# THE OUTSIDER'S METHOD, AN OUTLIER DETECTION SYSTEM AS LAWYER OF QUALITY CONTROL TOOL AT CENTRAL BALANCE SHEET DATA OFFICE

by

ANTONIO LORENTE SALMERÓN

THESIS presented as requirement for obtaining the Master's degree in Statistics and Information Management

Advisor: Professor Jorge Miguel Ventura Bravo

## DEDICATION

To my beloved Mother ("Puchum") and Wife (Vicky) and to my amazing sons Antonio, Carlos and Pablo you are the meaning of my life.

### ABSTRACT

Handling large amounts of granular data of non-financial corporations' balance sheet and profit and loss statement to fulfil the assigned functions of the Central Balance Sheet Data Office (CBSDO) requires the design and implementation of various layers of quality control that combined with the review of expert analysts to ensure databases with a statistical quality at the expected height of the Statistics Department of an institution such as Banco de España.

Recently, under the umbrella of the quality control systems of the CBSDO, a new outlier detection system has been designed and implemented, the "**Outsider's method**", through which those observations that deviate considerably from the behaviour of companies regarding sector clustering, according to NACE classification, and size, will be eliminated from database and will maintain those that still have a behaviour that is far from standard but consistent with the reality of mentioned Non-financial corporations.

The purpose of this project is to explain the methodology of this new system, obtain results for different extractions periodically established over several years, analyse these results, and finally test the system's validity by comparing it with other detection methods traditionally used by other statistical entities.

#### **KEYWORDS**

Non-financial corporations; CBSDO; outlier; quality control, clustering, validate

JEL Classification: C40, C55, C58

#### **INTRODUCTION**

#### **BACKGROUND AND PROBLEM IDENTIFICATION**

#### 1.1.1. Background:

This project report will be carried out in the Banco de España, more specifically in the Central Balance Sheet Data Office (CBSDO) that belongs to the Statistics Department which in turn is part of the General Directorate of Economy, Statistics and Research

Banco de España is the national central bank, within the framework of the Single Supervisory Mechanism (SSM), the supervisor of the Spanish banking system along with the European Central Bank. Its activity is regulated by the Law of Autonomy of the Banco de España.

Banco de España is one of the members of the EUROSYSTEM that is the monetary authority of the euro area and comprises the European Central Bank (ECB) and the national central banks of the Member States whose currency is the euro. Its primary objective is to maintain price stability.

One of the main tasks entrusted to the General Directorate of Economy, Statistics and Research is Compiling, analysing and disseminating the statistics entrusted to the Banco de España.

Banco de España's Central Balance Sheet Data Office is a service that analyses the economic and financial information voluntarily submitted by Spanish non-financial corporations, which improves the knowledge about these corporations, enables financial accounts for the Spanish economy to be drawn up, and which analyses corporate performance and the effects of monetary policy measures on corporate financing and results.

The European Committee of Central Balance-Sheet Data Offices (ECCBSO) is a consultative body created in 1987 by a group of European National Central Banks (NCBs) managing Central Balance Sheet Data Offices (CBSOs). Banco de España's CBSDO is one of its members. The Committee has developed a database named Bank for Accounts of Companies Harmonized (BACH); Is a database containing harmonized annual accounts statistics of European non-financial enterprises. Hence, the database was conceived as a useful tool both for country comparisons and to analyse the structure and performances of the non-financial companies in Europe.

RSE database provides information for the comparative analysis of individual corporations with aggregates of non-financial corporations, enabling the corporation to be positioned in the crossmatching of sector of activity and size in which the corporation fits. The RSE database offers information on 29 significant ratios for economic and financial analysis of the aggregates of non-financial corporations obtained from the cross-matching of three characteristics: activity, size and country.

#### 1.1.2. Problem Identification

To ensure the quality of CBSDO products, that they are constructed from micro data, it is necessary to implement several quality controls, one of them consist of eradicate those observations that that can distort aggregated information due to excessive specific weight in their respective samples and subsamples.

There are many definitions of outlier that can be found through the literature, for example, an outlier is generally considered to be a data point that is far outside the norm for a variable or population (e.g., Jarrell, 1994; Rasmussen, 1988; Stevens, 1984). Hawkins described an outlier as an observation that "deviates so much from other observations as to arouse suspicions that it was generated by a different mechanism" (Hawkins, 1980). Outliers have also been defined as values that are "dubious in the eyes of the researcher" (Dixon, 1950) and contaminants (Wainer, 1976).

As a result, they can potentially skew or bias any analysis performed on the dataset. It is therefore very important to detect and adequately deal with them.

Outliers can arise from several different mechanisms or causes. Anscombe (1960) sorts outliers into two major categories: those arising from errors in the data, the ones that we want to wipe out, and those arising from the inherent variability of the data, the ones that we are very interested in keep because they provide very relevant information about the behaviour of the population and can allow us to explain various phenomena, which without them would not be possible..

Not all outliers are illegitimate contaminants, and not all illegitimate scores show up as outliers (Barnett & Lewis, 1994).

It is therefore important to consider the range of causes that may be responsible for outliers in a given data set:

- Outliers from data errors. Outliers are often caused by human error, such as errors in data collection, recording, or entry.
- Outliers from sampling error. Another cause of outliers is sampling. It is possible that a few members of a sample were inadvertently drawn from a different population than the rest of the sample.
- Outliers from faulty distributional assumptions. Incorrect assumptions about the distribution of the data can also lead to the presence of suspected outliers (e.g., Iglewicz & Hoaglin, 1993)
- Outliers as legitimate cases sampled from the correct population. Finally, it is possible that an outlier can come from the population being sampled legitimately through random chance. It is important to note that sample size plays a role in the probability of outlying values.

Within a normally distributed population, it is more probable that a given data point will be drawn from the most densely concentrated area of the distribution, rather than one of the tails (Evans, 1999; Sachs, 1982). As a researcher casts a wider net and the data set becomes larger, the more the sample resembles the population from which it was drawn, and thus the likelihood of outlying values becomes greater.

The outliers should only be discarded when we are completely sure they were a result of an experimental or transcription error. Otherwise removing outliers may result in underestimated variance.

#### **STUDY OBJECTIVES**

John Tukey (1977) introduced several methods for exploratory data analysis, one of them was the Boxplot. The Boxplot is a graphical display where the outliers appear tagged. Two types of outliers are distinguished:

An observation "x" is declared an extreme outlier if lies outside of the interval (Q1-3\*IQR, Q3+3\*IQR). Notice that the center of the interval is (Q1+Q3)/2 and its radius is 3.5\*IQR, where IQR=Q3-Q1, called the Interquartile Range, is a robust estimator of variability.

An observation x is declared a mild outlier is lies outside of the interval (Q1-1.5I\*QR, Q3+1.5\*IQR). The interval has a center at (Q1+Q3)/2 and its radius is 2\*IQR.

The numbers 1.5 and 3 are chosen by comparison with a normal distribution.

Following Tukey's theory, the two methods selected to validate the "outsider's method" are the interquartile range method used by the European Central Bank and EUROSTAT or the exclusion of data below percentile 3 and over percentile 97 as in the Bank for the Accounts of Companies Harmonized – database that contains aggregated and harmonized information on the annual accounts of the non-financial corporations of selected European countries (BACH).

