In a weakly collisional, low-electron-beta plasma, large-scale Alfvén turbulence transforms into inertial kinetic-Alfvén turbulence at scales smaller than the ion microscale (gyroscale or inertial scale). We propose that at such kinetic scales, the nonlinear dynamics tends to organize turbulent eddies into thin current sheets, consistent with the existence of two conserved integrals of the ideal equations, energy and helicity. The formation of strongly anisotropic structures is arrested by the tearing instability that sets a critical aspect ratio of the eddies at each scale a in the plane perpendicular to the guide field. This aspect ratio is defined by the balance of the eddy turnover rate and the tearing rate, and varies from $(d_e/a)^{1/2}$ to d_e/a depending on the assumed profile of the current sheets. The energy spectrum of the resulting turbulence varies from $k^{-8/3}$ to k^{-3}, and the corresponding spectral anisotropy with respect to the strong background magnetic field from $k_z \lesssim k_\perp^{2/3}$ to $k_z \lesssim k_\perp$.

Introduction. Large-scale low-frequency fluctuations in astrophysical systems such as the interstellar medium, the solar wind, and others, are associated with nearly incompressible magnetohydrodynamic (Alfvén) turbulence (e.g., Refs. [1–3]). The nonlinear Alfvén wave packets that compose such turbulence are three-dimensionally anisotropic: elongated along the strong background magnetic field and resembling current sheets in the perpendicular plane [1,4–21]. At scales smaller than the plasma microscales, such as the ion gyroscale or ion inertial scale, the shear-Alfvén modes transform into kinetic-Alfvén modes. The character of turbulence then changes qualitatively. Numerical and analytical studies suggest that the energy spectrum becomes relatively steep in the subproton range, with the spectral index between $-7/3$ and $-8/3$, and fluctuations become compressible, with density and magnetic field fluctuations comparable to each other (e.g., Refs. [22–27]). Available solar-wind measurements broadly agree with these predictions, with the measured energy spectral slope scattered around a slightly steeper value -2.8 [28–32].

Recently, it has been realized that magnetohydrodynamic (MHD) turbulence becomes affected by the tearing instability at scales larger than the usual Kolmogorov dissipation scale [33–37]. This means that the MHD energy spectrum inevitably gets modified by the tearing instability at small scales. This picture seems to be supported by recent numerical simulations [38,39], and it has also been extended to the case of a collisionless plasma [40–43]. The role of the tearing instability and reconnection at kinetic scales, however, remains significantly less understood. Our preliminary dimensional estimates [40] suggested that the spectrum of tearing-mediated kinetic-Alfvén turbulence should become relatively steep, with the spectral exponents ranging from $-8/3$ to -3. In the present Rapid Communication, we propose a self-consistent phenomenological theory of tearing-dominated kinetic-Alfvén turbulence.

Since large-scale Alfvén turbulence transforms into kinetic turbulence at small scales, kinetic-scale turbulence is important for energy dissipation in a weakly collisional plasma (e.g., Refs. [24,44,45]). In addition, kinetic-scale turbulence may be crucial for scattering plasma particles and, in particular, for shaping non-Maxwellian velocity distribution functions of the energetic electrons in the solar wind (e.g., Refs. [46,47]). Our study also provides a possible theoretical framework for the very recent measurements of electron-only reconnection events in the Earth's magnetosheath [48] by NASA's Magnetospheric Multiscale (MMS) mission [49]. Our results are consistent with these events being related to reconnection-mediated kinetic-Alfvén turbulence at subproton scales [40,50]. Indeed, the electron plasma beta is smaller than one in the Earth magnetosheath, meaning that the electron inertial scale, where the magnetic reconnection can operate, is larger than the electron gyroscale, where strong kinetic dissipation comes into play. It is also important to note that a similar ordering of the plasma parameters is also characteristic of the regions close to the solar corona (e.g., Refs. [51,52]), which will soon be studied by the recently launched NASA Parker Solar Probe mission (e.g., Ref. [53]).

