried out in a laboratory of Ghent University in Belgium. The laboratory, shown in Figure 2, roughly has an L-shaped form. The long side (Figure 2(b)) approximately has length 16 m and width 5 m, while the small side (Figure 2(c)) approximately has length 8.5 m and width 5 m. We selected one transmitter position and 15 receiver positions (see Figure 2(a)). Of these positions, 8 positions (i.e.  $R_1$ - $R_8$ ) were considered as light-of-sight positions, where a free space path exists between transmitter and receiver, 4 positions (i.e.  $R_9$ - $R_{12}$ ) were regarded as obstructed-LoS (OLoS), where the signals undergo a reflection and/or a diffraction, and 3
  - positions (i.e.  $R_{13}$ - $R_{15}$ ) are non-LoS (NLoS) scenarios, as a plasterboard wall is present between transmitter and receiver.

Figure 1: Sparse channel: (a) an example channel realization of CM1 with tap spacing of t = 1/6 ns. (b) measured channel between transmitter and  $R_1$  receiver with tap spacing of t = 4/5 ns

(a)

(b)

(c)

Figure 2: Measurement environment: (a) Schematic representation, (b) Long side of laboratory, (c) Small side of laboratory.

Figure 3: UWB antenna with an automated positioning system

- At both the transmitter and receiver sides, omnidirectional UWB antennas of type electrometrics EM-6865 [22] were placed 1.5m above ground level, as shown in Figure 3. To measure the complex gain for each combination of transmit and receive pair, we used a Rohde & Schwarz ZNB8 vector network analyzer (VNA). The VNA calibration included the feeder cables to eliminate
- their effect on the measurement data. We created at both sides a  $[4 \times 4]$  virtual antenna array by using an automated positioning systems. At each of the receiver positions, channel measurements were performed, and the channel was obtained by averaging these measurement data. An example of the resulting discrete-time CIR for receiver position  $R_6$  is shown in Figure 1(b), for a tap spacing t = 4/5 ns. As can be observed, the CIR contains only a few dominant taps, i.e. most taps have a near-zero or zero amplitude, implying the channel can indeed be considered as sparse. Similar results were obtained for the other

#### 3. Compressive Sensing Based Channel Reconstruction Scheme

receiver positions.

In this section, we discuss the reconstruction of the CIR using CS methods, and analyze the effect of two parameters, i.e. the dictionary size and sparsity of CIR, on the CE. Let us first revisit the principle of CS. Let us assume we want to reconstruct a sparse signal  $\varphi$  from an observation  $\rho$ 

$$\boldsymbol{\rho} = \boldsymbol{\Upsilon} \boldsymbol{\varphi} + \mathbf{n}_0 \tag{8}$$

<sup>150</sup> where  $\mathbf{n}_0$  is additive noise and  $\boldsymbol{\Upsilon}$  is called the measurement matrix. To obtain accurate estimates of  $\boldsymbol{\varphi}$ , the measurement matrix  $\boldsymbol{\Upsilon}$  should satisfy the restricted isometry property (RIP), i.e. it should be nearly orthonormal when operating on the sparse vector  $\boldsymbol{\varphi}$ . In following subsections, we derive the observation model, discuss the RIP of the measurement matrix and the accuracy of the reconstructed sparse channel, and evaluate the effect of the system parameters on the performance.

# 3.1. CS-Based Channel Reconstruction

Following [3], we consider a frame-based UWB MB-OFDM transmission system, in which several known OFDM symbols are placed in a preamble for channel estimation and synchronization, followed by a payload frame containing the OFDM data symbols. During the transmission of the payload frame, the IEEE 802.15.3a standard [11] assumes that the channel remains unchanged.

To estimate the channel impulse response, we consider a preamble, where the frequency domain pilots  $\mathbf{X} = [X(0), X(1), \dots, X(N-1)]$  are selected randomly, and the resulting UWB MB-OFDM symbol is repeated  $N_p$  times. We assume a long cyclic prefix is preceding the preamble, to avoid distortion of the preamble due to transition effects at the start of the preamble, and no guard interval is added between the pilot OFDM symbols. Hence, the time-domain samples of each of the  $N_p$  pilot OFDM symbols can be written as:

$$x(k+iN) = x(k) = \frac{1}{\sqrt{N}} \sum_{n=0}^{N-1} e^{j2\pi\frac{kn}{N}} X(n)$$
(9)

with k = 0, ..., N - 1 and  $i = 0, ..., N_p - 1$ . After transmitting the preamble over the channel with impulse response **h**, we obtain the the received sequence:

$$y(m) = \sum_{i=0}^{N_p - 1} \sum_{k=0}^{N-1} x(k)h(m - k - iN) + w(m)$$
(10)

where w(m) is zero-mean additive white Gaussian noise with variance  $N_0$ , and h(l) = 0 for l < 0 or  $l \ge L_{taps}$ , with  $L_{taps}$  the number of taps within the total CIR duration. In this paper, we restrict our observation to the  $NN_p$  samples from the pilot preamble to avoid interference with the subsequent data symbols. We assume this preamble is shorter than the total CIR length, i.e.  $NN_p < L_{taps}$ . However, in order to allow accurate reconstruction of the channel, the preamble must be long enough to capture the contributions of the majority of the dominant components of the channel. As a result, the observation vector (10) can be rewritten as

$$\mathbf{y} = \mathbf{\Phi}\mathbf{h} + \mathbf{w},\tag{11}$$

where  $\mathbf{h} = [h(0), h(1), \cdots, h(L_{taps} - 1)]^T$ , and the elements of the  $NN_p \times L_{taps}$ measurement matrix  $\mathbf{\Phi}^1$ , which are obtained by substituting (9) into (10), are given as

