Abstract

Special experiments are designed to obtain the solid reactants directly from a liquid solder during phase transformation. Series of such tests performed throughout reflow, which enables to investigate the entire formation process of intermetallic Ag₃Sn plates out of liquid SnAgCu solder bumps. The results show that Ag₃Sn plates are formed first in the middle of the cooling stage. In the plane, they have two preferable growth directions. By varying thermal conditions during reflow, the formation mechanism of these plates is discussed.

Key words: solder; solidification; crystal growth; intermetallics

1 Introduction

In the eutectic SnAgCu solder, one of the most promising Pb-free materials for interconnections in electronic packages, Ag is basically introduced to reduce the melting point as well as modify metallurgical and mechanical characteristics of this alloy. During soldering, Ag combines with Sn, forming Ag₃Sn intermetallic compounds (IMCs). In

normal cases, Ag_3Sn IMCs are present in β -Sn matrix in the form of small particles (or fibres), composing eutectics in a SnAgCu grain [1-3]. However, such particles are not the only morphology of Ag_3Sn IMCs. Sometimes, large Ag_3Sn plates, which can stretch across the entire joint, are found [3-5]. Since Ag_3Sn plates are brittle and their size in some cases is comparable with that of the joint, their morphology and distribution can play an important role in mechanical properties, and, consequently, influence the reliability of the joint. It has been reported that cracks can initiate and propagate along the interface between Ag_3Sn plates and the solder [6, 7], and that the existence of Ag_3Sn plates can reduce joint's ductility [8, 9]. Therefore, the formation of these unusual plates has attracted considerable attention [10-12]. Thorough investigations are required. In this paper, an experiment, which is able to capture Ag_3Sn IMC plates in a molten SnAgCu solder at an arbitrary moment of reflow, is implemented. By a series of these tests through reflow, the nucleation and growth behaviour of Ag_3Sn in a SnAgCu solder material is present. Based on the results from reflow with varying thermal conditions, their formation mechanism is discussed.

2 Experiments

In order to obtain the solid reactants out of the liquid solder, one possible solution is to terminate the liquid-to-solid phase transformation by removing the molten solder in the middle of reflow. The experiments are specially designed with this aim. Sketch of the set-up is present in Fig. 1a. A circle printed circuit board (PCB) specimen is prepared with Cu pads on the edge. The solder materials are placed on Cu pads. The PCB specimen is fixed to spindle, and inserted into an oven. The temperature of solder bumps is measured via a

thermal couple. When the solder bump reaches a specific temperature during reflow, spinning of the spindle is triggered. The remaining liquid solder is removed from the Cu pads due to the centrifugal force, leaving there only solid reactants. By a series of these spinning tests at different moments of reflow, the whole process of formation of solid reactants out of the liquid phase can be present. The solder material applied in this study is a commercial Sn3.8Ag0.7Cu paste, containing 13% flux by weight. Fig. 1b presents the pre-designed temperature profiles for the tests. The maximum deviation from these curves in the tests is within ± 5 K.

3 Results

The first temperature regime studied in reflow experiments is present by Curve 1 in Fig. 1b. It reflects three typical thermal conditions during reflow: temperature increase, dwelling, and cooling. A series of spinning tests are conducted to study the formation of Ag_3Sn plates starting from the melting point (T_m), 490 K, of the solder material to its final solidification following this temperature profile. Increments between two consecutive tests are controlled with precision of 5 K and 30 seconds. No trace of Ag_3Sn plates is observed during entire stages of temperature increase and dwelling. The first time that Ag_3Sn plates are found is at point A (501 K) in the final cooling stage of Curve 1. Several spinning tests are conducted at this point. Ag_3Sn IMCs are found in some of these specimens, but not in all, indicating that this point is close to the nucleation point for Ag_3Sn plates in Curve 1. Figure 2a presents the obtained morphology on the pad at this point. It can be seen that a micro- Ag_3Sn plate is formed in Zone M on the pad. Focusing on the bottom part of the plate - the

interface between Cu_6Sn_5 IMCs and the plate (Fig. 2b) - it seems that the plate grows from the IMC layer.

The second investigated moment is Point B (493 K) in Fig. 1b, which experiences a further cooling from Point A to a temperature just above the melting point of the eutectic SnAgCu solder. It presents a transition growth stage of Ag_3Sn plates. An image of the pad at this point is given in Fig. 2c; it shows that large amounts of small Ag_3Sn plates are formed. To illustrate the morphology of these plates in detail, a local area of Fig. 2c is given in Fig. 2d. It can be seen that the plate grows from the IMC interface to the location of the molten solder. In most cases, a plate can have several sub-plates, forming a leaf-like shape at this stage. A characteristic feature of this process is that the angle between these sub-plates is close to 90° , indicating that there are two preferable growth directions in plane. To illustrate the growth behaviour, a plate in Fig. 2d is used for further analysis. It can be seen that there are three sub-plates, which follow this 90° pattern. The top tip of each sub-plate is the major growth direction (MGD) of a sub-plate. Along the sub-plate's sides, the front edges have a saw-tooth like profile. The MGD of a saw tooth is parallel to that of an adjacent sub-plate. For instance, the MGD of saw teeth at the edge of sub-plate 1 is parallel to the MGD of sub-plates 2 and 3. The saw tooth profile at the edge is not stable, and can further evolve into a sub-plate (this is discussed below). Thus, a saw tooth presents the initial state of a sub-plate.

