# ABSTRACT <br> START-UP POWER REQUIREMENTS <br> OF AMMONIA FILLED AEROSPACE <br> THERMOSYPHON HEAT PIPES 

by Eric Chu

Boiling and condensing of internal working fluids are essential heat transfer concepts which heat pipe technology relies on for transporting a large amount of heat between two distanced points effectively. Tilt angle and working fluid saturation temperature have a direct impact on how well the evaporator is flooded. This paper focuses on how the tilt angle and the working fluid saturation temperature affect the start-up heat input requirements for an $S$ shaped axial grooved ammonia thermosyphon heat pipe. A series of experiments was performed by supplying and extracting heat to the evaporator and condenser of the thermosyphon heat pipe. Temperature of the evaporator and condenser was monitored to capture start-up behavior upon heat input. The evaporator temperature was found to be slightly elevated before the internal working fluid begins to boil. It decreased once boiling starts and initiates the thermosyphon process. The test results showed that the evaporator start-up temperature difference was found to be higher as fluid saturation temperature increases, and becomes lower as the fluid saturation temperature decreases. The start-up heat input requirement to initiate start-up in the evaporator was determined to be constant throughout the range of tilt angles and saturation temperatures.

## ACKNOWLEDGMENTS

I would like to express my deep gratitude to the committee members, Dr. Okamoto, Dr. Zaidi, and Dr. Thurlow for the valuable guidance they have given me, guiding the project to the finish line. Special thanks to Mr. Randy Pon, Dr. Okamoto, and San Jose State University for the opportunity to work on this project. Finally, I would like to thank my wife and my family for the continuous support they have provided me throughout the course of this project.

### 1.0 Introduction

Boiling and condensing of working fluids are essential heat transfer concepts which heat pipe technology relies on for transporting a large amount of heat between two distanced points effectively. Gravitational force plays a major role in the heat transfer limitation and characteristics of heat pipes that are designed differently. This paper will focus on how the tilt angle and initial temperature affect the start-up heat input requirements for an "S shaped" axial grooved thermosyphon heat pipe. The start-up heat input requirements have been analyzed at tilt angles of $90^{\circ}$ to $0^{\circ}$, from vertical to horizontal operation in increments of $10^{\circ}$ at a range of initial saturation temperature from $20^{\circ} \mathrm{C}$ to $60^{\circ} \mathrm{C}$ in increments of $10^{\circ} \mathrm{C}$.

Heat pipes are widely used in various applications including electronic cooling, aerospace, power generation cycles, heat recovery in HVAC systems, and in many other fields. They are designed differently for specific applications. Heat pipes are fixed volume, two-phase heat transfer devices that are able to transport heat over a distance effectively with a small temperature gradient. A heat pipe has a few different major parts, the evaporator, the condenser, and the adiabatic section. The internal working fluid absorbs heat and transforms into a vapor state internally at the evaporator section of a heat pipe. Then the vapor travels through the adiabatic section to the condenser section of the heat pipe due to the vapor pressure. The adiabatic section connects the evaporator and the condenser section of the heat pipe with no significant amount of heat transfer added to the overall system. The condenser section removes heat, which condenses the vapor that traveled from the evaporator section and sends the saturated liquid back to the
evaporator through the adiabatic section. Figure 1 shows a typical heat pipe's construction and operation.

Figure 1. Schematic and operation of a heat pipe [1].
An $S$ shaped axial grooved thermosyphon heat pipe is analyzed in this paper. This specific heat pipe belongs to a network of heat pipes used on a telecommunication satellite to help reject heat and maintain operational temperature for the electronics of the satellite's payload. Figure 2 and Figure 3 show the picture and the approximate location of the $S$ shaped heat pipe on a satellite.

Figure 2. S shaped thermosyphon heat pipes.

Figure 3. Satellite heat pipe network [4].
This S shaped thermosyphon heat pipe doesn't have an internal wick structure to assist the condensed fluid to return from the condenser to the evaporator. It is designed to operate in outer space in microgravity. Instead of having an internal wick structure, it has internal axial grooves as pictured in a cutaway section of the evaporator in Figure 4. This $S$ shaped heat pipe is filled with 39.4 grams of ammonia in a fixed internal volume of $0.000192 \mathrm{~m}^{3}$ with 25 evenly spaced internal axial grooves, which formed a 0.398 inch vapor core diameter and a 0.524 inch inner tube diameter. This heat pipe utilizes ammonia as its internal working fluid. The saturated liquid occupies and travels in between the grooves throughout the heat pipe while the saturated vapor travels in the center vapor core between the evaporator and condenser. Capillary action helps the saturated liquid to evenly distribute in between the axial grooves.