$$\Phi_{m,m'} = \frac{1}{\sqrt{N}} \sum_{n=0}^{N-1} X_{\lfloor \frac{m-m'}{N} \rfloor}(n) e^{j2\pi \frac{n(m-m')}{N}}$$
(12)

with  $\lfloor x \rfloor$  the floor of x. To reconstruct the channel, we define a  $L_{taps} \times M_{taps}$ dictionary  $\Psi$ , where  $M_{taps} < L_{taps}$  corresponds to an interval containing all dominant channel components. If the dictionary size  $M_{taps}$  is too small, not all dominant components will be recovered, but if it is selected too large, noisy samples will affect the ability to properly reconstruct the channel and at the same time the complexity of the algorithm will increase. Hence, the optimal value of  $M_{taps}$  must be determined by the receiver. We assume  $M_{taps} \geq NN_p$ and  $\Psi = [\mathbf{I} \mathbf{0}]^T$ , where  $\mathbf{I}$  is the  $M_{taps} \times M_{taps}$  identity matrix. Hence, we restrict

<sup>&</sup>lt;sup>1</sup>As can be observed in (12), the measurement matrix  $\mathbf{\Phi}$  is a Hermitian matrix containing the pilots **X** and components from the Fourier kernel. Hence, the measurement matrix can in general not be written as a partial Fourier matrix. While it is shown in the literature that, with exponentially high probability, the partial Fourier matrix satisfies the RIP, assuming the number of measurements is nearly linear in the sparsity level, the RIP characteristics of the matrix  $\mathbf{\Phi}$  will not be straightforward to show, as in general, this proof is a strongly NP-hard problem [23, 24]. Although we are not able to prove that the matrix  $\mathbf{\Phi}$  is RIP, we will demonstrate in the numerical results section that this measurement matrix can be used to accurately estimate the CIR.

our attention to the first  $M_{taps}$  taps of the  $L_{taps}$  taps of the CIR, which is a reasonable assumption as the tail of the CIR in the considered channel models contain only close-to-zero taps. To reconstruct the channel, we write the CIR **h** as a linear combination of  $M_{taps} \ll L_{taps}$  basis vectors from the dictionary  $\Psi$ :

$$\mathbf{h} = \boldsymbol{\Psi}\boldsymbol{\xi} \tag{13}$$

where  $\boldsymbol{\xi} = [\xi_1, \xi_2, \cdots, \xi_{M_{taps}}]^T$  is a  $M_{taps} \times 1$  vector. Because the channel is sparse, only  $K_s$  of the  $M_{taps}$  components of  $\boldsymbol{\xi}$  will have non-zero value. Therefore, we can rewrite  $\boldsymbol{\xi}$  as

$$\boldsymbol{\xi} = \mathbf{B}\boldsymbol{\theta} \tag{14}$$

where  $\boldsymbol{\theta} = [\theta_1, \theta_2, \dots, \theta_{K_s}]^T$  is the  $K_s \times 1$  vector of parameters to be estimated, while the selection matrix **B** determines the positions of the  $K_s$  non-zero channel taps, i.e.

$$B_{i,j} = \begin{cases} 1 & \text{if } i = v(j) \\ 0 & \text{otherwise} \end{cases}$$
(15)

where  $\mathbf{v} = [v(1), v(2), \dots, v(K_s)]$  is the  $K_s \times 1$  vector with the positions of the  $K_s$  dominant taps. Substituting (14) into (13), we obtain:

$$\mathbf{h} = \mathbf{\Psi} \mathbf{B} \boldsymbol{\theta} \tag{16}$$

Note that  $\boldsymbol{\theta}$  can be estimated using standard channel estimation techniques such as LS or MMSE, however, the main drawback of these approaches is that if the CIR length  $L_{taps}$  exceeds the preamble length  $NN_p$ , as in the problem at hand, the accuracy of the channel estimation is degraded. To overcome this issue, CS can be used. It is shown in [25, 26] that the channel estimation accuracy of CS outperforms that of LS and MMSE methods when  $L_{taps} > NN_p$ . Moreover, the complexity of the CS method is lower than that of the MMSE approach. Hence, provided that the measurement matrix  $\boldsymbol{\Phi}$  is incoherent with the dictionary  $\boldsymbol{\Psi}$ (which is the case in the problem at hand), the CIR can be estimated with high reliability through solving the following well-known convex  $l_1$ -norm optimization problem:

$$\hat{\boldsymbol{\xi}} = \min \|\boldsymbol{\xi}\|_1 \text{ s.t. } \mathbf{y} = \boldsymbol{\Phi} \boldsymbol{\Psi} \boldsymbol{\xi}.$$
 (17)

This convex optimization problem can be solved using linear programming techniques like subspace pursuit (SP), orthogonal match pursuit (OMP) and compressive sampling matching pursuit (CoSaMP). Let us take a closer look at the performance of the CS estimation. Assume the CIR has non-zero components at positions  $\mathbf{v}$ . The CS algorithm first has to estimate the positions  $\hat{\mathbf{v}} = [\hat{v}(1), \dots, \hat{v}(K_s)]$  of the dominant channel taps, and then it needs to estimate the values  $\hat{\mathbf{h}}_{\hat{\mathbf{v}}}$  of the dominating channel taps. To this end, we define, for given  $M_{taps}$  and  $K_s$ , the matrix  $\mathbf{A} = \boldsymbol{\Phi} \boldsymbol{\Psi} = [\boldsymbol{a}_1, \boldsymbol{a}_2, \dots, \boldsymbol{a}_{M_{taps}}]$ , and the submatrix  $\mathbf{A}_{\hat{\mathbf{v}}} = [\boldsymbol{a}_{\hat{v}(1)}, \dots, \boldsymbol{a}_{\hat{v}(K_s)}]$  of the matrix  $\mathbf{A}$ . The LS estimate of the dominant channel taps at positions  $\hat{\mathbf{v}}$  is given by

$$\hat{\mathbf{h}}_{\hat{\mathbf{v}}} = \boldsymbol{\Psi} (\mathbf{A}_{\hat{\mathbf{v}}}^{H} \mathbf{A}_{\hat{\mathbf{v}}})^{-1} \mathbf{A}_{\hat{\mathbf{v}}}^{H} \mathbf{y}$$
(18)

