**Abstract**

The effectiveness of arthroscopic repair of type II superior labrum anterior posterior lesion (SLAP) was unclear as previous studies examined this treatment with patients of combined types of SLAP lesions. To address this research gap, we evaluated the clinical and functional outcomes of arthroscopic repair for 16 patients (*Mean* = 24.2, *S.D.* = 6.5) with clinical evidence of isolated type II SLAP lesion. After having arthroscopic stabilizations with Bioknotless suture anchors (Mitek), the patients were offered post-operative rehabilitation programs (e.g., physiotherapy) for 6 months. The symptoms of SLAP lesion and the functions of the shoulder were assessed preoperatively and 28-month post-operatively by O'Brien test, Speed test, Yergason test, and University of California at Los Angeles rating for pain and function of the shoulder. Wilcoxon Signed Ranks test and McNemar test were employed to analyze the difference between assessment in pre-operation and post-operation phases. The result showed that patients' shoulder functions improved (UCLA Shoulder Score), and symptoms of SLAP lesion reduced (O'Brien test, Speed test, and Yergason test) significantly ( $p < 0.05$ ). Time for returning to play with pre-injury level was in average 9.4 months (range: 4-24), and no complication or recurrence was detected. We concluded that arthroscopic repair is an effective operation of type II SLAP lesion with good clinical and functional outcomes, however, athletes with high demand of overhead throwing activities are likely to take longer duration of rehabilitation attain fully recovery.

Keywords: Shoulder, SLAP, sports medicine, arthroscopy, surgery

## 1 Introduction

Historically, “dead arm” has been regarded as a career ending affliction for overhead throwing athletes, as the causes and treatment of this pathology were almost unknown until the recent advent of arthroscopy [3,5]. Advances in imaging techniques and the rapid developments and evolutions of arthroscopic surgery enabled surgeons to understand a lot of previously unknown shoulder pathologies and to treat them accordingly during the past two decades. The story of the “dead arm” was begun to be uncovered 23 years ago, when Andrews et al [2] carried out initial investigation and suggested that injuries in superior labrum-bicep anchors in glenoidhumeral joints was the major cause of the pathology. By then, there has been an increasing number of orthopedic and radiology literatures focusing on the diagnosis and treatment of this shoulder pathology.

Synder et al [24] defined this type of shoulder pathology, named superior labrum anterior posterior (SLAP) lesion, as the superior labrum-biceps tendon complex disruptions which involved of tearing and separation of the superior labrum, or both; in addition, the tearing or separation is developed posteriorly from the biceps tendon insertion and extending anteriorly. Besides, Snyder et al [24] pointed out that this lesion is not uncommon, while 6% of his arthroscopic operations were related to SLAP lesion. Maffet et al [14] also revealed that SLAP lesion presented in 12 % of his shoulder arthroscopy cases.

As we have previously mentioned, one of the interesting phenomena of the prevalence of SLAP lesion is that, the pathology is usually specified to athletes of particular sports, who developed the lesions from a compression force of the injured shoulder with the arm flexed and abducted upon a fall, or upon a traction injury to the arm [14]. Whereas Warner et al [28] described another group of patients of SLAP lesion developed the lesions by repetitive overhead pitching activities. This is probably resulted from eccentric loading of the bicep with a sudden increase in the tensile force of the anchor, during the cocking phase of a throw, and lesion is developed either by repetitive micro trauma or single major trauma.

From all his arthroscopic cases, Synder et al [24] identified four major types of injuries (outstretching injury, traction, direct trauma, external rotation) causing this superior glenoid labrum lesion, and thus categorize SLAP lesions into four types (Type I, II, III, IV) in terms of the mechanism of the injuries and arthroscopic evaluations. In the past decade, while more and more studies investigated the pathologies and treatment, ten types of SLAP lesions have been identified [3,12,16,19,20]. Among the ten types of SLAP lesion, type II lesion is the most common one, which is defined by “*superior labral fraying with stripping of the superior part of the labrum and attached biceps tendon from the underlying glenoid cartilage*” [3,19]. Later on, Morgan et al [16] further identified three distinct sub types of type II SLAP lesions (Type II A, B, and C). In particular, type IIA, IIB, and IIC represent anterosuperior labral lesion, posterosuperior lesion, and superior lesion with both anterior and posterior components respectively.