Figure 4. Evaporator cross-sectional view.

### 1.1 Literature Review

Previous studies analyzed the start-up characteristics of heat pipes. In a study conducted out by $\mathrm{Qu}, \mathrm{Wu}$, and Cheng [2], the start-up characteristics of three horizontal micro pulsating looped heat pipes were analyzed in 2012. The heat pipes were charged with several different types of working fluids for comparison. Heat was supplied at the evaporator and retrieved at the condenser of the micro pulsating heat pipe. The focus of this study was to analyze and determine the compatibility and start-up behavior of several different working fluids in the heat pipes. The data clearly show a significant change in temperatures at the evaporator and the condenser upon start-up. Figure 5 and Figure 6 show the start-up thermal test setup and temperature plots of the heat pipes over time.

Figure 5. Heat pipe test setup [2].

Figure 6. Heat pipe start-up characteristics [2].

There is a noticeable decrease in temperature at the evaporator, $T_{1}$, and increase in temperature at the condenser, $T_{5}$ and $T_{6}$. Temperatures were taken with thermocouples instrumented onto the body of the heat pipe, and heat was applied at the evaporator with a DC film heater while heat was extracted with supplied water at the condenser in this study.

In another study carried out by Mameli, Catarsi, Mangini, Pietrasanta, Miche, Marengo, Marco, Filippeschi [3], the start-up characteristics of a loop thermosyphon were analyzed in 2019. The study was conducted in the presence of microgravity during parabolic flights. The test data show a significant temperature decrease at the evaporator, and a noticeable temperature increase at the condenser upon start-up at 1070 seconds.

Figure 7 and Figure 8 show test data plots over time and the test setup.

Figure 7. Loop thermosyphon start-up data [3].

Figure 8. Micro gravity loop thermosyphon setup [3].

### 1.2 Objectives

The minimum start-up heat input requirements will be analyzed on the "S shaped" thermosyphon axial grooved heat pipe from tilt angles of $0-90^{\circ}$ in increments of $10^{\circ}$ at initial saturation temperatures of $20-60^{\circ} \mathrm{C}$ in $10^{\circ} \mathrm{C}$ increments. Start-up characteristics of the heat pipe will be evaluated to determine the amount of heat required to initiate the thermosyphon process inside the heat pipe.

### 2.0 Methodology

To provide tilt angle, heat supply, heat extraction, and temperature acquisitions to analyze the start-up characteristics of the $S$ shaped axial grooved heat pipe, a heat pipe testing apparatus was designed and constructed from 2011 to 2012 at San Jose State University with financial support from Space System Loral. The testing apparatus was designed to accept and provide heat supply, heat extraction, tilt angle, and temperature
acquisitions for "S shaped" heat pipes. The testing apparatus consists of an enclosure made of aluminum extrusion fitted with linear bearings. It provides tilt angles to the heat pipe assemblies. Electric resistance heaters provide heat to the evaporator while a water chiller provides chilled water to extract heat from the condenser. Figure 9 shows a picture of the heat pipe testing apparatus with the insulated heat pipe installed at a tilt angle.

Figure 9. Heat pipe testing apparatus.
The heat pipe was tested with a series of tilt angles and saturation temperatures to analyze the effect of tilt angle and saturation temperatures on minimum start-up power. A series of tests with tilt angles of $0-90^{\circ}$ in increments of $10^{\circ}$ at initial starting temperatures of $20-60^{\circ} \mathrm{C}$ were conducted. The entire heat pipe assembly was maintained
at a constant temperature by supplying temperature-controlled chilled water to the condenser before each test. The heat pipe assembly had to reach thermal equilibrium before each test. Boiling and condensation are not expected to happen inside the heat pipe before heat was being input at the evaporator. A constant heat load was supplied to the evaporator while temperature measurements were taken throughout the body of the heat pipe to monitor the start-up characteristics of the heat pipe. Figure 10 shows the experimental setup. Heat was supplied to the evaporator with electrical heating elements and a copper block was utilized as a heat spreader to minimize temperature differences across the evaporator. Heat was extracted at the condenser, which is attached to a cold plate heat exchanger supplied with running chilled water.

Figure 10. Experiment setup.

### 2.1 Analytical Work

### 2.1.1 Saturated Liquid vs. Vapor Ratio

The amount of saturated fluid collected at the evaporator has direct impacts on the minimum start-up heat input requirement of the heat pipe. Since heat pipes are closed, fixed volume, two-phase heat transfer devices, the ratio of saturated liquid to vapor is directly related to the internal fluid saturated temperature, which is the initial storage temperature of the heat pipe. The intended design of axial grooved thermosyphon heat pipes is to allow saturated working fluid to occupy between the axial grooves along with saturated vapor occupying the vapor core during normal operation with in microgravity in outer space. Orientation of the heat pipe does not affect the boiling performance of the working fluid in outer space without the presence of gravity; the boiling surfaces in between the grooves at the evaporator section would ideally always be wetted with saturated working fluid, ready to be boiled and transformed into vapor state in outer space. Figure 11 illustrates the location of the saturated fluid without the presence of gravity, shown in blue.