We assume that, at positions different from  $\hat{\mathbf{v}}$ , the reconstructed channel taps are set to zero, i.e.  $\hat{\mathbf{h}} = [0, \dots, 0, \hat{h}_{\hat{\mathbf{v}}}(\hat{v}(1)), 0, \dots, 0, \hat{h}_{\hat{\mathbf{v}}}(\hat{v}(K_s)), 0, \dots, 0]^T$ . Taking this into account, the MSE of  $\mathbf{h}$ , i.e.  $MSE = E[\|(\hat{\mathbf{h}} - \mathbf{h})\|_2^2]$  yields

$$MSE = \mathbf{h}_{\hat{\mathbf{v}}}^{H} (\mathbf{C} \boldsymbol{\Phi} - \mathbf{I})^{H} (\mathbf{C} \boldsymbol{\Phi} - \mathbf{I}) \mathbf{h}_{\hat{\mathbf{v}}} + \mathbf{h}_{\mathbf{v} \setminus \hat{\mathbf{v}}}^{H} \mathbf{h}_{\mathbf{v} \setminus \hat{\mathbf{v}}} + N_{0} trace(\mathbf{C}^{H} \mathbf{C})$$
(19)

where the first and third term originate from the contribution of the reconstructed channel at the positions  $\hat{\mathbf{v}}$ , and the second contribution from the nonzero channel taps that were not selected in the reconstruction, i.e. at positions  $\mathbf{v} \setminus \hat{\mathbf{v}}$ . In (19),  $\mathbf{C} = \mathbf{\Psi} (\mathbf{A}_{\hat{\mathbf{v}}}^H \mathbf{A}_{\hat{\mathbf{v}}})^{-1} \mathbf{A}_{\hat{\mathbf{v}}}^H$  and  $\mathbf{h}_{\hat{\mathbf{v}}} = [h(\hat{v}(1)), \cdots, h(\hat{v}(K_s))]^T$ . Defining  $\mathbf{e} = (\mathbf{C} \mathbf{\Phi} - \mathbf{I}) \mathbf{h}_{\hat{\mathbf{v}}}$ , the first term of (19) can be rewritten as

$$\mathbf{e}^{H}\mathbf{e} = \mathbf{e}_{\mathbf{v}\cap\hat{\mathbf{v}}}^{H}\mathbf{e}_{\mathbf{v}\cap\hat{\mathbf{v}}} + \mathbf{e}_{\hat{\mathbf{v}}\setminus\mathbf{v}}^{H}\mathbf{e}_{\hat{\mathbf{v}}\setminus\mathbf{v}}$$
(20)

i.e., the contribution of the positions that are both included in  $\mathbf{v}$  and  $\hat{\mathbf{v}}$  – or the dominant channel taps that were correctly identified with the CS algorithm – and the contribution from zero channel taps that were incorrectly identified as dominant channel taps ( $\hat{\mathbf{v}} \setminus \mathbf{v}$ ). Substituting (20) in (19), the MSE of  $\mathbf{h}$  can be decomposed as

$$MSE = e_h + e_n \tag{21}$$

where the first term  $e_h = \mathbf{e}_{\mathbf{v} \cap \hat{\mathbf{v}}}^H \mathbf{e}_{\mathbf{v} \cap \hat{\mathbf{v}}} + \mathbf{h}_{\mathbf{v} \setminus \hat{\mathbf{v}}}^H \mathbf{h}_{\mathbf{v} \setminus \hat{\mathbf{v}}}$  contains a channel-dependent term, originating from the estimation errors in the dominant components due to

- the CS reconstruction error, and the second term  $e_n = \mathbf{e}_{\hat{\mathbf{v}} \setminus \mathbf{v}}^H \mathbf{e}_{\hat{\mathbf{v}} \setminus \mathbf{v}} + N_0 trace(\mathbf{C}^H \mathbf{C})$ contains the contributions from the noise and the estimation errors at time instants that do not contain dominant channel components, but that are captured by the CS algorithm due to noise. Both terms depend on the selection of the parameters  $M_{taps}$  and  $K_s$  through the matrix  $\mathbf{C}$ . Preferably, the mismatch re-
- <sup>170</sup> lated to the compressive sensing must be made as small as possible. To obtain an accurate reconstruction of the channel, we need to select out of the  $M_{taps}$ channel components, the  $K_s$  taps with the largest energy, i.e. determine the positions of the non-zeros components of **B**, and estimate the values of  $\theta$  for the selected  $M_{taps}$  and  $K_s$ . The best performance of channel estimation is obtained when  $M_{taps}$  and  $K_s$  are matched to the effective duration and the dominant

#### taps of the channel.

# 3.2. Effect of the Dictionary Size and Sparsity

To solve the  $l_1$ -norm optimization problem discussed in the previous section, we will employ the CoSaMP algorithm [19], as it combines good estimation accuracy with low complexity. However, similarly as for the LS and MMMSE approaches, this algorithm requires the knowledge of the size  $M_{taps}$  of the dictionary, which must be matched to the effective duration of the channel, as well as the sparsity  $K_s$ , to be able to reconstruct the channel. In this section, we first theoretically analyze the effect of the dictionary size  $M_{taps}$  and sparsity  $K_s$ , as an improper choice of  $M_{taps}$  or  $K_s$  can strongly affect the channel estimation performance and thus will influence the bit error rate (BER) performance. Then, some simulations are conducted to verify our analysis.