Model. Kinetic-Alfvén dynamics retaining electron-inertia effects (the so-called inertial kinetic-Alfvén regime) have been investigated recently [14] (see also Refs. [54,55]). In the case when the fluctuations are highly oblique with respect to the uniform large-scale magnetic field $\mathbf{B}_0$, a closed two-field system of equations can be derived that describes the

*Corresponding author: boldyrev@wisc.edu

evolution of the magnetic fluctuations $\delta \mathbf{B}$. In this case $k_z \ll k_\perp$, so one can represent the fluctuating part of the magnetic field as $\delta \mathbf{B} = -\hat{z} \times \nabla \psi + \delta B_z \hat{z}$. We define the electron skin depth as $d_e = c/\omega_{pe}$, and introduce the dimensionless fields, $\psi' = \psi/(d_e B_0)$ and $b_z = \delta B_z/B_0$, which we will use henceforth, omitting the prime signs for notational simplicity. The resulting system of equations then takes the form [14]

$$\frac{1}{|\Omega_e|} \frac{\partial}{\partial t} \left(1 - d_e^2 \nabla_\perp^2\right) \psi$$
$$- d_e^4 [(\hat{z} \times \nabla b_z) \cdot \nabla] \nabla_\perp^2 \psi = -d_e \nabla_\parallel b_z, \quad (1)$$

$$\frac{1}{|\Omega_e|} \frac{\partial}{\partial t} \left(1 + \frac{2}{\beta_i} - d_e^2 \nabla_\perp^2\right) b_z$$
$$- d_e^4 [(\hat{z} \times \nabla b_z) \cdot \nabla] \nabla_\perp^2 b_z = d_e^3 \nabla_\parallel \nabla_\perp^2 \psi, \quad (2)$$

where $\beta_i = 8\pi n_0 T_i/B^2$ is the ion plasma beta (assumed order unity), and Ω_e is the electron cyclotron frequency. The nonlinearities in these equations enter through the terms in the square brackets, and through the field-parallel gradients in the right-hand sides, $\nabla_\parallel = \partial/\partial z - d_e(\hat{z} \times \nabla \psi) \cdot \nabla$. Since we are interested in the influence of the reconnection effects rather than the dissipation terms on the energy cascade, here we assume that the electron gyroradius is smaller than the electron inertial scale; this corresponds to the electron plasma beta, $\beta_e = 8\pi n_0 T_e/B^2 = 2\rho_e^2/d_e^2$, smaller than one. If the small electron gyroradius terms need to be retained, our system (1) and (2) has to be modified as it is done in Refs. [54,55]; such an analysis is, however, beyond the scope of the present work as we concentrate only on the scales above the electron gyroradius (and below the ion gyroradius).

Equations (1) and (2) have two ideal second-order invariants: energy and helicity. At scales large than the electron inertial scale, these invariants have the forms [56]

$$E = \frac{1}{2} \int \left[\left(1 + \frac{2}{\beta_i}\right) b_z^2 + d_e^2 (\nabla_\perp \psi)^2 \right] d^3 x, \quad (3)$$

and

$$H = \int b_z \psi \, d^3 x. \quad (4)$$

Role of helicity. The tendency of kinetic-Alfvén turbulence to form current sheets is known from numerical simulations and observations (e.g., Refs. [25,27,50,57,58]). Let us discuss how these may come about.

An analytical description of inertial kinetic-Alfvén turbulence has to account for both the energy and the helicity invariants. In a turbulent cascade that proceeds from large (MHD) to kinetic scales, the value of the helicity invariant [Eq. (4)] is set by the turbulence at the ion gyroscale. However, in the presence of the energy cascade, helicity cannot cascade to large wave numbers (e.g., Refs. [1,59]). The selective decay of energy in the presence of conserved helicity can lead to the formation of structures, which can be found from minimizing the functional

$$F = E - \mu H, \quad (5)$$

where μ is the Lagrange multiplier. We thus obtain

$$-d_e^2 \nabla_\perp^2 \psi = \mu b_z, \quad (6)$$

$$b_z = \mu (1 + 2/\beta_i)^{-1} \psi. \quad (7)$$

As can be verified, such configurations imply that $E = \mu H$, and the parameter μ is proportional to the inverse scale of the structure. The configurations minimizing E at constant H correspond to small μ, which reflects the tendency of decaying turbulence to create large-scale helical structures. A similar relaxation to large-scale helical structures is known to exist in magnetohydrodynamic turbulence (e.g., Refs. [1,60]).