The purposes of this project are:

- 1. To explain the methodology of this new system of detecting outliers, the "outsider's method".
- 2. Obtain results for different extractions periodically established over several years (bases).
- 3. Analyse these results, by a regular report system. And finally,
- 4. Test the system's validity by comparing it with other more traditional detection methods and used by other statistical entities.

#### STUDY RELEVANCE AND IMPORTANCE

At present day, there are numerous sources of information, databases, press, internet, and they have become a source of inspiration for numerous studies, articles and reports.

Not all this information can be considered reliable, nor should it be used if its methodology is not previously known and its quality contrasted.

Banco de España's CBSDO deals every year with more than eight hundred thousand balance sheets and profit and loss statement and we have complementary information voluntarily contributed by more than ten thousand non-financial companies, we also download from mercantile registrars and from companies' websites annual reports, in order to check or solve doubts regarding their annual accounts. All this information is checked by expert analysts and by in-house developed programs that ensure the coherency and consistency of the data received.

Even with all this, to pursue the purpose of providing the service of the economic and financial information of Spanish non-financial corporations, it is required to implement quality control mechanisms, such us the revision by an expert analyst of certain parameters of the accounting and corporate information provided. But this is not enough, due to this huge amount of interconnected information it is necessary to include another type of quality control based on statistics theory to improve the quality of CBSDO databases.

One of the most cited definitions in the literature regarding what an outlier is, is stated by David Hawkins in his monographs on applied statistics and probability in 1980: "An outlier is an observation that deviates so much from other observations that it arouses the suspicion of having been generated by a different mechanism" (Hawkins, 1980)

Based on statistics theory on outliers, recently it has been developed a new lawyer of quality control named "outsider's method" which it is intended to identify the most anomalous observations and, at the same time, their contribution, with respect to the node composed of the breakdown of sector and size, so that what is involved is to eliminate those observations that are really errors; while on the contrary, those observations will be maintained which, even when they deviate from the normal behaviour of their distribution, do correspond to a real and therefore explanatory behaviour of the reality of this phenomenon.

This outlier detection method, the "outsider's method" is based in sophisticated algorithms.

#### METHODOLOGY

All the micro data used in this report comes from Banco de España's Central Balance Sheet Data Office (CBSDO). This data is obtained from two databases:

- The CBB database created drawing on the annual accounts filed with the Mercantile Registers; Under the cooperation agreements signed with the Ministry of Justice and the Spanish Association of Property and Mercantile Registrars, Banco de España' s Central Balance Sheet Data Office and the Mercantile Registries have been working together to facilitate the statistical use of the annual accounts that companies are legally required to file with the mercantile registry of the province in which their registered office is located.
- The CBA database which compiles information voluntarily reported by corporations in a purpose-designed questionnaire.

Both databases are aggregated and integrated into a data source which, under the name of CBI, provides for the monitoring of aggregate results, with breakdowns by size and sector of activity of the Spanish non-financial corporations.

#### The use of this micro-data is strictly confidential and only can be used for statistical use.

#### **DEFINITION OF NODE**

In order to classify and group the microdata of the CBA and CBB databases and, therefore, of the CBI aggregate, two sector and size cut variables are established, sector and size:

a) Sector: according to NACE classification, at CBSDO fourteen sectors are identified, namely:
Table 3.1 Selected sectors according to NACE classification

SECTORS ACCORDING TO NACE CLASIFICATION
AGRICULTURE, FORESTRY AND FISHING
EXTRACTIVE INDUSTRIES
MANUFACTURING INDUSTRIES
SUPPLY OF ELECTRICAL POWER, GAS, STEAM AND AIR CONDITIONING
WATER SUPPLY, SANITATION ACTIVITIES, WASTE MANAGEMENT AND DECONTAMINATION
CONSTRUCTION
WHOLESALE AND RETAIL; REPAIR OF MOTOR VEHICLES AND MOTORCYCLES
TRANSPORTATION AND STORAGE
HOSTELRY
INFORMATION AND COMMUNICATIONS
REAL ESTATE ACTIVITIES
PROFESSIONAL, SCIENTIFIC AND TECHNICAL ACTIVITIES
ADMINISTRATIVE ACTIVITIES AND AUXILIARY SERVICES
OTHER SERVICES

- **b)** Size: according to the European recommendation four sizes can be identified:
  - i) Large (including public and dependent),
  - ii) Medium,
  - iii) Small (excluding micro) and
  - iv) Micro-enterprises

Table 3.2	Sizes according	European	recommendation

	SIZE CATEGORY									
VANIADLE	LARGE	MEDIUM	SMALL	MICRO						
NUMBER OF EMPLOYEES	N > 250	50 < N ≤ 250	10 < N ≤ 50	N < 10						
TURN OVER (millions)	TO > 50	10 < TO ≤ 50	2 < TO ≤ 10	TO < 2						
TOTAL ASSETS (millions)	TA > 43	10 < TA ≤ 43	2 < TA ≤ 10	TA < 2						

The node is defined as the crossing between sector and size, therefore for the project a total of 56 nodes will be identified.

#### VARIABLES TO ANALYZE

RSE is a database that compiles sectoral rates of non-financial corporations and provides information for the comparative analysis of individual corporations with aggregates of non-financial corporations, enabling the corporation to be positioned in the cross-matching of sector of activity and size in which the corporation fits.

The RSE database offers information on 29 significant ratios for economic and financial analysis of the aggregates of non-financial corporations obtained from the cross-matching of three characteristics: activity, size and country.

In this project seventeen ratios have been selected to analyse their distributions, search for anomalous observations try to identify and study them, the observations considered mistakes will be eliminated from database and those that still have a behaviour that is far from standard but consistent with the reality of mentioned will be maintained at database.

In the table 3.3 can be found a small methodological box with the name, abbreviations and content for the seventeen selected ratios (three debt ratios (E1, E2 and E3), four margin ratios (M1, M2, M3 and M4), three profitability (R1, R2 and R3), two of average periods (AVCP and AVPP) and five rates of variation (NA, FC, GOP, ONP and GVA).

# Table 3.3RSE selected ratios

RATIOS AND	RATES OF VARIATION ANALYZED TO DETECT OUTLIERS						
	E1 : Interest-bearing borrowing / Net Assets						
DEBT RATIOS	E2 : Interest-bearing borrowing / (Gross operarting profit + financial revenue)						
	E3 : Financial costs / (Gross operarting profit + financial revenue)						
	M1: GVA / Value of Output						
MARGIN RATIOS	M2: GOP / Value of Output						
	M3: GOP / GVA						
	M4: Profit Loss of the year / GVA						
AVERAGE PERIODS	ACCP (Average Customer Collection Period) Average Customer Balance / Turnover ASPP (Average Supplier Payment Period)						
	Average Supplier Balance / Purchases						
	R1 = (ONP + Financial costs) / Net Assets						
RATIOS	R2 = Financial costs / Interest-bearing borrowing						
	R3 = Ordinary Net Profit / Equity						
	NA (Net Assets)						
RATES	FC (Financial Costs)						
of	GOP (Gross Operating Profit)						
VARIATION	ONP (Ordinary Net Profit)						
	GVA (Gross Value Added)						

# "OUTSIDER'S METHOD" SYSTEM SELECTED BY CBSDO TO DETECT OUTLIERS AT CBB DATABASE

The method to be applied for the CBB database in the Banco de España's Central Balance Sheet Data Office is going to be named the "Outsider's method" it will be applied to the nodes formed by the crossing between the fourteen sectors according to NACE classification and the four sizes of the European recommendation and for each of the seventeen RSE ratios selected.