Reported treatment for SLAP lesion have found to be mixed, which ranged from

1  
2  
3 40 debridement of the lesions (for type I and III) [1,6] to surgical repair (for type II and IV  
4 41 lesion) [8,11,22,25]. Moreover, the surgical treatments of these various types of SLAP lesion  
5 42 differ from each other in terms of the fixation methods and operative devices, such as staples,  
6 43 metallic and absorbable suture anchors or tacks. As a result, it is difficult to justify the  
7 44 overall surgical outcomes of SLAP lesion while inconsistencies about the type of injuries  
8 45 and surgical treatment present within a single study. Although there have been dozens of  
9 46 relevant clinical studies about surgical treatment of SLAP lesion over the decades, most  
10 47 previous studies only consisted of SLAP cases with the combinations of SLAP lesions and  
11 48 other related intra-articular pathologies, like Bankart lesion or rotator cuff tear. Thus, the  
12 49 results of these studies may be confounded by subject effects, and the effectiveness of the  
13 50 surgical treatments of type II SLAP lesion was unclear.

14  
15  
16  
17  
18  
19  
20 51 To address this research gap, the purpose of this study is to evaluate the clinical and  
21 52 functional outcome of our patients, with isolated Type II SLAP lesion of the shoulder, who  
22 53 underwent arthroscopic stabilization as the surgical treatment of SLAP lesion, from July  
23 54 2003 to March 2005. Thus, the clinical and functional outcomes of arthroscopic treatment to  
24 55 isolated Type II SLAP lesion can be examined.

## 29 57 **Methods**

### 30 58 *Participants*

31  
32 59 In order to obtain our target sample, we revealed all patients of the Prince of Wales  
33 60 Hospital who showed clinical evidence of isolated Type II SLAP lesion during the period  
34 61 (July 2003–October 2005). They were also required to fulfill the following inclusion  
35 62 criteria:  
36  
37  
38

- 39 63
- 40 64 1. No history of shoulder dislocation or subluxation.
- 41 65 2. No intra-articular injuries of Type II SLAP lesion
- 42 66 3. No neurological complications affecting mobility and physical sensation
- 43 67 4. No previous surgery over the same shoulder
- 44 68 5. Non work-compensation cases
- 45 69 6. Age less than 40
- 46  
47  
48  
49

50  
51 71 After employing a prospective cohort study using magnetic resonance imaging (MRI)  
52 72 arthrogram, 23 cases of Type II SLAP lesion satisfied the above criteria, and were advised  
53 73 by their physicians to undergo arthroscopic stability operations. Among the cases, 20  
54 74 patients agreed to participate after being consented about the study purposes and their rights  
55 75 of participating the study. However, 4 patients were found to have concomitant  
56 76 intra-articular pathologies during arthroscopic examination, so they were then excluded  
57 77 from our study. Finally, our sample consists of 13 male and 3 female participants whose  
58 78 ages ranged from 15 to 38 (*Mean* = 24.2, *S.D.* = 6.5).

1  
2  
3 79 Among the 16 participants, fifteen had type II lesion on their right shoulders, and only 1  
4 80 had the lesion on the left shoulder. Before injury, 13 participants were actively involved in  
5 81 overhead sports (e.g., tennis, handball, badminton) in either elite or recreational levels, two  
6 82 others were believed to get injured by lifting heavy weights, and one was injured by landing  
7 83 with an outstretched hand after a fall. All patients received operation within 1 month after  
8 84 their first visit to the clinic, and were given physiotherapy and analgesics treatment after  
9 85 their operations.

#### 10 86 *Operative procedures*

11 87 After receiving general anaesthesia, patients were put into lateral decubitus position  
12 88 under traction of three to four kilograms. Diagnostic arthroscopy was performed via the  
13 89 standard posterior portal. Superior labrum was carefully tested with an arthroscopic probe  
14 90 through an anterior-superior portal. Not uncommonly a Type II SLAP lesion looks normal  
15 91 upon arthroscopic examinations, but became obvious when it is tested with an arthroscopic  
16 92 probe for its stability. Other associated intra-articular structures, including the rest of the  
17 93 labrum, bicep tendon, the anterior, inferior and posterior capsules, undersurface of the  
18 94 rotator cuff, and the articular cartilage, were throughout examined.