Figure 11. Saturated liquid filled axial grooves.

The working fluid behaves differently on ground level with the presence of gravity. This axial grooved thermosyphon heat pipe requires the evaporator be oriented lower than the condenser for the saturated liquid to drain properly from the condenser back to the evaporator with the presence of gravity. The saturated liquid floods the entire evaporator section of the heat pipe including the vapor core due to the density difference between the vapor and liquid state of the working fluid. The boiling surface at the evaporator is affected depending on the total mass of the working fluid, the saturation temperature of the working fluid, and the tilt angle between the evaporator and condenser. If the evaporator is oriented higher than the condenser, the saturated liquid will not be able to return from condenser to evaporator properly due to gravity. It will have to rely on the combination of capillary action and axial groove geometry to travel against gravity. Figure 12 shows the fluid level of the cross-sectioned section of the heat pipe highlighted in green at $20^{\circ} \mathrm{C}$ with 39.4 grams of working fluid charge.

Figure 12. Cross-sectioned view of heat pipe.

The saturation pressure of the working fluid is directly proportional to the operating temperature of the heat pipe. Since the heat pipe is a closed system two-phase thermodynamic heat transfer device, the internal fluid pressure is equal to the saturation pressure of the working fluid. Ammonia has a maximum critical pressure at 11280 kPa at $132.4^{\circ} \mathrm{C}$. Besides the high working pressure near the critical temperature, the enthalpy of vaporization of a working fluid becomes smaller as it approaches its critical temperature; therefore, ammonia heat pipes should not operate close to this temperature range. Figure 13 shows the saturation pressure and temperature relationship over ammonia's operating temperature range.

Figure 13. Ammonia NH3 saturation pressure vs. temperature chart [8].

Liquid and vapor volume fraction of the heat pipe's working fluid was analyzed to understand how the internal boiling surface area of the heat pipe evaporator can be affected by the saturation temperature of the working fluid and tilt angle of the heat pipe. For a working fluid contained in a fixed volume container, its fluids properties are dependent on temperature and pressure. The saturated vapor and liquid volumetric ratios can be calculated with a known volume, temperature, and mass of the working fluid. Equation 1 to Equation 6 analyze the quality, $x$, of the saturated working fluid contained in a fixed volume by utilizing the specific volumes of the saturated liquid and vapor.

$$
v_{\text {avg }}=\frac{\text { Volume }_{\text {heat pipe }}}{\text { Mass }_{\text {Ammonia Charge }}}
$$

$$
\begin{equation*}
x=\frac{v_{\text {avg }}-v_{\text {liquid }}}{v_{\text {vapor }}-v_{\text {liquid }}} \tag{1}
\end{equation*}
$$

$$
\begin{equation*}
\text { Volume }_{\text {liquid }}=[1-x]\left(\text { Mass }_{\text {Ammonia Charge }}\right)\left(v_{\text {liquid }}\right) \tag{2}
\end{equation*}
$$

$$
\begin{equation*}
\text { Liquid Volume Fraction }=\frac{\text { Volume }_{\text {liquid }}}{\text { Volume }_{\text {heat pipe }}} \tag{4}
\end{equation*}
$$

Vapor Volume Fraction $=\frac{\text { Volume }_{\text {vapor }}}{\text { Volume }_{\text {heat pipe }}}$

The fluid properties used to determine the quality of the saturated fluid vary over the operating temperature range of the working fluid. The quality, x , defined in Equation 2 increases as temperature increases. As a result, the ratio of saturated vapor inside the heat pipe increases along with temperature. However, the specific volume of the saturated vapor decreases as temperature rises while the specific volume of the saturated liquid increases along with temperature. Therefore, the saturated liquid occupies a larger volume inside the heat pipe as temperature increases. Table 1 compares the vapor volume and liquid volume over a wide range of operating temperatures. Figure 14 and Figure 15 show how the vapor volume and liquid volume of the working fluid inside the heat pipe change over a wide range of operating temperatures.

Table 1. Vapor and Liquid Volume Ratio vs. Temperature Chart

Figure 14. Saturated vapor volume ratio vs. temperature plot.

Figure 15. Saturated liquid volume ratio vs. temperature plot.