#### "PHI" FUNCTION

The aforementioned method is basically that, for each observation and each ratio, the function  $\phi$  is calculated as the difference between the value of the ratio for the node and its marginal value, that is, the value it would take excluding observation, see Box 4.1.

This magnitude expresses in some way the contribution of each observation to its node implicitly pondering its contribution to the numerator, its contribution to the denominator and the quantile in which it is found. The absolute value expresses its greater or lesser contribution and the sign if its inclusion increases or decreases the ratio

#### Box 4.1 $\varphi$ Function

R for Ratio N for Numerator D for Denominator i for each company j for each node

By ordering the distribution in a decreasing way, to the left are the observations that increase the ratio significantly (positive tale), in the center the observations that are no relevant to be analysed, (zone zero) and to the right, those that make the ratio decrease significantly (negative tale), so that, in order to find atypical data, it is sufficient to study the tales to analyse the whole node.

#### Chart 4.1 The tales, and the zone cero, the $\varphi$ function areas

OUTLIER

#### DEFINITION

(Barnett and Lewis, 1994) indicate that an outlying observation, or outlier, is one that appears to deviate markedly from other members of the sample in which it occurs.

(Johnson, 1992) defines an outlier as an observation in a data set which appears to be inconsistent with the remainder of that set of data.

In our project, the problem consists of finding those observations of the tales of the distribution that behave very differently from the observations closest to it, for which the empirical study, twenty observations have been considered sufficient.

First analysis shows the masking effect produced by an extreme outlier in the rest of the measurements and the large differences in level observed between them. To solve the first problem the function  $\phi$  was recalculated for the truncated distributions and for the second one a new function was defined in terms of differences.

For each tail it was compared with its regression line and the distance between the two curves for each observation was measured in order to detect outliers when comparing it with a threshold. It was observed that, although the curves were adjusted to a very low number of schemes, there was a great difference in levels, which would require different thresholds.

Given the difficulty of empirically setting a threshold for each ratio and node, parameterize the threshold by size, ratio, sector was replaced by number of observations of the node, the possibility of comparing each observation not with an external threshold, but with an appropriate statistic was evaluated so that it is the tail itself that determines the threshold.

The fact that what is relevant, is the comparison of the observation with the immediate ones to it, excludes any order statistic, which drive us to use the arithmetic mean. In addition, as several

outliers might be found is also discarded and for the same reason the comparison with the rest of the non-outlier's part.

Fixed the statistic as the average of the tail and defined the outlier as that observation that exceeds more than ten times the average, it remains to solve the problem of excessive weight that may have in the same outlier, for what is proposed to increase the tails to fifty observations.

The results obtained were satisfactory for the tails containing all the observations, but insufficient for those nodes in which they do not have enough observations, these tails can only reach a very low number of elements.

To solve this problems, the arithmetic mean was replaced by the geometric mean and multiplied it by a corrective coefficient for the nodes with not enough observations, which are fixed, so that the initial condition for the most usual case of tails with a single outlier and twenty observations is equivalent to the previous one of ten times the average.

To simplify the calculations, logarithms are taken in the  $\phi$  function and the "Ind" (Ind comes from index) function is defined as:

#### Box 4.2 "Ind" function

(iv)

Therefore, *those observations in which their "Ind" function are greater than one are defined as outliers*.

#### **EXTRACTIONS**

The CBSDO carries out four extractions of information from its CBB database throughout the year (base), subjecting the outlier's detection procedure to hundreds of thousands of companies before preparing their statistical products:

- October of the year n, to obtain the **advance** information used in the Annual Report, and the BACH and RSE databases, for the last available observation (n-1).
- February of the year n + 1, to obtain the aggregates that are used in the product **MENF** (Multiplier of Non-Financial Companies), which are the source of the Financial Accounts of the Spanish Economy, and of the National Accounts of Spain.
- June of the year n + 1, for updating the **BACH and RSE** databases.
- October of the year n + 1, for the definitive (**final**) sample of the data of year n-1 that are presented in the Annual Report.

So, every October we obtain two different extractions:

- 1) the final sample of the previous year base (n-1), and
- 2) The advance sample of current year base (n).

Data collected from 2015 Advance sample to 2017 Advance sample, data of more than seven hundred thousand companies every year (base) distributed as table 4.1 shows:

YEAR	SAMPLE	N° of COMPANIES
2.015	AVANCE	317.116
2.015	MENF	594.130
2.015	BACH_RSE	668.230
2.015	FINAL	737.410
2.016	AVANCE	418.423
2.016	MENF	547.491
2.016	BACH_RSE	659.903
2.016	FINAL	753.458
2.017	AVANCE	564.914

#### Table 4.1Number of companies in every extraction, from 2015 to 2017

#### **SAS** PROGRAM

To deal with this huge amount of data, a statistical tool is required, the program finally selected was SAS. The work flow process can be seen at chart 4.3, and follows the next steps:

Chart 4.3 SAS program for Outsider's Method for outliers detection

- Defining the paths by assigning the process libraries
- Import the data with the accounting information for the calculation of the numerators and denominators of the ratios
- The program that calculates the numerators and denominators of the ratios (program "prepara")
- The query that calculates the ratios for every company. ("ratio1")
- The program that calculate the function φ and calculate the nodes and order the observations in their respective node according to the descending value of φ. ("ratio2")
- The program that calculates the function "Ind" and prepare the final output of the program that includes the companies that has Ind>1 which is the condition to be categorized as outlier.

#### **RESULTS OF SAS PROGRAM.**

Once the SAS program is executed it is obtained two excel files as a raw information:

1) "Colas.xls"

#### Table 4.2"Colas.xls" raw output

RATIO	id	NIF	NOMB	SUBTIPO	NUM	DEN	PHI	COLA	NUMT	DENT	No	loga
E1	2342188			N	0	-53.35075	0.00015593	A1<+	7.44037	-1622.42424	1	-8.76610873
E1	1964830			N	-220.93268	-24.26857	0.03001797	A3<+	751.95362	-7465.71132	1	-3.50595895
E1	184314			N	114145	136420	0.0559543	B1>+	420051.87	1488262	22 1	-2.88321991
E1	74582			R	6174	253124	0.05284311	B1>-	420051.87	1488262	1	-2.94042793
E1	67809			R	10315.1289	16485.8077	0.03199965	B2>+	41157.626	256014.035	1	-3.44203046

In this excel file it can be found:

- a. Ratio in which the program detects an outlier
- b. Id: code to identify the company (used to overtake confidentiality constrictions)
- c. NIF: Fiscal Id of the firm (hidden due to confidentiality reasons)
- d. NOMB: Name of the firm (hidden due to confidentiality reasons)
- e. Any: year of the annual accounts from which the data are obtained
- f. NUM: Numerator of the Ratio
- g. DEN: Denominator of the Ratio
- h. NUMT: Numerator of the ratio for the whole node
- i. DENT: Denominator of the ratio for the whole node
- j. PHI: Value of the  $\phi$  function
- k. COLA: four-digit code that identify: (example: A1<-)
  - i. A: identify the sector: Agriculture, Forestry and Mining...
  - ii. 1: identify the size: Large
  - iii. <-: identify the tale: (left + or right -)
- I. Loga: is the logarithm of the  $\phi$  function

2) "Outlier.xls"

#### Table 4.3 "Outlier.xls" raw output

RATIO	id	NIF	NOMB	SUBTIPO	NUM	DEN	PHI	COLA	NUMT	DENT	No	loga	INDICE	NODO
E1	2342188		)	N	0	-53.35075	0.00015593	A1<+	7.44037	-1622.42424	1	-8.8	2.5	A1
E1	1964830			N	-220.93268	-24.26857	0.03001797	A3<+	751.95362	-7465.71132	1	-3.5	1.1	A3
E1	184314			N	114145	136420	0.0559543	B1>+	420051.87	1488262	1	-2.9	1.2	B1
E1	74582			R	6174	253124	0.05284311	B1>-	420051.87	1488262	1	-2.9	1.2	B1
E1	67809			R	10315.1289	16485.8077	0.03199965	B2>+	41157.626	256014.035	1	-3.4	1.1	B2

In this file it can be found the same information as in previous one, but including also:

a) INDICE: Is the "Ind" function, all observations in which "Ind>1" will be considered outliers.