19 95 After identification of the SLAP lesion, an arthroscopic shaver or a burr was introduced  
20 96 via the antero-superior portal to debride the superior glenoid bone edge till the good  
21 97 bleeding raw area was prepared. Based on particular extent of the SLAP tear, we used  
22 98 different portals to fix the lesion for the patients. For anterior extension of the SLAP tear, we  
23 99 tackled lesions via the anterior-superior portals. For posterior extension of the lesion, we  
24 100 used trans-rotator cuff portals, as suggested by O'Brien et al [10]. These portals were  
25 101 approximately 1-2 cm lateral to the lateral edge of the acromion. Spectrum suture passer  
26 102 device (Linvatec) was used to deliver a PDS-1 suture via either superior labrum or working  
27 103 portals, which depended upon the location of the lesion. The free distal limb of the PDS-1  
28 104 suture was retrieved through the anterior-superior portal, or an anterior-mid glenoid portal.

29 105 Except two cases, all patients' Type II SLAP tears were fixed with bioabsorbable  
30 106 knotless suture anchors (Bioknotless Anchor, Mitek) by the technique described by Thal  
31 107 [17], at 2, 1, 11 or 10 o'clock region according to the pattern of labral tear. The utility loop  
32 108 suture ends of the Bioknotless anchors were then loaded into the proximal open loop end of  
33 109 the PDS-1, and were pulled from the other portal through the labral tissue using "poor man  
34 110 shuttle" technique. Tension was maintained along both suture ends while passing the anchor  
35 111 in. After the utility loop passed via the superior labrum, one of the strands of the loop was  
36 112 captured under the anchor prongs, and then the anchor was driven into the drill hole under  
37 113 direct vision, until the anchor was completely engaged. Precautions were taken to ensure  
38 114 that the suture loop was not twisted while the anchor was being inserted, and the anchor was  
39 115 not inserted too deeply into the drill hole, as these two situations may lead to the abrasion of  
40 116 the sutures, and thus breakage. The number of anchors used in this study ranged from 2 to 4  
41 117 (*Mean* = 2.6, *S.D.* = .7), while two to three absorbable anchors are usually enough to provide

1  
2  
3 118 a stable repair to most SLAP lesions. The operation time, type of SLAP lesions, number of  
4 119 anchors and hospitalized days are listed in table 1.

5  
6 120 *Post-operative rehabilitation*

7 121 Post-operatively, the patients followed a standard rehabilitation protocol of shoulder  
8  
9 122 lesion surgery [9]:

10 123 Week 1: - Sling immobilization at all times

11 124 Week 2-3: - Codman circumduction

12 125 - Passive range of motion (0-90 abduction)

13 126 - External rotation adduction

14 127 - No external rotation in abduction

15 128 Week 4-6: - Discontinue sling

16 129 - Progressive passive range of motion (PROM) to full in all planes

17 130 - Passive posterior capsular and internal rotation stretching

18 131 - Passive and manual scapulothoracic mobility program

19 132 - External rotation in abduction

20 133 Week 7-16 - Progressive strengthening of the rotator cuff, scapular stabilizers and  
21 134 biceps

22 135 Month 4-6: - Internal throwing program on level surface

23 136 - Return to full throwing activities

24 137

25 138 In addition, during the first 4 post operative weeks, the patients were advised to restrain  
26 139 from external rotation in the abduction for reducing the possibilities of re-injury due to  
27 140 peel-back mechanism. Finally, patients were also advised not to resume throwing sports  
28 141 activities until improvement in their shoulders' range of motion, rotator cuff strength, and  
29 142 biceps strength, were observed compared to their preoperative status. All the patients were  
30 143 able to comply with the rehabilitation program and attend follow-up reassessment regularly  
31 144 in our clinic, with an average follow-up of  $27.6 \pm 2.6$  months (range: 24-31).

32 145 *Assessments and analysis*

33 146 Participants were asked to undergo O'Brien test [17] for detecting SLAP lesion.  
34 147 O'Brien test [17] is a newly developed compression test to diagnose labral tears and  
35 148 pathological conditions of the acromioclavicular joint, and was clinically found to be highly  
36 149 reliable in detecting SLAP injuries. In the test, patients are asked to sit in an upright position  
37 150 and elevate their shoulder with the arm in full extension. Examiner then adducts the arm for  
38 151  $10^\circ$ , and rotates internally until the thumb points downwards. The arm in the position is then  
39 152 pushed downwards repeatedly with supination of the arm. A sensation of pain or clicking  
40 153 inside the joint indicates the presence of labral or SLAP tear.