First, we consider the effect of the dictionary size  $M_{taps}$  on the performance. On the one hand, if the dictionary size is too small, the search window will not be able to 'catch' all significant channel taps, causing a degradation of the channel estimation performance. On the other hand, if we select the dictionary size too large, not only the complexity of the algorithm will increase, but also the estimation process will include samples having near-zero amplitude, implying noise will start to play a larger role. As a result, increasing the dictionary size will have a detrimental effect on both the performance and the complexity.

195

Similarly, if the sparsity  $K_s$  is too small, not enough significant signal components will be uncovered in the channel reconstruction process. As part of the channel taps with non-negligible energy will not be included in this way, the BER performance will be degraded. However, if the sparsity is too large, the

<sup>200</sup> algorithm will start to include signal components with close-to-zero amplitude, indicating that the channel estimation error will increase due to the relatively large effect of the noise on these close-to-zero channel components. Moreover, increasing the sparsity will augment the computational complexity of the algorithm.

- The dependency of the MSE on  $M_{taps}$  and  $K_s$  is illustrated in Figure 4, in which a pilot preamble with N = 128 and  $N_p = 1$  is transmitted to reconstruct the CIR for a signal-to-noise ratio (SNR)  $E_b/N_o$  of 30dB. The results are averaged over 500 random CM1-based channel realizations with  $M_{taps,opt} =$ 180 effective taps and  $K_{s,opt} = 30$  dominant taps. As explained, the MSE
- will first reduce when  $M_{taps}$  is increased, and slightly increases again when  $M_{taps} > M_{taps,opt}$ . Decomposing the MSE into the channel-dependent term (first term of (21), Term1 in Figure 4) and the noise-dependent term (second term of (21), Term 2 in Figure 4), we observe in Figure 4(a) that both the channel-dependent term and noise-dependent term grow when  $M_{taps}$  reduces,
- for  $M_{taps} < M_{taps,opt}$ . When  $M_{taps}$  reduces, dominant taps will start to fall outside the interval [0,  $M_{taps}$ ], implying those taps cannot be reconstructed by the algorithm, so the mismatch between the true and reconstructed channel increases, i.e. the channel-dependent term grows. At the same time, as not enough dominant taps will be present in the interval [0,  $M_{taps}$ ], the algorithm
- will start to reconstruct noise-dominated taps, implying the noise-dependent term also increases. This latter effect is larger when  $K_s$  is larger, as the algorithm tries to reconstruct more close-to-zero taps. When  $M_{taps} > M_{taps,opt}$ , the increase of the MSE as function of  $M_{taps}$  is mainly due to the increase of the

noise-dependent term, as the channel-dependent term is quasi-independent of  $M_{taps}$ , because the dominant taps are mainly contained in the first part of the

interval, i.e. in  $[0, M_{taps,opt}]$ .

225

230

Further, we stated that when  $K_s$  is too small, some dominant channel taps will not be reconstructed, while when  $K_s$  is too large, noise will start to play a larger role. This is observed in Figure 4(b). When  $K_s < K_{s,opt}$ , the MSE is dominated by the channel-dependent term, while this term becomes independent of  $K_s$  when  $K_s > K_{s,opt}$ , i.e. all dominant taps will be reconstructed. On the other hand, the noise-dependent term grows with  $K_s$ , as more noise-dominated taps will be taken into account.

#### 4. Parameter Estimation

The dictionary size  $M_{taps}$  and the sparsity  $K_s$  both affect the precision of channel estimation. Hence, knowledge about the parameters  $M_{taps}$  and  $K_s$  is indispensable. However, in realistic scenarios, prior information about these two parameters is often not available, so we will estimate these parameters based on the preamble. In this section, we first discuss the simplex method to jointly estimate  $M_{taps}$  and  $K_s$ . As the complexity of the simplex method is very high, we then propose a simpler, sub-optimal method to estimate  $M_{taps}$  and  $K_s$ . We show that the performance degradation of our method compared to the simplex method is small. Finally, we compare the complexity of the proposed method with that of the simplex method and the MMSE estimator.

# 245 4.1. Joint estimation

To jointly optimize  $M_{taps}$  and  $K_s$ , we need to solve the following optimization problem:

$$< M_{taps,opt}, K_{s,opt} >= \underset{M_{taps}, K_s}{\operatorname{argmin}} \| \boldsymbol{\Phi} \boldsymbol{\Psi} \hat{\boldsymbol{\xi}} - \mathbf{y} \|_2$$
s.t.  $\mathbf{y} = \boldsymbol{\Phi} \boldsymbol{\Psi} \boldsymbol{\xi}.$ 
(22)

which can be solved with the well-known simplex algorithm. This method can accurately estimate  $M_{taps}$  and  $K_s$ , as will be illustrated in Section 5. Although

Figure 4: MSE and its constituent terms as function of (a)  $M_{taps}$  for different  $K_s$  and (b)  $K_s$  for different  $M_{taps}$ .

it is stated in [27] that the simplex algorithm in general needs polynomial time, in the worst case, the simplex algorithm applied to the problem at hand has com-

plexity  $\mathcal{O}\{M_{taps,opt}^2 K_{s,opt} \log_2(M_{taps,opt}) \log_2(K_{s,opt})\}$ . As this complexity is still very high, the simplex algorithm is unsuitable for practical implementation in UWB MB-OFDM systems.