#### OUTLIER KEY VS TRACE OF OUTLIER KEY.

The results obtained are subjected to a stability control, to analyse the anomalous values in the different extractions and to study the evolution of the nodes to which they belong in successive bases.

With this objective, two keys have been designed:

- "Outlier" key: that takes value one for those companies in which in at least one of the ratios an anomalous observation was found, and zero, otherwise.
- Key "Trace of Outlier": value that shows the characterization and evolution of the company as an outlier throughout the four extractions of a base.

This trace allows to know if a company has been or is classified as an outlier in any of the extractions of data as well as to follow up on which of them has ceased to be, if it had lost that condition.

This key is relevant to assess the "outsider's method", as the number of observations in each of the four extraction is growing, approximately by one hundred thousand companies by extraction.

According to the design of this outliers detection system the purpose is to find those observations that deviates extraordinarily from the normal behaviour of their node and also contributes to explain the differences on the behaviour, so it is expected that most of the outliers detected in the first extraction (advance) should remain till last extraction (final).

To check the outlier classification according to extraction it is defined the following table of possible values:

DESCRIPTION KEY TRACE OF OUTLIER	VALUE OF THE KEY		MAP OF ES KEY TRAZE (				
		ADVANCE	MENF	BACH_RSE	FINAL	2015	2016

#### Table 4.4Values of key trace of outlier

TOTAL OUTLIERS	5197	5319
% OF OUTLIERS THAT REMAIN AS AOUTLIERS SINCE IT HAS BEEN MARKED WITH THAT CONDITION	34%	36%
% OF OUTLIERS THAT LOSE THAT CONDITION	66%	64%
% OF outliers that lose that condition but at the final extraction remain as outlier	20%	14%

In the "MAP OF EXTRACTIONS" is coloured in blue, when an observation is classified as outlier and in white when it ceases to be.

As it can be deducted from the table, the number of outliers and the percentages of them, that remain as outlier since they have been marked with that condition, and the percentage of outliers that lose that condition seems to be very stable in the two bases.

On the other hand, the % of outliers that lose that condition but at the final extraction remain as outliers diminish by 6% in 2.016 base, the figures related to the observations that are considered outliers at MENF and FINAL extractions decrease from 45 in 2.015 to 7 in 2.016.

At the end the % of observation that at the final extraction are considered as outliers either because since they acquire the condition of outlier they do not lose it until the end or because even if they have lost it in some extraction they end up maintaining it in the final extraction is higher than 50%, as can be expected according to the design of the outsider's outlier detection system.

# ANALYSIS OF RESULTS OBTAINED BY THE "OUTSIDER'S METHOD". THE OUTLIERS REPORT.

To analyse the results obtained with the outsider's method, after every extraction it is implemented an outlier regular report, which it is useful to be able to see from a higher perspective the performance of the method.

In this report it can be observed:

- Number of companies labelled as outliers in the extraction, this number always must necessarily match with the "Outlier key" and represent the total number of companies identified as outliers at CBB database.
- Company with the highest "Ind" function, accompanying the identification number of this one it is included the ratio affected and the sector and size to which this firm belongs.
- Selection of companies with more ratios labelled as outliers, more than 6 of the 17 ratios analysed marked as outliers. See table 4.5

Table 4.5Companies with more than 6 ratios labelled as outliers

This is a very illustrative panel, as it gives the clue on those companies with many potential mistakes, those companies are checked afterwards by an expert analyst, in order to be sure, and to avoid including them in our CBB database, because they are not effectively representing a correct behaviour of the reality of the firm.

When the expert analyst find a company marked as outlier but its behaviour represents the reality of the firm, the mark of outlier of this company is immediately removed, and therefore it is included again in our CBB database.

Also, we can find a heat map, from beige to red, all the outliers according to the value of the "Ind" function, from lower to higher value.

- Ratio with the highest number of outliers labelled
- Companies with the highest "Ind" in each ratio:

This panel helps to analyse the behaviour of sectors and ratios and their outliers' patterns. As it can be seen in the table 4.6 some of the observations (companies) are repeated in several ratios as the highest value of the "Ind" function. That drive us to go again to the micro data and analyse the company in order to check by an expert analyst if this behaviour comes from a mistake in reporting or other similar reason or on the contrary, it is presenting the right development of the company, in that situation, the key of outlier is immediately removed.

#### Table 4.6 Companies the highest "Ind" in each ratio

Ratios of outliers per extraction and number of companies marked as outliers pre extraction:
*Table 4.7* Outliers by extraction and Companies marked as outliers by extraction

BASE	EXTRACTION	Nº OF COMPANIES	№ OF OUTLIERS	RATIO OF OUTLIERS PER EXTRACTION	COMPANIES MARKED AS OUTLIERS	RATIO OF COMPANIES MARKED AS OUTLIERS PER EXTRACTION
2,015	AVANCE	317,116	11,316	3.57%	3,263	1.03%
2,015	MENF	594,130	15,972	2.69%	5,072	0.85%
2,015	BACH_RSE	668,230	16,293	2.44%	5,197	0.78%
2,015	FINAL	737,410	16,403	2.22%	5,197	0.70%
2,016	AVANCE	418,423	15,082	3.60%	4,668	1.12%
2,016	MENF	547,491	15,846	2.89%	4,974	0.91%
2,016	BACH_RSE	659,903	16,265	2.46%	5,184	0.79%
2,016	FINAL	753,458	16,471	2.19%	5,319	0.71%
2,017	AVANCE	564,914	15,747	2.79%	4,994	0.88%

This table shows by base, year of the reported financial statements, and extraction, the number of companies analysed and the results of the SAS program, as it can be seen the ratio of outliers per extraction varies from 3.60% in the advance samples, as it can be expected because of the smaller number of companies analysed by the temporality of the extraction, to 2.22% in the final sample. It is to be highlighted that for 2017 base, the number of companies analysed has grown and is similar to the second extraction (MENF), around 2.70%, and the ratio of outliers per extraction behaves in the same way.

As it is mentioned, when an observation has one of the ratios labelled as an outlier, this one is considered as an outlier, as it can be checked at the ratio of companies marked as outliers per extraction, it is approximately half of the results shown at the column of ratio of outliers per extraction. That bring us to the conclusion that approximately half of the companies marked as outliers has more than one outlier among its ratios.