41 154 Besides, Speed test [9] and Yergason test [30] were performed for assessing patients'  
42 155 biceps tendon instability or tendonitis. These two tests are not specific for detecting SLAP  
43 156 lesion, as recent studies showed that Speed test and Yergason test are not sensitive clinical

1  
2  
3 157 tests for detecting SLAP lesion [10] in particular shoulder region (e.g., posterior SLAP  
4 158 lesion for Speed test). However, we decide to include these two tests to provide additional  
5 159 information as they are classical test for diagnosing shoulder injuries, and it is not clear  
6 160 about their sensitivities in detecting lesion specifically for type II lesion.

7  
8  
9 161 Moreover, The University of California at Los Angeles rating for pain and function of  
10 162 the shoulder [7] was adopted to assess the patients' shoulder joints functions. The scale  
11 163 consists of five items. The two items corresponding for the range and strength (manual  
12 164 muscle-testing) of active forward flexion are graded by physicians in a 6-point-likert scale  
13 165 (0 indicates worst condition, and 5 indicates best condition). The other three corresponding  
14 166 for the pain and function of shoulders, and satisfaction towards their shoulders are  
15 167 self-reported by patients. Pain and function are measured in 10-point-likert scale with the  
16 168 scores of 1 and 10 representing the worst and best condition respectively. The satisfaction  
17 169 score is assessed in a 6-point-likert scale as pain and function do. Therefore, the scores of  
18 170 the five items composite into a UCLA Shoulder Score [6] with a maximum of 35 marks,  
19 171 while patients receiving 34-35 marks, 29-33 marks, and 29 marks or lower are classified as  
20 172 having excellent, good, and poor shoulder function respectively [6].

21 173 These assessments were performed preoperatively (the day before surgery) and  
22 174 postoperatively ( $27.6 \pm 2.6$  months after the surgery) by two orthopaedics specialists with  
23 175 more than 15 years of clinical experience. In addition, at the final postoperative assessment,  
24 176 participant were asked to report their pre-injury activity levels, injury mechanisms, duration  
25 177 of symptoms, and the time required to return to pre-injury activity levels. (See table 2)

26 178 In this study, the effect of the operative treatment of type II SLAP lesion were  
27 179 examined by comparing the difference of test scores patients obtained in their pre-operative  
28 180 assessment and post-operative assessment, in which participant served as their own control.  
29 181 McNemar test (for categorical variables) was employed to examine the categorical variable  
30 182 of O'Brien test. As the problem of non-normality, which violates the assumptions of t-test,  
31 183 might possibly presented in our small sample, we examined the normality of continuous  
32 184 variables like UCLA shoulder scores and sub-scores by Shapiro-Wilk tests to determine  
33 185 whether Wilcoxon Signed Ranks test (for skewed population) or paired sample t-test (for  
34 186 normally distributed sample) should be used for analyzing the continuous variables.  
35 187 Significant difference of the test scores between pre-operative assessment and  
36 188 post-operative assessment were indicated by significant  $p$  values  $<.05$ .

37 189

## 38 190 **Results**

### 39 191 *Intra-operative findings*

40 192 The operations took 71 minutes on average (S.D. = 14; range: 52-105). Arthroscopic  
41 193 screening based on the morphology of the Type II SLAP lesions revealed that, there were  
42 194 seven cases of superior-anterior lesion (Type IIA), five cases of superior-posterior lesion  
43 195 (Type IIB), and four cases of combined superior-anterior-posterior lesions (Type IIC), where

1  
2  
3 196 the lesions were located around the bicep anchor region, namely the 12 o'clock position.  
4 197 The lesions were repaired with two to four anchors (Mean= 2.6, SD = 0.7), distributed  
5 198 equally from two to ten o'clock area. Intra-operatively, there were two episodes of breakage  
6 199 of anchors during the insertion due to incorrect approaching angle with respect to the drill  
7 200 hole. There were also two episodes of suture abrasion and then breakage noted  
8 201 intra-operatively. One of the cases was because of twisting of the suture loop during anchor  
9 202 insertion, and the other case was related to too deep suture anchorage into the glenoid bone.  
10 203 Both problems were noted intra-operatively and another suture anchor was placed right next  
11 204 to it for repairing the labrum.