#### 4.2. Adaptive CE Method

As jointly optimizing  $K_s$  and  $M_{taps}$  is a challenging task, we first take a look at the effect of both parameters on the BER performance, to be able to reduce the computational burden of the optimization. In Figure 5, we show the BER of the pilot sequence as function of the dictionary size  $M_{taps}$  and sparsity  $K_s$ , with N = 128 and  $N_p = 1$ . Comparing Figs. 4(a) and 5(a), we observe that the minimum of the BER coincides with the minimum of the MSE, i.e. at

 $M_{taps,opt} = 180$ , if  $K_s$  is sufficiently large. This optimal value of  $M_{taps}$  for the BER does neither depend on the sparsity  $K_s$  nor on the SNR  $E_b/N_o$ . On the other hand, from Figure 5(b), where the BER is shown as function of the sparsity  $K_s$ , we find that when  $M_{taps}$  is smaller than the optimum  $M_{taps,opt} = 180$  found in Figure 5(a), i.e. for  $M_{taps} = 140$ , the BER is largely independent of the value

of  $K_s$ , while when  $M_{taps} \ge M_{taps,opt}$ , the BER shows a clear minimum at an intermediate value of  $K_s$ , i.e. at  $K_{s,opt} = 30$ . As the optimal value of  $M_{taps}$ is not prior known at the receiver, this implies that we need to first estimate the dictionary size, to avoid that no optimum value for the sparsity can be found. Similar results were obtained for the other channel models. Hence, in the following, we propose an estimation algorithm for  $M_{taps}$  and  $K_s$ , where in

the first phase, the optimal value of  $M_{taps}$  is determined, and in the second phase, the optimal value of  $K_s$ . In both phases, we employ a dynamic search algorithm.

#### 4.2.1. Algorithm 1: $M_{taps}$ optimization

275

First, we will describe the algorithm to estimate  $M_{taps}$ . In this algorithm, we need an initial value for  $K_s$ . First, we note that, when  $K_s > K_{s,opt}$ , the

Figure 5: BER performance as function of (a)  $M_{taps}$  for different  $K_s$  and (b)  $K_s$  for different  $M_{taps}$ .

optimal value  $M_{taps,opt}$  becomes (quasi-) independent of  $K_s$ . Further, we notice from Figure 5 that selecting  $K_s > K_{s,opt}$  will have a smaller effect on the BER than selecting  $K_s < K_{s,opt}$ . Therefore, we select  $K_{s,initial} > K_{s,opt}$ . As no prior

- <sup>280</sup> knowledge is available, we set  $K_{s,initial}$  to the maximum possible value that can be estimated with the preamble, i.e.  $K_{s,initial} = NN_p$ . To find  $M_{taps,opt}$ , we define an initial search interval  $[M_{min}, M_{max}]$ . For the lower limit, we set  $M_{min} = NN_p$ . To motivate this lower limit, we note that in practice, if the length of the pilot preamble is shorter than the effective CIR length, the chan-
- nel can not be estimated accurately. Hence, we assume that in the design phase, the length of the pilot preamble is selected in a proper way, i.e. that it is able to catch all dominating channel components. Therefore, it is clear that the length  $NN_p$  of the pilot preamble is an appropriate lower limit for  $M_{taps}$ . For the upper limit, we select  $M_{max} = 5NN_p$ , as it is shown in [28] that if the length  $NN_p$
- of the pilot sequence is smaller than 20% of the CIR length, the CIR cannot be reconstructed accurately. Note that if the optimal value  $M_{taps,opt}$  falls outside this initial search interval, the algorithm can adapt the search range automatically (see lines 10-13, Algorithm 1). However, for both simulated channels and measured channels, we did not encounter any case where the optimal  $M_{taps,opt}$
- was located outside this initial search interval, meaning the search interval was selected properly. Within the initial search interval, we select  $N_b$  equidistant values for  $M_{taps}$ , i.e. with step size  $M_{step} = \lfloor (M_{max} - M_{min})/N_b \rfloor$ . For each of the  $N_b$  selected values  $M_{taps}$ , we reconstruct the CIR with the CoSaMP algorithm, and use the reconstructed channel to recover the data of the pilot
- sequence and to compare the resulting bits with the known pilot symbols to obtain the BER, which serves as the optimization criterion in our algorithm. From these  $N_b$  test values, we select the value  $M_{taps,opt}$  that minimizes the BER. We tighten the search interval around the found value of  $M_{taps,opt}$ , i.e.  $[M_{taps,opt} - M_{step}, M_{taps,opt} + M_{step}]$ , reduce the step size with a factor  $N_b/2$
- (see line 3 of Algorithm 1), and continue the search procedure until the step size becomes smaller than or equal to the threshold  $M_{step,min}$ , which we chose  $M_{step,min} = 1$  in our simulations.

# 4.2.2. Algorithm 2: $K_s$ estimation

- The dynamic window search algorithm to find  $K_{s,opt}$ , which is shown in Algorithm 2, is similar to the algorithm to find  $M_{taps,opt}$ . The initial search interval for  $K_s$  is set to  $[K_{min}, K_{max}] = [1, NN_p]$ , i.e. the minimum and maximum  $K_s$  that can be estimated with a preamble length  $NN_p$ . Similarly as in Algorithm 1, we select  $N_b$  equidistant test values for  $K_s$ , with step size  $K_{step} = \lfloor (K_{max} - K_{min})/N_b \rfloor$ , and reconstruct the CIR with the selected value
- of  $K_s$  and  $M_{taps,opt}$  from Algorithm 1, and compute the resulting BER of the pilot sequence. We gradually refine our search interval until the step size  $K_{step}$ is smaller than or equal to the threshold  $K_{step,min} = 1$ . The outputs of this algorithm are  $K_{s,opt}$  and the reconstructed CIR.