Evolution of number of outliers by base, extraction and ratio
With the aim of analysing the stability of the number of outliers per ratio and extraction, it is performed the table 4.8 in which it can be observed that in most of the ratios and for all the extractions, the number of outliers found remains very stable despite in every further one of each base, the number of companies grows, around 100,000 by each extraction.

This leads to asses this method that identifies the observations that deviates more from the normal distribution and also contributes more to the variation of their respective node making this method a very efficient lawyer of quality control due to the reduced number of abnormal observations explain the most important part of the variation of the node. This stability of number of outliers per extraction and ratio can be checked graphically at chart 4.4

#### Table 4.9 Evolution of $N^{\circ}$ of outliers by base, extraction and size

#### Chart 4.5 Evolution of number of outliers by base, extraction and size

At chart 4.5 can be checked that in average and for all the extractions, approximately 25 % of the outliers belong to the Large companies, 20% belong to Medium, 25% to Small's and finally about 30% of the outliers belong to Micro's, as can be expected, as at the outsider's method it is measured the

contribution of the observation to its node, and the 30% in which the number of observations are much bigger and the distributions can widen the range of the outlier caliber and the contribution to its node.

Similar figures can be seen regarding the number of companies marked as outlier by base, extraction and size at table 4.10 and chart 4.6:

		size								
	EVOL	EVOLUTION OF № OF COMPANIES MARKED AS OUTLIERS BY BASE, EXTRACTION AND SIZE

# Table 4.10Evolution of Nº of companies marked as outliers by base, extraction and<br/>size

In the following two pages we can see the Table 4.11 that represents the evolution of number of outliers detected by size sector and extraction, to the right it can be found charts corresponding to every sector, size and extraction in which it is represented graphically the evolution of the aforementioned labelled outliers.

This allows a quick assessment of the outsider's method through analysing the performance of the outliers founded throughout the extractions by a simple view of the charts.

#### Table 4.11 Evolution of number of outliers by sector size and extraction (cont.)

### AN INTRODUCTION TO THE SECOND PART OF THE THESIS, METHODS TO COMPARE AND VALIDATE THE RESULTS OBTAINED BY THE OUTSIDER'S METHOD.

The results of the Outsider's method seem to be very promising, for two reasons mainly:

- The proportion of outliers detected in relation to the total observations in each sample analysed overtime.
- The stable trends of number of outliers, by size and by sector through all the extractions.

But in order to ensure the quality and effectiveness of this method, and finally to validate its selection as a definitive lawyer of quality control at Banco de España' s CBSDO is mandatory to compare its results with other outlier detection methods with a proven history of use.

The methods, to be selected to do such validation, are frequently used in institutions like ECB, Eurostat, BACH or the Spanish National Statistics Institute; therefore, they will serve as a framework in which we can compare, test and validate the outsider's method.

Those methods will be:

- 1. P3-P97 (1<sup>st</sup> method)
- 2. IQR (2<sup>nd</sup> method)
- 3. Highest and Lowest observations (3<sup>rd</sup> method)

It will be used another statistical tool, the one selected is STATA, the main reason to use a different tool is due to ensure the resilience of CBSDO to risks derived from technological dependence.

The Stata code, it will be run by each of these three methods to each of the nine sample extractions and the results obtained will be subsequently compared with the ones obtained by outsider's method.

Finally, in the chapter of conclusions, the main hypothesis will be to validate the outsider's method as a method of quality control applicable in the CBSDO, and it is desired that this can be contrasted.

#### FIRST METHOD: (P3 – P97)

This approach will try to find out observations with extreme data and a high contribution to the aggregated data, those companies (observations) are eliminated of the sample, which is exactly the same purpose of the outsider's method.

This method is used in many institutions such EUROSTAT, INE (Spanish National Statistical Institute), etc.; and its results are widely accepted.

It is based in:

- cut-off points (fences),
  - $\circ$  above the percentile 97, and
  - o below the percentile 3
- Contribution of each observation to the whole aggregated data.

#### Table 4.11 First method to validate outsider's method: P3 – P97

MICRODATA: OUTLIERS FILTERS

Individual data will be excluded if: any ratio $\mathbf{C}$ [percentil 3, Percentil 97], AND (K <sub>N</sub> >25*KM <sub>N</sub> , or K <sub>D</sub> >25*KM <sub>D</sub> )	Individual data will be excluded if: any rate $\clubsuit$ [percentil 3, Percentil 97], OR N <sub>t-1</sub> or N <sub>t</sub> =0, and K <sub>N</sub> >25*KM <sub>N</sub>								
where: N=Numerator D= Denominator $K_N =  N  / \sum  N $ $K_D =  D  / \sum  D $ $KM_N = Simple average(K_N)$ $KM_D = Simple average(K_D)$									

It has been designed an Stata code to be run in each extraction, the results of this P3\_P97 method on the different extractions can be seen in the following table 4.12

Table 4.12	Results obtained by P3	P97 method and com	parison with outsider's met	hod
			p

The match ratio between the P3\_P97 method and the outsider's method it is proved to be fairly constant in all extractions and slips around 45%.

The number of companies marked as outliers by the P3\_P97 method is much greater than the results obtained by the outsider's method.

In table 4.13 it can be found that the % of companies marked as outliers by the outsider's method is around 1% over the total companies of the sample while the same figure for the P3\_P97 is around 12% in all extractions.

### Table 4.13Coverage ratios of firms marked as outliers over the total obtained by P3\_P97method and comparison with outsider's method

	EXTRACTIONS												
INTERSECTION P3_P97 Vs OUTSIDER'S	AVANCE	FINAL	BACH_RSE	MENF	AVANCE	FINAL	BACH_RSE	MENF	AVANCE				
	2017	2016	2016	2016	2016	2015	2015	2015	2015				
% FIRMS MARKED AS OUTLIERS OVER TOTAL													
OUTSIDER'S	0.9%	0.7%	0.8%	0.9%	1.1%	0.7%	0.8%	0.9%	0.8%				
P3_P97	11.9%	12.2%	12.2%	12.1%	12.1%	12.2%	12.2%	12.1%	12.1%				

It is very important for Banco de España, to be accurate in our quality control procedures, in one hand to eliminate those observation that disturb our sample, but in other to lose the less observations possible and in order to have the sample with the widest possible coverage. So, the number of companies expelled from the sample by the P3\_P97 method is not acceptable while the number of them by the outsider's method seems to be more reasonable.

#### SECOND METHOD: INTERQUARTILE RANGE (IQR)

This method for identifying outliers is used at ECB, EUROSTAT<sup>1</sup>, BACH and many other institutions, and its results are widely accepted.

The main elements of this method are:

- Lower quartile (Q1),
- Upper quartile (Q3), and
- The caliber, (k)

This method contains cut-off points (fences), k(Q3-Q1), above the upper quartile and below the lower quartile: [Q1 - k(Q3-Q1), Q3 + k(Q3-Q1)]

Observations beyond the fences are considered as potential outliers. In our proposal, k=25, with the aim of excluding only very extreme data, especially, because it must be taken into account that in some of our distributions, the first and third quartiles may have values very close to zero, which would imply that the interquartile range would be very wide and would not have a discriminating character when distinguishing anomalous observations of other normal and representative of the sample reality.

In this method is included, as a variable, the contribution of the observation to the aggregated data. It is considered relevant to analyse with this not homogeneous methodological approach because it can be tested the correlation of the extreme observations founded by the outsider's method with the extreme observations that this method will be found.