#### 12 205 *Outcome assessment*

13 206 McNemar test showed that significant difference was observed between the test-retest  
14 207 assessment of O'Brien test, Speed test, and Yergason test ( $p < .05$ ). Patients with a positive  
15 208 signs of O'Brien test Speed test, and Yergason test significantly reduced in the  
16 209 post-operative phase.

17 210 Shapiro-Wilk tests revealed that all UCLA shoulders scores in the pre-operative  
18 211 assessment, and post-operative assessment were significantly skewed ( $p < .05$ , despite the  
19 212 post-operative UCLA total score ( $p = .06$ ). Therefore, Wilcoxon Signed Ranks test was used,  
20 213 and the result showed that significant difference were observed in all dimensions of UCLA  
21 214 Shoulder assessment scores, and thus, the composite score of UCLA ( $p < .05$ ) between the  
22 215 pre-operative and post operative assessment. Specifically, the shoulders' pain, function,  
23 216 active forward flexion, strength, satisfaction, and overall function (composite scores) of  
24 217 their shoulders significantly increased in the post-operative phase ( $p < .05$ ). Details are  
25 218 shown in table 2.

26 219 In addition, based on the grading system of UCLA assessment, 100% of patients in the  
27 220 pre-operative phase were categorized as having poor shoulder function (Mean=18.1,  
28 221 SD=3.3), while in the post-operative assessment, 31.3%, 43.8%, and 25.0% of patients were  
29 222 categorized as having excellent (Mean=35.0, SD=0), good (31.6, SD=1.9), and poor  
30 223 function (26.3, SD=2.1). See table 2 for details.

#### 31 224 **Discussion**

32 225 The purpose of the study was to examine the effects of surgical treatment of isolated  
33 226 type II lesion. The results showed that arthroscopic repair of isolated Type II SLAP lesion  
34 227 achieved excellent to good results in majority of patients (N=14, 87.5%), which was  
35 228 comparable to other series, with a mixed combinations of pathologies associated to SLAP  
36 229 lesion, as reported by different authors [8,11,14,22,24,25,28] (80-100% good outcomes).

#### 37 230 *Clinical outcomes*

38 231 Compared to the results of the pre-operative assessments, positive signs from O'Brien  
39 232 test, Speed test, and Yergason test significantly reduced in the post-operative assessment,  
40 233 providing supporting evidence for the effectiveness of the arthroscopic treatment of type II  
41 234

1  
2  
3 235 SLAP lesion. UCLA scores increased sharply from an average of 18.1 (SD = 3.3) to 31.3  
4 236 (SD = 3.7), which indicated the shoulder function improved significantly after the surgical  
5  
6 237 treatment. According to the categorization of UCLA shoulder assessment [7], the percentage  
7  
8 238 of patients having poor shoulder function reduced from 100% at the pre-operative  
9  
10 239 assessment, to only 25% at the post-operative assessment. While the UCLA total scores of  
11  
12 240 these 25% patient on average increased to 26.3 (SD = 2.1), a value closed to good function  
13  
14 241 category. These evident support the effectiveness of arthroscopic treatment of type II SLAP  
15  
16 242 lesion.

17 243 Despite of clinical assessments, the recovery duration patients need for returning their  
18  
19 244 pre-injury activities levels is also an important success indicator towards treatment. In our  
20  
21 245 study, all patients started to regain active and passive range of motions from the fourth  
22  
23 246 weeks after the operations. At six months after the operation, 14 patients (88%) regained  
24  
25 247 active range of motion within 9 months post-operatively. All patients regained their full  
26  
27 248 range of motion upon the final assessment without complications. Filed and Savoie [8]  
28  
29 249 reported that all their patients returned to athletic activities without limitations. However, we  
30  
31 250 argue that the recovery of SLAP lesion after the operation might depend on pre-injury  
32  
33 251 activity levels of the patients. In our study, elite athletes who required frequent overhead  
34  
35 252 activity required longer duration of rehabilitation and time to return to pre-injury activity  
36  
37 253 level. Eleven patients (69%) regained pre-injury activity level within nine months after the  
38  
39 254 operation (average = 7.0 months), and four patients, who previously performed intense and  
40  
41 255 frequent overhead activities (2 tennis, 1 badminton, and 1 cricket) in elite levels returned to  
42  
43 256 their pre-injury levels after an obviously longer period of post-operation rehabilitation  
44  
45 257 (Mean = 11.0 months). The remaining one elite handball athlete could not resume his  
46  
47 258 pre-injury activity level at 24 months after the operation, because of residual pain and  
48  
49 259 weakness of the supraspinatus. In line with our study, Burkhart et al [4] and Kim et al [11]  
50  
51 260 both reported that throwing athletes produced statistically inferior results for SLAP lesion  
52  
53 261 than non-throwing athletes. They usually took longer period of time to recover, and  
54  
55 262 sometimes even failed to show return to their pre-injury performance.