#### 4.3. Complexity Analysis

320

To show that the proposed algorithm is suitable for practical implementation, we evaluate the computational complexity of the algorithm. This computational complexity, which is expressed in terms of the number of complex multiplications (NCM), is compared to the complexity of the MMSE estimator. The main share of the computations in the proposed algorithm stems from the

- <sup>325</sup> CoSaMP algorithm that is used to reconstruct the CIR for each combination of  $M_{taps}$  and  $K_s$ . From [19], the number of complex multiplications required in the CoSaMP algorithm equals  $\mathcal{O}\{M_{taps} \log_2(M_{taps}) \log_2(K_s)\}$ . Hence, this complexity depends on the considered  $M_{taps}$  and  $K_s$ . In the  $M_{taps}$  optimization algorithm, given in Algorithm 1,  $K_s$  is fixed to  $K_{s,initial}$ , but  $M_{taps}$  changes
- <sup>330</sup> during the course of the optimization. As in this optimization process, the dictionary size  $M_{taps}$  will converge to  $M_{taps,opt}$ , we approximate the complexity of the CoSaMP algorithm by  $\mathcal{O}\{M_{taps,opt} \log_2(M_{taps,opt}) \log_2(K_{s,initial})\}$ . Within each inner loop,  $N_b + 1$  values of  $M_{taps}$  are tested, and the inner loop is executed  $\mathcal{O}\{\log_{N_b}(4NN_p)\}$  times, leading to the complexity  $\mathcal{O}\{(N_b$
- +1) $M_{taps,opt} \log_2(M_{taps,opt}) \log_2(K_{s,initial}) \log_{N_b}(4NN_p)$ }. Similarly, in the  $K_{s}$ optimization algorithm, where  $M_{taps}$  is fixed to  $M_{taps,opt}$ , the complexity is approximated by  $\mathcal{O}\{M_{taps,opt} \log_2(M_{taps,opt}) \log_2(K_{s,opt})\}$ , as during the optimiza-

tion process,  $K_s$  grows closer to  $K_{s,opt}$ . Further, per inner loop,  $N_b + 1$  values of  $K_s$  are tested and the inner loop is executed  $\mathcal{O}\{\log_{N_b}(NN_p)\}$  times, resulting in a complexity  $\mathcal{O}\{(N_b + 1)M_{taps,opt}\log_2(M_{taps,opt})\log_2(K_{s,opt})\log_{N_b}(NN_p)\}$ . The total complexity of the algorithm therefore equals  $\mathcal{O}\{(N_b + 1)M_{taps,opt}\log_2(M_{taps,opt}) \cdot [\log_2(K_{s,initial})\log_{N_b}(4NN_p) + \log_2(K_{s,opt})\log_{N_b}(NN_p)]\}$ .

To compare the complexity of the proposed algorithm with the complexity of the MMSE estimator and the simplex algorithm, which are  $\mathcal{O}\{(NN_p)^3\}$ and  $\mathcal{O}\{M_{taps,opt}^2K_{s,opt}\log_2(M_{taps,opt}) \log_2(K_{s,opt})\}$  respectively, we consider the case where  $M_{taps,opt} = 5NN_p$ ,  $K_{s,opt} = NN_p$  and  $N_b = 5$ . As in most situations,  $M_{taps,opt}$  and  $K_{s,opt}$  will be smaller than these values, the true complexity will be smaller than the complexity shown in Figure 6. As can be observed in the figure, compared with MMSE estimator and the proposed method, the high com-

- plexity of simplex method makes it impracticable in channel estimation. Comparing the MMSE estimator and our method, we find that when  $NN_p > 112$ , the proposed method has lower complexity than the MMSE method. Moreover, taking into account that the worst case values of  $M_{taps}$  and  $K_s$  were taken to compute the computational complexity of our method, in practical situations,
- the complexity reduction compared to the MMSE approach will be much larger than shown in the figure.

# 5. Numerical Results

In this section, we verify the performance of the proposed adaptive CE method. The channel models (CMs) used in our simulations are based on the UWB communication environments and propagation scenarios considered in the IEEE 803.15.3a standard [11] (see Table 1 for the parameters of these CMs). For each of the four considered CMs, 500 random channel realizations are generated, each having the same channel length  $L_{taps}$ , with  $L_{taps} = 600, 730, 1300, 2150$  for CM 1 to 4, corresponding to  $K_s = 30, 45, 92$  and 163 dominant non-zero taps,

that are distributed over the first  $M_{taps} = 180, 202, 341$  and 698 taps of the channel, respectively. In the simulations, we set the bandwidth to 528 MHz, in

Figure 6: Complexity comparisons of MMSE, the simplex algorithm and the proposed algorithm.

Bandwidth (MHz)	528				
RF Carrier Frequency (MHz)	5544				
Frequency bandwidth (MHz)	$5280 \sim 5808$				
Number of Subcarriers $N$	128	256	512	1024	
Subcarrier Spacing $\Delta f$ (MHz)	4.1251	2.0625	1.0313	0.5157	
Sampling Rate (MHz)	528				

Table 2: Parameters of the MB-OFDM System

the frequency band 5280-5808 MHz, which corresponds to band #5 in [29]. Further, we take the number of subcarriers equal to 128, 256, 512 and 1024, which corresponds to a carrier spacing of 4.1251 MHz, 2.0625 MHz, 1.0313 MHz and 0.5157 MHz, respectively. The sampling rate used in our simulations equals the bandwidth. An overview of the parameters is given in Table 2.