Table 4.12Second method to validate outsider's method: IQR

<sup>1</sup>Practical guide to data validation in EUROSTAT (2.007): "Among all the different measures and graphs, the boxplot deserves a special reference, because it is particularly good in showing the main characteristics of the data and the existence of outliers. In fact, it was designed to do so. Letting Q1 and Q3 denote the first and the third quartiles respectively and IQR = Q3 –Q1 the interquartile range, the commonly used rule is the following:

• A data value i X is considered a moderate outlier if X< Q1 - 1.5\*IQR or if X >Q3+ 1.5\*IQR.

• A data value i X is considered a severe outlier if X< Q1 - 3\*IQR or if X >Q3+ 3\*IQR.

The values Q1 - 3\*IQR - and Q3 + 3\*IQR are called the lower and upper outer fences respectively and the values Q1 - 1.5\*IQR - and Q3 + 1.5\*IQR are called the lower and upper and inner fences respectively. The boxplot clearly marks the eventual outliers, often using different symbols for moderate (for example, an asterisk) and for severe (for example, a circle) outliers. Moreover, the value taken for the lower whisker is the lowest observation below Q1 that does not cross the lower inner fence, and the value taken for the upper whisker is the highest observation above Q3 that does not cross the upper inner fence, i.e.:

- Lower whisker = min {X: Q1 -1.5\*IQR <= X<= Q1}.
- Upper whisker = max {X: Q3 <= X<= Q3 + 1.5IQR}.

This choice for the whiskers makes outlier detection easier."

These box plots produce graphical representation and allows to usually pinpoint the outlying observations, in the previous x-scale chart values, for the normal data are included within the limits set by the whiskers which, are fixed by the difference of the interquartile range and by the chosen caliber. Box plots make no assumptions about the data distribution model but are reliant on a human to note the extreme points plotted on the box plot.

It has been designed an Stata code to obtain the companies marked as outliers by this method, the results of the IQR method on the different extractions can be seen in the following table 4.13

		EXTRACTIONS

 Table 4.13
 Results obtained by IQR method and comparison with outsider's method

The match ratio between the IQR method and the outsider's method proves to be fairly constant in all extractions and slips around 12%.

9

The number of companies marked as outliers by the IQR method is similar to the results obtained by the outsider's method.

In table 4.14 it can be found that the % of companies marked as outliers by the outsider's method is around 1% over the total companies of the sample while the same figure for the P3\_P97 is around 12% in all extractions.

## Table 4.14Coverage ratios of firms marked as outliers over the total obtained by IQR methodand comparison with outsider's method

	EXTRACTIONS												
INTERSECTION IQR25 Vs OUTSIDER'S	AVANCE	FINAL	BACH_RSE	MENF	AVANCE	FINAL	BACH_RSE	MENF	AVANCE				
	2017	2016	2016	2016	2016	2015	2015	2015	2015				
% FIRMS MARKED AS OUTLIERS OVER TOTAL													
OUTSIDER'S	0.9%	0.7%	0.8%	0.9%	1.1%	0.7%	0.8%	0.9%	0.8%				
IQR	1.4%	1.1%	1.3%	1.4%	1.6%	1.1%	1.3%	1.4%	1.2%				

The preliminary conclusions of this validating method would consist in:

- Reduced percentage of coincidence between this IQR method and the Outsider's one, the reasons behind this are linked to the distributions of the different nodes, even though the caliber to set up the fences is designed to be extremely wide, seems that the differences of interquartile ranges (Q3 Q1) make the outlier selection even wider, and that is the main reason for the reduced coincidence of both methods.
- The percentage of firms marked as outliers over the total are closer in this two methods and are more acceptable if compared with P3\_P97 percentages.

Finally, to compare the results obtained by these two validating methods, the list of companies marked as outliers were merged and the results can be seen in the following table 4.15

#### Table 4.15Results obtained by IQR method and comparison with P3\_P97 method

NUMBER OF FIRMS MARKED AS OUTLIERS THAT DON'T MATCH	734	857	1,244	718	470	624	399	620	488			

It can be highlighted the high ratio of coincidence of the companies selected by the IQR method compared with the ones selected by the P3\_P97 is around 90% in all extractions.

In Both methods, P3\_P97 and IQR, the condition to be declared outlier is a combination of

- 1. Being out of the respective cut-off points (fences);
- below percentile 3 and above percentile 97 in the case of the P3\_P97 method and

- In the case of IQR, the value of the variable in absolute value is over 25 times the interquartile range measured by the difference between the third quartile and the first one.
- 2. Having a contribution to it respective node over 1%

With this methodology we are comparing two very similar approaches, the two aforementioned validating methods (P3\_P97 and IQR) with the outsider's method with its  $\varphi$  function, that includes both conditions, the contribution of the observation to its own node measured by the difference between the value of the node for that observation and the value of that node would have if that observation were not in the sample; and the cut-off points obtained by ordering by node the  $\varphi$  function values obtained for every company in the sample and selecting those that for each node in absolute value belongs to the 20 greatest.

(i) 
$$R_i = N_i / D_i$$
  
(ii)  $\varphi = \frac{\sum Nj}{\sum Dj} - \frac{\sum Nj - Ni}{\sum Dj - Di}$   
(iii)  $\varphi_i \ge \varphi_{i+1}$ 

R for Ratio N for Numerator D for Denominator i for each company j for each node

And to avoid the masking effect, and to properly define the condition of outlier, declare those observations in which their "Ind function" in Absolut value are greater than one are defined as outliers.

(iv)

$$Ind = \frac{\ln(\varphi) - Mean(\ln(\varphi))}{e^*(1 - \frac{1}{n})}$$

#### THIRD METHOD: LOWEST AND HIGHEST OBSERVATIONS

This method is the oldest to find extreme observations, it has the problem of the masking effect Bendre & Kale (1985) define the masking effect in cases of tests for outliers and quantified by the loss in power due to the presence of more than the anticipated number of discordant observations in the sample. In other words, it is said that an outlier masks a second one that is close by if the latter can be considered an outlier by itself, but not if it is considered along with the first one.

Despite this problem what we want to be sure it's that the outsider's method doesn't discriminate many extreme observations due to their not significant contribution of the observation to the whole aggregated data.

So, this will be a very simple but effective approach that will consist of obtaining the three highest and lowest observation of every node and for every extraction and correlate those to the respective results obtained with the outsider's method.

#### Chart 4.6 Third method to validate outsider's method: Highest and Lowest observations

A Stata code has been programmed in order to obtain the three highest and lowest observation for each node, and the results of the confrontation of this method, only based in the extremeness of the observations, with the outsider's method that consider both extremeness and contribution, can be observed in the following table 4.16.:

Table 4.16	Results obtained by Highest-Lowest (HL) method and comparison with the							
outsider's method								

					EXTRACTIONS	;			
INTERSECTION HL Vs OUTSIDER'S	AVANCE	FINAL	BACH_RSE	MENF	AVANCE	FINAL	BACH_RSE	MENF	MENF
	2017	2016	2016	2016	2016	2015	2015	2015	2015

% MATCHING BETWEEN HL & OUTSIDER'S	8%	6%	7%	8%	9%	7%	7%	8%	8%
NUMBER OF OUTLIERS THAT MATCH	411	331	348	383	413	340	344	394	394
% NO MATCHING BETWEEN HL & OUTSIDER'S	<b>92%</b>	94%	93%	<b>92</b> %	91%	<b>93</b> %	93%	<b>92%</b>	97%
NUMBER OF OUTLIERS THAT DON'T MATCH	4,583	4,988	4,836	4,591	4,255	4,857	4,853	4,678	4,678
% OF OUTLIERS PER EXTRACTION MATCHING BETWEEN HL & OUTSIDER'S	0.510%	0.389%	0.439%	0.524%	0.668%	0.390%	0.444%	0.535%	0.700%
% OF OUTLIERS PER EXTRACTION OUTSIDER'S	0.884%	0.706%	0.786%	0.909%	1.116%	0.690%	0.788%	0.926%	1.155%

As can be expected the degree of coincidence is reduced, around 8% in every extraction due to the different methodology of both methods, many of the observations that could be declared as outlier by the HL method, are considered in that condition because they are so extreme but due to their reduced contribution to their respective node, the outsider's method will not declare them as outliers.