56 263 Though there was significant improvement in terms of clinical test scores in the  
57  
58 264 post-operative phase, it is important to note that reported pain persisted in minority of cases  
59  
60 265 (N=3), including night pain. MRI were employed post-operatively for these patients and  
266  
267 revealed that their SLAP lesions did not present, which evidenced by the marked difference  
268  
269 in supraspinatus tendinosis, and articular side tear of the supraspinatus tendon. We  
270  
271 suggested that the pain could be explained by the occult pathology beyond our clinical  
272  
273 detection, and thus residual pain and signs of impingement syndrome persisted even though  
274  
275 we had tackled the SLAP lesion. Further studies may examine the operative pain  
276  
277 phenomenon, in terms of the causes, screening methods, and treatments.

#### 278 *Surgical treatments of SLAP lesion*

279 Over the past two decades, a number of technical innovations have been developed for

1  
2  
3 274 the surgical treatment of SLAP lesion (e.g., metal screws, metal staples, suture, and  
4 275 absorbable tack or screw), however, dozens of argument and concerns have been pointed out  
5  
6 276 regarding the use of these metal implants. For examples, it has been suggested that metal  
7  
8 277 implant may possibly injure the articular cartilage upon insertion, and subsequently protrude  
9  
10 278 into the joint, or become loosen [19,31,32]. For this reason, surgeons began to put more  
11  
12 279 attention in using absorbable sutures. Field and Savio [8], who used absorbable sutures,  
13  
14 280 reported good clinical results in the operation of SLAP lesion. Similarly, Snyder et al [23]  
15  
16 281 and Burkhart et al [4] demonstrated encouraging results by using absorbable tacks, but both  
17  
18 282 of them illustrated problems of tack fragment which required removal post-operatively.  
19  
20 283 There have also been concerns over the development of synovitis [4], and possibly bony  
21  
22 284 lysis [23] at the anchor site. In this study, we used Bioknotless suture anchors (Mitek) as  
23  
24 285 described by Thal [27]. It has been reported to provide a secure process, low profile of repair,  
25  
26 286 and improved healing potentials [27], as part of the tissue is pulled into the drill hole rather  
27  
28 287 than on the top of the anchor. Moreover, it avoids the added complexities of arthroscopic  
29  
30 288 knot tying, thus, the processes of surgery become more efficient [27].

### 26 289 *Limitation*

27  
28 290 In this study, O'Brien test was the only test which is specifically for detecting SLAP  
29  
30 291 lesion. Further studies should include more shoulder SLAP lesion test, such as  
31  
32 292 compression-rotation test and crank test, which have been suggested to be as sensitive as  
33  
34 293 O'Brien test in detecting SLAP lesion in general [21,22].

35  
36 294 Although type II SLAP lesion is the most common type of SLAP lesion [15,19],  
37  
38 295 recruiting participants with isolated type two SLAP lesion was somehow difficult, as most  
39  
40 296 type II SLAP lesion cases were combined with either type of SLAP injuries or rotator cutoff  
41  
42 297 pathologies [2,6,8,11,12,14,25,28], so the sample size was relatively small, which was one  
43  
44 298 of the major limitation in our study.

### 41 299 *Conclusion*

43 300 Our study showed that arthroscopic stabilization of Type II SLAP lesion is effective  
44  
45 301 treatments evidenced by good clinical and functional outcome in majority of patients.  
46  
47 302 However, it was observed that athletes with high demand of overhead throwing activities  
48  
49 303 were likely to take longer duration of rehabilitation attain fully recovery.