370

We first assess the probability of miss detection of  $M_{taps}$  and  $K_s$ , i.e.  $P_{miss}$ ,  $M_{taps} = P(M_{taps,opt} \neq M_{taps,real})$  and  $P_{miss,K_s} = P(K_{s,opt} \neq K_{s,real})$ . To this end, we consider the case of CM1, and transmit a pilot preamble of length  $NN_p = 128$ , in which N = 128 and  $N_p = 1$ . In Figure 7, the probability of miss detection of  $M_{taps}$  and  $K_s$  is shown for the proposed algorithm, and compared

Figure 7: Probabilities of miss detection for  $M_{taps}$  and  $K_s$ .

with those for the simplex algorithm which is implemented using the function of fminsearch in Matlab. The figure demonstrates that when  $E_b/N_o$  increases, the probability of miss detection of both  $M_{taps}$  and  $K_s$  reduces, and drops below 5% when  $E_b/N_o$  is sufficiently large. Hence, both algorithms can determine the parameters  $K_s$  and  $M_{taps}$  with high accuracy. Although the proposed algorithm has a slightly higher probability of miss detection, the much lower complexity of the proposed algorithm makers it more suitable for practical use. We also evaluated the probability of miss detection for the other channel models CM 2 to 4, and the results are similar to that of CM1.

Next, we evaluate the performance of the proposed channel estimator and compare the results with the performance of OMP, SP and CoSaMP. For each of the considered algorithms, we estimate the CIR for 500 channel realizations of CM1, and compute the normalized mean-squared error (NMSE)  $E[||(\hat{\mathbf{h}} - \mathbf{h})||_2^2]/||(\mathbf{h})||_2^2]$ . For the OMP, SP and CoSaMP algorithms, we assume no prior knowl-

 $|||(\mathbf{h})||_2^2|$ . For the OMP, SP and CoSaMP algorithms, we assume no prior knowledge of  $M_{taps}$  and  $K_s$  is available, and we set  $M_{taps} = 256$  and  $K_s = 60$  for these algorithms. As can be observed in Figure 8, the proposed algorithm outperforms the other algorithms. This can be attributed to the optimized dictionary size and sparsity in our method, resulting in a more accurate reconstruction of the

Figure 8: NMSE of the proposed method and other CS reconstruction methods.

<sup>395</sup> CIR, especially at higher  $E_b/N_o$ .

To evaluate the BER performance of the proposed estimator, we transmit for each channel realization a pilot preamble of  $NN_p$  pilot symbols, followed by 5000 OFDM symbols, each containing 1024 data symbols, where the data is modulated using quadrature phase-shift keying (QPSK). The BER of CM *i* is obtained by averaging the BER of the transmitted data over 500 channel

- <sup>400</sup> *i* is obtained by averaging the BER of the transmitted data over 500 channel realizations of CM *i*. The BER performance of the proposed algorithm is compared with the performance of other CS methods, i.e. SP, OMP and CoSaMP, traditional CE methods, i.e. LS and MMSE, and the case where the channel is known. For the SP, OMP and CoSaMP methods, the same values for  $M_{taps}$
- and  $K_s$  are used as mentioned for Figure 8. For CM1, the results are shown in Figure 9, assuming N = 128 and  $N_p = 1$ . Taking into account that the length of this pilot preamble is shorter than the effective CIR length, which was 180 in our simulation, the channel estimators are not able to extract all dominant CIR components. This results in a degradation of the BER compared
- <sup>410</sup> to the case where the channel is perfectly known at the receiver. Comparing the BER results, we observe that the proposed method outperforms all other CEs, although the gap with the BER of the known channel is still relatively

Figure 9: BER performance of the proposed method compared to other selected methods for CM1.

large. By increasing the pilot preamble length, by e.g. selecting  $N_p = 4$  and  $N_p = 8$ , this gap will become smaller (see Figure 10), as more CIR components will be found. For  $N_p = 8$ , several of the estimators, including the proposed one, exhibit a performance close to the ideal case with known channel. However, the required pilot preamble is quite long, which will limit the data throughput and thus its practical applicability. Therefore, this pilot preamble will be shortened, implying the proposed method will be an excellent solution to estimate the channel in a practical implementation.

Furthermore, we show the BER performance for the other channel models. In Figure 11, the BER performance of the proposed method and other selected methods is shown, assuming  $N_p = 1$ , 2 and 4 pilot symbols of length N = 128are used for CM2, CM3 and CM4, respectively. Our proposed method found for the considered cases that the optimal dictionary size was  $M_{taps,opt} = 202$ , 341 and 698, and the optimal sparsity equalled  $K_{s,opt} = 45$ , 92 and 163, for CM2, CM3 and CM4, respectively. We observed in our simulations that these numbers for  $M_{taps,opt}$  and  $K_{s,opt}$  are in accordance with the average effective duration and the number of dominant taps of the CIRs. With these parameter settings,

 $_{430}$  we are able to recover about 85% of the power contained in the CIR. Figure 11

Figure 10: BER performance of the proposed method compared to other selected methods for different lengths of the pilot preamble: (a)  $NN_p = 512$  (b)  $NN_p = 1024$ .

Figure 11: BER performance of the proposed method compared to other selected methods for CM2, CM3 and CM4.

confirms the results from Figure 9, i.e. the proposed estimator outperforms the other CE methods when the length of the pilot preamble is shortened for practical reasons, so that not all dominant channel components can be retrieved. Similarly as for CM1, when the length of the pilot preamble would be increased, the difference between the performance of the considered CEs and that of the case with known channel will become smaller.

435

Finally, we applied the proposed method for the channels, measured with the setup from Section 2.2. In this paper, we just show the results for channels between transmitter and receiver positions  $R_6$ ,  $R_{12}$  and  $R_{14}$ , corresponding to a LoS, OLoS and NLoS scenario, and denoted by Channel 6, Channel 12 and Channel 14, respectively. The results for the other channels are similar to the results of these three channels. From the measured data, we determined the effective durations of Channel 6, 12 and 14, i.e. they are 168, 241 and 369

<sup>445</sup> 1,1 and 2 pilot symbols of length N = 128 to reconstruct Channel 6, 12 and 14, respectively. Further, to evaluate the BER performance of our method, we transmitted 5000 OFDM symbols modulated by QPSK. The average BERs of

respectively, and the values of sparsity are 37, 61 and 91. We select  $N_p =$ 

Figure 12: BER performance for real, measured channels of channel 6, channel 12 and channel 14.

the three channels are shown in Figure 12. Compared with OMP and CoSaMP, the proposed method achieves a lower BER. Although the pilot sequence has the
same length for Channel 6 and 12, the effective duration and sparsity of Channel 6 are smaller than those of Channel 12, so the BER performance of Channel 6 is much better. Moreover, thanks to the longer pilot sequence, the average BER of Channel 14 is lower than that of Channel 12, even though Channel 14 has a longer effective duration and more dominant taps. Note that we can improve the
BER for Channel 12 by using the same pilot sequence length as for Channel 14.