In the thickness direction, the Ag_3Sn plate can be divided into two regions: (i) a transition zone that includes the active faces at the plate's edges; and (ii) the main body with quasi-uniform thickness. In the transition zone, there are generally four (sometimes two) active faces near the tip of a saw tooth or sub-plate. The active face has a flat and

smooth surface at the micro scale as shown in Fig. 2f. During the growth, Ag_3Sn can form on this existing surface in some order, maintaining the flat surface and resulting in a sharp blade at the edge. The transition zone is more active in growth. Its evolution controls the growth of the entire plate in the plane direction. In the quasi-uniform thickness zone, the growth in the direction perpendicular to the plate is completed layer by layer. This is demonstrated by several layers, with steps at their edge, formed on the plate as shown in Fig. 2f. Such growth maybe considerably slow, which results in the plate-like morphology of Ag_3Sn IMCs. To find out the internal lattice orientation of the plate, a transmission electron microscopy (TEM) sample is prepared on the tip of one plate in Fig. 2f. The TEM image and the corresponding diffraction pattern are given in Figs. 3a and b, respectively. Ag_3Sn IMCs have the orthorhombic crystal structure. The diffraction pattern and energy-dispersive X-ray (EDX) on TEM confirms that the thinning area is a single crystal of Ag_3Sn . The diffraction pattern also shows that the normals to the (110) and (001) planes are close to the two preferable growth directions (in plane) of Ag_3Sn plates, respectively.

Figure 2e presents the morphology obtained on the pad at Point C on Curve 1 (485 K), which is between the theoretical melting point and the actual solidification temperature of $\text{Sn}_{3.8}\text{Ag}_{0.7}\text{Cu}$ solder, and therefore presents the final morphology of Ag_3Sn plates in the solder bump. As can be seen, Ag_3Sn plates have grown to a considerably large size at this moment. Some plates reach several hundreds micrometers, which is comparable to the scale of the solder bump. One large plate in Fig. 2e shows that besides a significant growth of the Ag_3Sn plate along its MGD, a small saw-tooth structure at the external edge has grown into large ones. Some of them become individual sub-plates. This phenomenon is more

pronounced in Figs. 4e and 4f, which are also obtained at a temperature (485 K) below T_m (Point J on Curve 2). The long needle-like reactants in Fig. 2e is Cu_6Sn_5 IMCs.

4 Discussions

To find the formation scenario for Ag_3Sn plates, several more thermal conditions during reflow are investigated: (i) a continuous temperature increasing from T_m to Point F (538 K) following Curve 3 in Fig. 1b; (ii) dwelling at 518 K for about 25 mins from Point D to E in Fig. 1b; and (iii) secondary reflow of a solidified specimen (without spinning) to the maximum temperature (Point G, 527 K) of Curve 1 in Fig. 1b. No Ag_3Sn plates are observed in these tests. In the first two cases, Ag_3Sn plates are not generated. In the last one, Ag_3Sn that is generated during the first reflow is dissolved. Under conditions of the increasing temperature and dwelling, the substrate is consumed, which increases the Cu content in the liquid solder. According to the concept of local nominal composition (LNC) [13], the ratio of Sn to Ag remains the same in the “filler” material. Following this evolution, Ag_3Sn cannot be generated according to the SnAgCu equilibrium phase diagram. When the temperature decreases, Cu_6Sn_5 IMCs precipitate from the liquid solder at the interface [14], which consumes both Cu and Sn, and, correspondingly, increases the Ag content at the local area near the solder/substrate interface. When the composition reaches a certain value, Ag begins to precipitate in the form of Ag_3Sn IMCs. Therefore:

- (i) Ag_3Sn IMC plates are only formed under a decreasing temperature, and in the middle of the cooling stage rather than at the beginning;
- (ii) Ag_3Sn IMCs nucleate predominantly at the solder/substrate interface;

(iii) Under a condition of temperature increasing in the secondary reflow, interfacial CuSn IMCs are dissolved [14]; Solubility of Ag in the molten solder increases. Therefore, Ag_3Sn IMCs are also dissolved in the secondary reflow.

To verify this analysis, a different temperature profile, Curve 2 in Fig. 1b, is used for the tests to investigate the formation behaviour of Ag_3Sn IMCs. Again, Ag_3Sn IMCs is first found in the middle of the cooling stage (Point H, 501 K). Similar growth behaviour is achieved in the subsequent cooling stage as shown in Fig. 4. The temperature of Point I is 493 K. Figure 4c shows that Ag_3Sn plates are formed in all types of orientation with two or three sub-plates. The specific number of sub-plates is influenced by the orientation of the plate. As analyzed, there are two preferable growth directions for a plate. If one of these directions is parallel or nearly parallel to the Cu substrate, three sub-plates can be formed on one plate, two of them being directly connected to the Cu pad. In other orientations, two sub-plates are formed. Some of these features are consumed by a further growth as shown in Fig. 4e.

It should be noted that the experimental approach can only capture reactants that are still connected to the Cu substrate. There is possibility that Ag_3Sn IMCs are formed in the body of the liquid solder bump, but are removed during spinning.

5 Conclusions

This paper presents the formation behaviour of Ag_3Sn plates in the eutectic SnAgCu Pb-free solder bump during the entire process of reflow. The results show that under all investigated temperature conditions, including the increasing temperature, dwelling and secondary reflow, Ag_3Sn plates are only formed starting at the middle of the cooling stage

of the reflow. This explains why the high cooling rate can suppress their formation: it limits their growth time. The results also show that these plates nucleate preferably at areas near the solder/substrate interface. However, there is possibility that plates are formed away from the interface, and are not present due to the nature of the applied technique; In the plane, a Ag_3Sn plate has two preferable growth directions, which are close to the normals to the (110) and (001) planes, respectively.