#### COMBINATION OF THE THREE VALIDATING METHODS

In order to continue the process of validating and assessing the outsider's method and to finally implement it as a quality control at Banco de España's CBSDO, it is necessary to combine these three methods, two based in the combination of extremity and contribution and the other one based only in extremity with the outsider's method.

The idea it is simple but effective and consist of constructing the union of the three methods and then compare it results with the outsiders. The schema of this methodology can be observed in the following chart 4.7:

Chart 4.7 Combination of all methods schema

And the results of this combinations can be seen on table 4.17:

After merging the companies marked as outliers by the union of the three validating methods with the ones selected by the outsider's method the results are satisfactory, over 60% of coincidence.

Although satisfactory, these results do not leave us fully satisfied for two reasons mainly:

## **1.** Around 40% of the companies marked as outlier by the outsider's method, are not considered by the combination of the other three methods

The reason behind this behaviour comes after analysing empirically the statistical distributions of the nodes; It seems that the number of the highest 20 absolute values of the  $\phi$  function perhaps it is too wide.

In order to avoid the masking effect, maybe, we were too cautious, and the result of that is that we are wiping out some observations that contribute significantly and that are extreme, but not so extreme to be considered as outliers.

This appreciation is important, because that mean that we are excluding from our sample some observations that that would be very explanatory of the behaviour of each particular node.

This problem is common to all outlying detecting methods, but this is not enough excuse for not trying to continue improving our outlying detecting system.

# 2. The number of companies marked as outliers by the outsider's method is around five thousand per extraction.

The aim of the CBSDO is to be as accurate as possible, and to exclude the minimum companies of our sample. So, our wish is to reduce that number considerably.

Noticing these two very important aspects, the outsider's method can be considered as good as any of the other conventional methods.

In order to improve this quality control and fine tune its results according to Banco de España's CBSDO requirement, in the next chapter is presented the approved proposal of outlying detection method.

### METHOD APPROVED AS A QUALITY CONTROL TOOL FOR DETECTING OUTLIERS OF CBB'S DATABASE

The method selected follow a quite rationale approach, if the problems of the original outsider's method consist of the not enough small number of companies discarded, and that some of them should not be discarded because they are not so extreme; the solution should consist of only reject among the observations selected by the original method, the ones that are the most extreme, so that is the intersection of the original outsider's method with the HL method (the three highest and the three lowest observations of each variable for each node).

From now on I will refer to the approved method as the outsider's method.

Graphically, the methodology of this approach can be seen on the chart 4.7

#### Chart 4.7 Outsider's method

The results obtained by the outsider's method can be seen at table 4.18

YEAR	EXTRACTION	NUMBER OF COMPANIES	NUMBER OF OUTLIERS	NUMBER OF COMPANIES MARKED AS OUTLIERS	RATIO OF COMPANIES MARKED AS OUTLIER OVER TOTAL

Table 4.18 results obtained by the outsider's method

Also, it can be seen graphically at chart 4.8

Chart 4.8 Outsider's methods results: N. of Outliers Vs N. of companies marked as outliers

The number of outliers and the number of companies marked as outliers have a good ratio over the total companies of the sample, around 0.7% of the total of companies of the sample, in this regard, Hubert and Vandervieren (2008) propose a new outlier identification rule for skewed univariate data based on a so-called adjusted boxplot. Their idea was to modify the whiskers of the standard boxplot according to the degree of asymmetry in the data distribution, which can be robustly estimated by the medcouple. The expressions of the whiskers extremities of this adjusted boxplot were found from extensive simulations of a wide range of (moderately) skewed distributions and such that, in absence of contamination by outliers, approximately 0.7% of the observations lie outside the interval delimited by both whiskers (as it is the case for the standard boxplot and Gaussian data).

The aim of the Banco de España's CBSDO is losing the smaller number of companies as possible, in order to get the maximum coverage of our sample to the population of non-financial corporations. That's why we are selecting among the five thousand companies detected as outliers by the original outsider's method, only those that furthermore are among the three highest or the three lowest of their respective nodes.

Also, it can be seen at chart 4.9 and table 4.19 the evolution of number of outliers by year, extraction and ratio

In both, chart and table can be appreciated the stability in all extractions per ratio, especially in those which have similar number of companies and therefore more comparable.

Total	1,778	1,515	1,462	1,548	1,545	1,501	1,392	1,781	1,791						

Table 4.19Evolution of number of outliers by year, extraction and size

As can be observed from the chart, around 40% of the outliers belong to Medium sized companies, 25% belong to Large or Small companies and finally the rest, less than 10% belongs to Micro companies. This trend remains stable on each extraction.

These results differ from the results obtained by the original method in which approximately an almost equal distribution of 25% of outliers was obtained for each class.

The rationale behind this variation can respond to various motivations such us as, the niche of medium-sized companies has a lower coverage in our sample with respect to the rest of the other categories in relation to the total population; or such us, that the cut of the three major or minor

observations of the highest-lowest method, free of weighting, affects to a lesser extent to the micro companies and on the contrary much more to the companies of medium size.

This behaviour is repeated when the number of companies declared as outliers is analysed and can be seen in the following table 4.20 and chart 4.11 with the evolution of the number of companies marked as outliers

		Evolution of number of companies marked as outliers by year, extraction and size													
	MENF	BACH_RSE	FINAL	AVANCE	MENF	BACH_RSE	FINAL	AVANCE	MENF

Total	394	344	340	413	383	348	331	411	399						

#### Table 4.20Evolution of number of companies marked as outliers by year, extraction and size

As previously commented the behaviour is very similar to the outlier's one.

Finally, the cut of maximum disaggregation, that is to say, the one that corresponds by year, sector extraction and size, can be observed in the graphical tool module designed and that shows a high stability in the number of outliers identified with such disaggregation and that it is observed in the table 4.12 of the next pages:

#### CONCLUSIONS

To ensure the quality of CBSDO products, that they are constructed by large micro data sets, it has been revealed as necessary to implement several statistical quality controls, to eradicate those observations that that can distort aggregated information due to excessive specific weight in their respective samples and subsamples.

A new outlier detection system has been designed and implemented, the "**Outsider's method**", through which, those observations that deviate considerably from the behaviour of companies regarding sector clustering, according to NACE classification, and size, will be eliminated from database and will be maintained those that still have a behaviour that is far from standard but consistent with the reality of mentioned Non-financial corporations.

In this project it was explained the methodology used to develop this new system, obtained results for different extractions periodically established over several years, analysed these results, and finally tested the system's validity by comparing it with other detection methods traditionally used by other statistical entities.