One can, however, check that solutions of Eqs. (6) and (7) correspond to vanishing nonlinearities in Eqs. (1) and (2). In a turbulent steady state, however, the nonlinearities cannot vanish as they are responsible for a constant energy flux over scales. We may nevertheless expect that structures generated in such turbulence should qualitatively resemble those described by Eqs. (6) and (7); they should lead to reduced, but not identically zero, nonlinear terms. Let us denote the characteristic wave numbers of such a structure in the x-y plane as k_x and k_y, which implies $\mu^2 \sim k_x^2 + k_y^2$. The helicity then scales as $H \sim \mu \psi^2$, while the nonlinear terms are proportional to $k_x k_y \psi^2$. The nonlinear interaction is minimized at constant helicity when one of the wave numbers becomes significantly smaller than the other, which is consistent with the formation of very anisotropic current sheets.

Let us denote the shorter dimension of such a current sheet as $a \sim 1/k_x$ and the longer one as $l_y \sim 1/k_y \gg a$. A fluctuating magnetic field $\mathbf{b}_\perp = -\hat{z} \times \nabla \psi$ corresponding to such a structure is aligned with the y direction within a small angle $\sim a/l_y$, while its magnitude varies on a scale a in the x direction. This, in general, reduces the nonlinear terms in Eqs. (1) and (2) by a factor $\sim a/l_y$ with respect to their dimensional estimates. For instance, the nonlinear term in the right-hand side of Eq. (1) is estimated as $(\hat{z} \times \nabla \psi) \cdot \nabla b_z \sim (a/l_y) \psi b_z / a^2$.

Strongly anisotropic current sheets are thus to be expected in inertial kinetic-Alfvén turbulence. Motivated by the recent studies mentioned in the Introduction, we may now inquire as to their stability to the tearing mode.

Tearing instability at subproton scales. In order to formulate our theory of kinetic-Alfvén turbulence mediated by the tearing instability, we first need to analyze the tearing mode arising in a very anisotropic current sheet described by Eqs. (1) and (2). We introduce local coordinates such that the x and y axes are across and along the reconnecting current sheet, respectively, and z is along the large-scale field B_0. We denote the thickness of the current sheet (in the x direction) as a, its length (in the y direction) as $\sim 1/k_0$, and assume that it is uniform in the z direction.

We represent the reconnecting part of the magnetic field in such a structure as $\delta \mathbf{B}_\perp = b_a f(x) \hat{y} + \mathbf{b}_\perp(x, y)$, where $f(x)$ describes the profile of the reconnecting (sheared) field, and $\mathbf{b}_\perp = -\hat{z} \times \nabla \tilde{\psi} = (\partial \tilde{\psi}/\partial y, -\partial \tilde{\psi}/\partial x)$ is a small perturbation. Regarding the sheared part of the parallel magnetic field, we may assume that it is negligible, so that only the tearing perturbation is left, $b_z = \tilde{b}_z(x, y)$ [61]. Following standard procedure, we Fourier transform the perturbations in the

y direction,

$$\tilde{\psi} = \bar{\psi}(\xi) \exp(ik_0 y) \exp(\gamma t), \quad (8)$$

$$\tilde{b}_z = -i\bar{b}_z(\xi) \exp(ik_0 y) \exp(\gamma t), \quad (9)$$

where $\xi = x/a$. As we will see, the fastest growing tearing mode is the largest mode that can fit in an eddy, i.e., its length scale in the y direction is $\sim 1/k_0$. In what follows, we use only the variables $\bar{\psi}$ and $\bar{b}_z$ and omit the overbar sign. Linearizing Eqs. (1) and (2) with respect to the small perturbations, we obtain the system of equations governing the tearing mode in the kinetic-Alfvén case,

$$\lambda\psi - fb_z = \lambda\frac{d_e^2}{a^2}\psi'', \quad (10)$$

$$-f(\psi'' - \epsilon^2\psi) + f''\psi = \lambda b_z'' - \lambda\frac{a^2}{d_e^2}\left(1 + \frac{2}{\beta_i}\right)b_z, \quad (11)$$

where the dimensionless growth rate is $\lambda = \gamma/(k_0 v_{A,e})$, the *electron*-Alfvén speed is defined with respect to the reconnecting part of the magnetic field, $v_{A,e} = b_a/\sqrt{4\pi m_e n_0}$, and all the derivatives are with respect to ξ. As can be verified after the tearing-mode solution is obtained, λ is a small parameter. It also turns out that the fastest growing tearing mode corresponds to sufficiently anisotropic current sheets, so that $\epsilon \equiv k_0 a$ is a small parameter as well.