<sup>455</sup> BER for Channel 12 by using the same pilot sequence length as for Channel 14. In that case, the BER of Channel 12 turned out to be better than for Channel 14 (results not shown in the figure). Similar to the results of the simulated channels, the performance difference between the CS-based CE methods and the known channel will be reduced when the length of pilot preamble increases.

460

#### 6. Conclusion

In this paper, we propose an adaptive CS-based parameter estimation algorithm for UWB MB-OFDM systems. Our method extends the CoSaMP method by also estimating the dictionary size  $M_{taps}$  and sparsity  $K_s$ , needed to accu-

- rately estimate the channel. Although state-of-the-art estimators are able to achieve close-to-optimal performance when the pilot preamble length is sufficiently long to extract all CIR components, such pilot preamble lengths are often not suitable for practical implementation as they limit the data throughput. Therefore, in practice the pilot preamble is often shortened. However, this
- results in a degradation of the system performance. We show in this paper that in such a situation, our method outperforms state-of-the-art channel estimators considerably, as the estimated  $M_{taps,opt}$  and  $K_{s,opt}$  better match the effective duration and the sparsity of the CIR. Moreover, as the proposed method has low complexity, it is suitable for practical implementation. In this paper, we
- <sup>475</sup> not only restricted our attention to theoretical channel models, we also evaluated our algorithm for measured channels obtained with the measurement setup described in this paper. The results for these measured channels are similar to the results of the theoretical channel models, meaning that our method can be employed in practical scenarios.

**Algorithm 1**  $M_{taps}$  estimation algorithm

1: I	Initialization: Set $K_{s,initial} = NN_p$ , searching block $[M_{min}, M_{max}]$ ,				
İ	$M_{min} = NN_p, M_{max} = 5NN_p$ , pilot sequence <b>X</b> , received pilot sequence <b>y</b> ,				
t	the number $N_b$ of test values, $M_{step} = +\infty$ and $M_{step,min} = 1$ .				
2: 1	while $M_{step} > M_{step,min}  \mathbf{do}  \% \ outer \ loop$				
3:	$M_{step} \leftarrow \lfloor (M_{max} - M_{min}) / N_b \rfloor;$				
4:	for $m = 0 : N_b$ do % inner loop				
5:	$M_{taps} \Leftarrow M_{min} + m * M_{step};$				
6:	Obtain $\hat{\mathbf{h}}$ with CoSaMP using $M_{taps}$ , $K_{s,initial}$ , $\mathbf{X}$ and $\mathbf{y}$ ;				
7:	Calculate $BER_m$ with $\hat{\mathbf{h}}$ ;				
8:	end for				
9:	$m_{opt} \leftarrow \arg\min_m BER_m$				
10:	if $m_{opt} = 0$ or $m_{opt} = N_b$ then				
11:	$M_{taps,opt} \leftarrow M_{min} + m_{opt} * M_{step};$				
12:	$M_{max} \leftarrow M_{taps,opt} + NN_p;$				
13:	$M_{min} \Leftarrow M_{taps,opt} - NN_p;$				
14:	else				
15:	$M_{taps,opt} \leftarrow M_{min} + m_{opt} * M_{step};$				
16:	$M_{max} \Leftarrow M_{taps,opt} + M_{step};$				
17:	$M_{min} \Leftarrow M_{taps,opt} - M_{step};$				
18:	end if				
19: <b>e</b>	end while				
20: (	20: Output $M_{taps,opt}$ .				

# Algorithm 2 $K_s$ estimation algorithm

 Initialization: Set M<sub>taps,opt</sub>, searching block [K<sub>min</sub> K<sub>max</sub>], K<sub>min</sub> = 1, K<sub>max</sub> = NN<sub>p</sub>, pilot sequence **X**, received pilot sequence **y**, the number N<sub>b</sub> of test values, K<sub>step</sub> = +∞ and K<sub>step,min</sub> = 1.
 while K<sub>step</sub> > K<sub>step,min</sub> do % outer loop

- 3:  $K_{step} \leftarrow \lfloor (K_{max} K_{min})/N_b \rfloor;$
- 4: for  $k = 0 : N_b$  do % inner loop
- 5:  $K_s \leftarrow K_{min} + k * K_{step}$
- 6: Obtain  $\hat{\mathbf{h}}$  with CoSaMP using  $M_{taps,opt}$ ,  $K_s$ ,  $\mathbf{X}$  and  $\mathbf{y}$ ;
- 7: Calculate  $BER_k$  with  $\hat{\mathbf{h}}$ ;
- 8: end for
- 9:  $k_{opt} \Leftarrow \arg\min_k BER_k$
- 10:  $K_{s,opt} \leftarrow K_{min} + k_{opt} * K_{step};$
- 11:  $K_{max} \leftarrow K_{s,opt} + K_{step};$
- 12:  $K_{min} \leftarrow K_{s,opt} K_{step};$
- 13: end while
- 14: Output  $K_{s,opt}$ , CIR  $\hat{\mathbf{h}}$  estimated with  $M_{taps,opt}$  and  $K_{s,opt}$ .