To validate the "Original Outsider's method", the results were compared with the union of the result of the three traditional methods selected, namely

- P3-P97 (1<sup>st</sup> method)
- IQR (2<sup>nd</sup> method)
- Highest and Lowest observations (3<sup>rd</sup> method)

This comparison revealed:

- 1. That 60% of the results coincided. But Around 40% of the companies marked as outlier by the outsider's method, are not considered by the combination of the other three methods. The reason behind this behaviour comes after analysing empirically the statistical distributions of the nodes and seems that the number of the highest 20 absolute values of the  $\phi$  function were too wide. In order to avoid the masking effect, maybe, we were too cautious, and the result of that is that we are wiping out some observations that contribute significantly and that are extreme, but not so extreme to be considered as outliers.
- 2. The number of companies marked as outliers by the outsider's method is around five thousand per extraction.

In order to improve this quality control and fine tune its results according to Banco de España's CBSDO requirement, it was presented the approved outliers detection method.

The *improved "outsider's method*" consist of only reject among the observations selected by the original method, the ones that are the most extreme, so that is the intersection of the original outsider's method with the HL method (the three highest and the three lowest observations of each variable for each node).

The number of outliers and the number of companies marked as outliers have been reduced up to a very good ratio over the total companies of the sample, around 0.7% of the total, also the stability on

the evolution of the identified outliers, by size, by sector, by extraction, and finally the revision of the firms marked as outliers by specialists, Not all outliers are illegitimate contaminants, and not all illegitimate scores show up as outliers (Barnett & Lewis, 1994), implement that this new figures meet the requirements and needs of such an institution as Banco de España's CBSDO.

To finish with, I would like to emphasize that this method has just been used for the realization of the Spanish part of last benchmark that updated data from all the National Central Banks that provide information to ECB Statistics databases from the base 2008 to the last one in force, that of 2017, and that the results obtained, for the final sample of Each of the bases has followed the same patterns and trends as those analysed in the study of this project, and that can be checked at annexes section.

#### **ANNEXES**

#### BENCHMARK (2.009 - 2.017)

A benchmark review is a regular extraordinary review, coordinated between the countries of the EU, Eurostat and the European Central Bank and coordinated between several statistical domains (BP / IIP and NA). It differs from regular routine reviews in that it affects longer periods (full time series if necessary). They allow us to review long periods and accumulate changes that, if introduced in isolation, could lead to successive contradictory results (effects of different signs on the fundamental aggregates that end up being compensated between the different changes). They are necessary because new sources of information appear or existing ones change, unsatisfactory results are observed that require varying the calculation methods or the elaboration procedures are aligned with certain recommendations of the relevant international forums. The result is better quality statistics, more consistent and more adapted to international standards.

Recently a benchmark review has recently been carried out, which has affected the data provided by the CBSDO and has included a review for said data for the period between 2009 and 2017 (the latest available data).

In this review, an extraction of outliers using the "outsider's method" has been carried out for the CBB database. In the following tables and charts, the homogeneity and stability of the results obtained can be observed over time; and that together with the analysis previously described in the thesis confirm the goodness of this new system of detection of anomalous observations.

## **CHARTS INCLUDING STATISTICAL DISTRIBUTIONS**

In this Annex, a set of charts that serve as a sample and example of the analyses performed for the 17 variables under study have been represented, these graphics range from:

- Histograms that show the underlying frequency distribution of the sets of discrete data.
- Kernel distributions, that can be useful to visualize just the "shape" of some data, as a kind of continuous replacement for the discrete histograms,
- Quantile-Quantile charts, that allows to check how close the distribution of a data set is to some ideal distribution or compare the distribution of two data sets. As we are interested in comparing with the Gaussian distribution, the normal probability chart can be used, in which the data is sorted and plotted the i-th data against the corresponding quantile. Gaussian Hoaglin, Mosteller and Tukey (1993) suggested taking the i-th quantile. If we replace one of the samples with the quantiles of the normal distribution we can compare the empirical percentiles of a data set, with the theoretical percentiles of a normal distribution.
- The box-plots provide a quick way to examine the data. A box-plot is nothing more than a flat representation of some of the most outstanding features of a data set.

These charts allow the inspection of the data and its underlying distribution for example, normality, outliers, skewness, etc. The distribution of observations for each variable should be examined, selecting as possible outliers those cases whose values fall outside the ranges of the distribution. The main issue is the establishment of a threshold for the designation of a possible outlier. This can be done graphically using histograms or box diagrams or numerically, by calculating typified scores. For small samples (of 80 or even fewer observations), the suggested guidelines identify as possible outliers those cases with standard values of 2.5 or higher. When the sample sizes are larger, the guidelines suggest that the threshold value be 3.

The box-plots provide information that is midway between descriptive statistics and a representation of a Histogram, its main advantage is that since it is a flat representation several box-plots can be observed simultaneously in the same graph, which allows the study of the dynamic of the evolution of some important characteristics of the distribution of the variable in question, for example existence, appearance or disappearance of outliers, dispersion or concentration of the data, as well as the symmetry or asymmetry of the distribution. In fact, one of the basic utilities of box-plots is the graphic analysis of outliers.

Kernel density estimation are closely related to histograms, but can be endowed with properties such as smoothing or continuity through the use of a suitable core.

One of the main problems in practical applications is that the necessary probability distribution is generally not available, but rather should be derived from other existing information (for example, sample data). KDEs are similar to histograms in terms of being a non-parametric method, so there are no restrictive assumptions about the shape of the density function, but KDE is much more superior than histograms in terms of accuracy and continuity, therefore, the reason to use KDE, is because we get, in this way, a finite set of values for continuous random variables. The use of a nucleus instead of discrete probabilities, promotes the natural continuity in the underlying random variable.

In summary, all these graphic tools of exploratory analysis are of the utmost utility when it comes to knowing what we are facing and allowed to advance in the analysis, development and validation of the outsider's method, as well as in their improvement.

Attached, only some of the examples used, with several breakdowns, by variables, by sizes, by combinations of variable and size, variable and sector, etc.

Chart 14.2.1 Box-plots and histograms with kernel distributions of the variable rate of variation of Gross Value Added of agriculture, forestry and fishing sector with breakdown by size.

Chart 14.2.2 Box-plots and histograms with kernel distributions of the variable rate of variation of Gross Value Added of large companies breakdown by sector

## Chart 14.2.3 Histograms with kernel distributions of sector of Wholesale and retail repair of motor vehicles and motorcycles, size of micro companies with breakdown by variables

Chart 14.2.3 (Cont) Histograms with kernel distributions of sector of Wholesale and retail repair of motor vehicles and motorcycles, size of micro companies with breakdown by variable

Chart 14.2.4 Box-plots, Histograms with kernel distributions and Quantile-quantile charts (Q-Q plots) of the variable rate of variation of Net Assets of small companies breakdown by sector

Chart 14.2.4 (Cont) Box-plots, Histograms with kernel distributions and Quantile-quantile charts (Q-Q plots) of the variable rate of variation of Net Assets of small companies breakdown by sector

Chart 14.2.4 (Cont) Box-plots, Histograms with kernel distributions and Quantile-quantile charts (Q-Q plots) of the variable rate of variation of Net Assets of small companies breakdown by sector.

Chart 14.2.5 Box-plots of the "*\varphi* function" and "Ind function" of the variable rate of variation of Gross Value Added breakdown by sector and size