Due to the smallness of the parameter λ, the right-hand sides in Eqs. (10) and (11) are relevant only in the inner region of the mode, where the derivatives are large. As will be shown later, the inner scale δ_{in} is much smaller than d_e in the case of a small tearing parameter [the so-called Furth-Killeen-Rosenbluth (FKR) regime [62]], and it approaches d_e in the case of a large tearing parameter (the so-called Coppi regime [63,64]). So, in our analysis we may neglect the last term in the right-hand side of Eq. (11) as this will not qualitatively change the solution.

A useful observation is that Eqs. (10) and (11) describing the kinetic-Alfvén tearing instability are then structurally identical to the MHD tearing equations [e.g., Eqs. (11) and (12) in Ref. [65]] with the only modification that the magnetic diffusivity η should be replaced by γd_e^2 in the kinetic-Alfvén case (see a similar discussion in, e.g., Refs. [66–68]). This reflects the fact that in our case of a collisionless plasma, reconnection is driven by electron inertia rather than resistive effects. This allows us to straightforwardly derive the growth rate and the corresponding inner scale of the tearing instability.

The results depend on the assumed profile of the reconnecting magnetic field $f(\xi)$. As in previous work (e.g., Refs. [35,40,65]), we consider two plausible profiles that yield qualitatively different scalings of the tearing mode: the Harris profile [69], $f(\xi) = \tanh(\xi)$; and a sinusoidal profile, $f(\xi) = \sin(\xi)$. For the Harris profile, the tearing growth rate in the low Δ' (FKR) regime is

$$\gamma \sim \frac{v_{A,e}}{a}\frac{1}{(k_0 a)}\left(\frac{d_e}{a}\right)^3, \quad (12)$$

and the corresponding inner scale is

$$\delta_{\text{in}} \sim d_e\left(\frac{d_e}{a}\right)\frac{1}{(k_0 a)}. \quad (13)$$

Both the growth rate and the inner scale increase as the anisotropy parameter $k_0 a$ decreases. The anisotropy of the FKR mode cannot, however, be arbitrarily large. The FKR solution is applicable when $k_0 a \gg d_e/a$, which justifies our assumption that the inner scale of the tearing mode is smaller than the electron inertial scale. At $k_0 a \sim d_e/a$, the FKR regime crosses over to the Coppi regime (a large Δ' regime), at which point the tearing mode has the fastest growth rate

$$\gamma_* \sim \frac{v_{A,e}}{a}\left(\frac{d_e}{a}\right)^2, \quad (14)$$

and the inner scales approaches d_e.

For the sinusoidal magnetic profile, the FKR tearing growth rate is given by

$$\gamma \sim \frac{v_{A,e}}{a}\frac{1}{(k_0 a)^3}\left(\frac{d_e}{a}\right)^3, \quad (15)$$

and the corresponding inner scale is

$$\delta_{\text{in}} \sim d_e\left(\frac{d_e}{a}\right)\frac{1}{(k_0 a)^2}. \quad (16)$$

The FKR regime is applicable when $k_0 a \gg (d_e/a)^{1/2}$; it transitions to the Coppi regime at $k_0 a \sim (d_e/a)^{1/2}$, at which scale the tearing rate reaches its maximal value

$$\gamma_* \sim \frac{v_{A,e}}{a}\left(\frac{d_e}{a}\right)^{3/2}. \quad (17)$$

The corresponding inner scale at this point becomes comparable to d_e.

We now use the tearing growth rates and anisotropies of the corresponding tearing modes just derived to address the influence of the tearing instability on kinetic-Alfvén turbulence.

Kinetic-Alfvén turbulence mediated by tearing instability. The helicity-conservation arguments presented earlier suggest that a typical turbulent eddy in the inertial interval ($d_i \gg a \gg d_e$) is anisotropic in the plane perpendicular to the local mean magnetic field, i.e., $k_0 \ll 1/a$. From Eqs. (1) and (2) we may then estimate the characteristic nonlinear time of such a structure as

$$\gamma_{nl} \sim k_0 v_{A,e}\left(\frac{d_e}{a}\right). \quad (18)$$

Obviously, as the anisotropy of the structure increases (that is, k_0 decreases), the nonlinear rate (18) will decrease, while the tearing growth rate, Eq. (12) or (15), will increase. There is, therefore, a limitation on the anisotropy of the structures that can be created by turbulence; very anisotropic structures will be destroyed by the tearing instability. By equating the nonlinear rate (18) to the tearing rate (12) or (15), one finds that, remarkably, the rates balance when $\gamma = \gamma_*$ in both cases. The evolution rate of such a critically anisotropic eddy will therefore be governed by the corresponding fastest tearing rate.

In other words, conservation of helicity subject to energy dissipation suggests the tendency of the turbulence to form elongated, quasi-one-dimensional structures. These, however, cannot survive the tearing instability if their field-perpendicular anisotropy is such that the fastest tearing mode fits in such a structure. We conjecture, therefore, that the

tearing instability is the physical mechanism that sets the eddies' aspect ratio in the field-perpendicular direction.

From Eq. (3) we expect $b_z \sim \nabla_\perp \psi \sim b_a$ at each scale a in the inertial range of the turbulence. We can estimate the energy flux at this scale as $\varepsilon \sim b_a^2 \gamma_* = $ const. We then derive

$$b_a \propto a d_e^{-2/3}, \tag{19}$$

$$b_a \propto a^{5/6} d_e^{-1/2}, \tag{20}$$

for the tanh and sin profiles, respectively. The corresponding Fourier energy spectra of tearing-mediated kinetic-Alfvén turbulence are then [40]

$$E(k_\perp)dk_\perp \propto k_\perp^{-3} dk_\perp, \tag{21}$$

$$E(k_\perp)dk_\perp \propto k_\perp^{-8/3} dk_\perp. \tag{22}$$

Our model also allows us to derive the anisotropy of the turbulent eddy with respect to the background magnetic field. The linear frequency of the kinetic-Alfvén wave, $\omega = k_z V_{A,e} k_\perp d_e (1 + 2/\beta_i)^{-1/2}$, where $V_{A,e}$ is a constant electron-Alfvén velocity defined with the background field B_0. Balancing this equation with the nonlinear evolution rate γ_* at scale $a \sim 1/k_\perp$ (the critical balance condition), we find using Eqs. (19) and (20) the field-parallel size of the eddy,

$$k_z \propto k_\perp, \tag{23}$$

$$k_z \propto k_\perp^{2/3}, \tag{24}$$

for the tanh and sin cases, correspondingly.

The energy spectra (21) and (22) are not far from those obtained from direct solar-wind measurements, and they seem to be broadly consistent with numerical simulations. Measurements of the guide-field anisotropy are, however, more subtle and they are currently less definitive compared to the measurements of the spectra. Existing phenomenological models, not involving tearing effects, predict energy spectra ranging from $-7/3$ to $-8/3$ and anisotropy relations from $k_z \propto k_\perp^{1/3}$ to $k_z \propto k_\perp^{2/3}$ (e.g. Refs. [25,70,71]); the steepening of the spectrum beyond $-7/3$ is attributed in these models to either the Landau damping or intermittency effects. Our theory, on the contrary, does not invoke dissipation effects or intermittency; the mechanism we propose is different and complementary to the previously developed models. According to our results, steeper energy spectra and weaker k_z vs $k_\perp$ anisotropy may be indicative of the presence of tearing effects in kinetic-Alfvén turbulence.

Discussion and conclusion. We have proposed a conceptual framework to describe a turbulent cascade in the inertial kinetic-Alfvén regime—relevant to the Earth's magnetosheath region and to the solar wind in the proximity of the solar corona. The existence of two ideal invariants of the model equations (energy and helicity) is demonstrated to imply the formation of current sheets, whose instability to the tearing mode becomes a critical physical mechanism governing turbulence at these scales. As in previous recent work [35,40], we conjecture that the turbulent cascade is determined by the timescale associated with the fastest tearing instability at each scale. This assumption enables us to compute the expected

energy spectra, Eqs. (21) and (22) for two idealized, limiting-case magnetic field configurations: a hyperbolic tangent (Harris) and a sinusoidal profile. Reconnecting magnetic fields occurring in realistic turbulence are probably described by profiles ranging between these two configurations, suggesting that the energy spectra power-law exponent may in fact lie between $-8/3$ and -3.

We note that our analysis is also applicable to the turbulence of inertial whistler modes, which generally exist in the same environments as kinetic-Alfvén modes but at higher frequencies. Although these modes belong to a different branch of the plasma dispersion relation and exist at frequencies higher than those of kinetic-Alfvén modes, the equations governing nonlinear oblique whistler modes are structurally identical to the equations governing the kinetic-Alfvén modes. As can be shown (e.g., Ref. [14]), the whistler equations can be obtained from system (1) and (2) if one neglects the term $1/\beta_i$. Our theory is, therefore, applicable to the systems described by electron MHD as well.

It is worth analyzing our results in the context of MMS' observations of "electron-only" reconnection [48]. Note first that any reconnection event occurring in the framework described by Eqs. (1) and (2) will have a typical outflow velocity of $v_{A,e}$ (the electron Alfvén speed computed with the reconnecting component of the magnetic field), consistent with the observations. Second, we can use our model to compute the scale below which such reconnection cannot involve the ions. Indeed, the length of the current sheet (eddy), set by the tearing mode, is $1/k_0 \sim a^2/d_e$ for the Harris profile, or $1/k_0 \sim a(a/d_e)^{1/2}$ for a sinusoidal profile. Therefore, requiring $1/k_0 \ll d_i$ results in $a \ll \sqrt{d_i d_e}$ or $a \ll d_i^{2/3} d_e^{1/3}$, respectively. It is encouraging that the measured thickness of the reconnection layer is $a \sim 4 d_e$, compatible with these (rough) estimates.

Lastly, we remark that our findings have important implications for numerical studies of turbulence at these scales. First, the inner scale of the tearing mode occurring in *any* eddy in the range $d_i \gg a \gg d_e$ is approximately d_e. Second, helicity conservation (an essential ingredient in the turbulent cascade model that we propose here) implies that correctly capturing this range requires a consistent determination of helicity at the ion scales—which, in a real plasma, is naturally set by the cascade through the MHD scales. In other words, the usual numerical strategy of studying kinetic-scale turbulence with turbulent forcing imposed at around the ion scales may need to be reconsidered. The implication is that numerical simulations of inertial kinetic-Alfvén turbulence may need to range from large MHD scales all the way to sub-d_e scales to correctly capture the relevant physical mechanisms at play—a rather demanding requirement.

[37] Probably the earliest study of the role of reconnection in MHD turbulence can be found in Ref. [72]. This work, however, was based on the Iroshnikov-Kraichnan model of MHD turbulence [73,74], which was later understood to be incorrect (e.g., Refs. [75–77]). A more detailed analysis of the results of Ref. [72] and their comparison to Refs. [33,34], can be found in Ref. [65].

[56] For completeness, the full expressions for the energy and generalized helicity, applicable at all scales, are $E = \frac{1}{2} \int [b_z(1 + \frac{2}{\beta_i} - d_e^2 \nabla_\perp^2)b_z - d_e^2 \nabla_\perp^2 \psi(1 - d_e^2 \nabla_\perp^2)\psi] d^3x$, and $H = \int (1 + \frac{2}{\beta_i} - d_e^2 \nabla_\perp^2)b_z \cdot (1 - d_e^2 \nabla_\perp^2)\psi \, d^3x$.

[61] It can be demonstrated that the presence of sheared component of δB_z is mathematically analogous to the presence of a sheared velocity field. We have recently shown, however, that it does not qualitatively affect the fastest growing tearing mode [65].