The wetted internal boiling surface area decreases as the saturated liquid volume decreases when the saturated temperature is lowered. The evaporator internal boiling surface area might not be fully flooded with saturated liquid at a low saturated temperature. Figure 16 shows how a partially flooded evaporator would look at low saturation temperatures and a fully flooded evaporator at a high saturation temperature.

Figure 16. Partially flooded evaporator cutaway sections.
Figure 17 depicts the saturated liquid level inside the evaporator over a wide range of saturation temperatures. The volume of saturated liquid inside the heat pipe was calculated using Equation 2 and Equation 3. The evaporator becomes less flooded as temperature decreases. The wetted boiling surface area decreases as the evaporator becomes less flooded. The highlighted yellow and green overlays represent saturated liquid contained inside the evaporator at a vertical $90^{\circ}$ tilt angle orientation.

Figure 17. Saturation temperature effect on flooded evaporator section.
The saturated liquid and vapor ratios are also a function of the working fluid mass.
At a constant pressure, the saturated liquid level inside the heat pipe varies depending on the total mass of the working fluid contained in the fixed volume which will affect how well the evaporator's boiling surface area is flooded.

Table 2 shows the relationship of saturated liquid and vapor's volumetric ratio with the total mass of the working fluid contained in a fixed volume at $20^{\circ} \mathrm{C}$. Figure 18 shows how the saturated liquid's volumetric ratio increases proportionally with the mass of working fluid.

Table 2. Fluid Volume Ratio vs. Ammonia Mass Chart

| 0.100 | $14.9 \%$ | $85.1 \%$ |

Figure 18. Liquid volume ratio vs. ammonia mass plot, $192 \mathrm{cc}, 20^{\circ} \mathrm{C}$.

### 2.1.2 Flooded Evaporator Section vs. Tilt Angle

Tilt angle also affects how well the evaporator is flooded. As tilt angle decreases from the vertical $90^{\circ}$ orientation, the working fluid inside the evaporator conforms with the contour of the internal axial grooves and begins to occupy the adiabatic section of the heat pipe. The evaporator becomes less flooded, and the saturated liquid spills out into the condenser section and occupies both evaporator and condenser section of the heat pipe as the tilt angle decreases to $0^{\circ}$ horizontal orientation. Figure 19 depicts the tilt
angles' effect on the working fluid inside the heat pipe. The highlighted yellow and green sections represent saturated liquid.

Figure 19. Tilt angle effect on flooded evaporator section.

### 2.2 Heat Pipe Thermal Conductivity Calculation

Thermal conductivity of the heat pipe is determined from the temperature difference, conduction distance, heat transfer surface area, and the rate of heat transfer between the evaporator and condenser. Equation 7 explains the relationship between the variables.

$$
\begin{equation*}
\frac{\dot{Q}_{\text {input }}}{A_{\text {flange }}}=-k\left[\frac{T_{\text {evaporator }}-T_{\text {condenser }}}{L_{\text {heat pipe }}}\right] \tag{7}
\end{equation*}
$$

The amount of heat loss to the ambient environment between the evaporator and condenser needs to be subtracted from the overall rate of heat transfer for the thermal conductivity calculation to be accurate. Heat loss analysis of the heat pipe assembly will
be further discussed in Section 2.3 and Section 2.4. The conduction distance and heat transfer surface area used for thermal conductivity calculation is shown in Figure 20.

Figure 20. Length of heat pipe an flange area.

### 2.3 Heat Loss Calculation

Heat loss modeling is a critical part for an accurate thermal conductivity measurement of the heat pipe. Convection of heat from the heat pipe body and heat source is caused by temperature difference between heat pipe surface and room air. Calculation of the total amount of heat loss is required for an accurate heat pipe thermal conductivity determination. Insulation is applied to insulate over the surface of the heat pipe, chiller block, and heater block to minimize heat loss from convection. Air flows constantly inside the heat pipe enclosure box as a safety feature. The variation from the heat loss range is caused by the wide operating temperature range of the heat pipe from $20^{\circ} \mathrm{C}$ to
$60^{\circ} \mathrm{C}$ while the ambient room temperature remains at $20^{\circ} \mathrm{C}$. Heat loss calculation and measurements results are found in Sections 2.3.2 and 2.4.

### 2.3.1 Insulation

Insulation material needs to provide enough thermal resistance for proper insulation.
Extruded polystyrene foam insulation sheets with a thermal conductivity value of $0.036 \mathrm{~W} / \mathrm{mK}$ was selected for constructing the insulation system. Figure 21 shows a sheet of extruded polystyrene foam.

Figure 21. Extruded polystyrene foam sheet.

An insulation system was designed with extrude polystyrene foam to insulate the entire heat pipe assembly. Multiple layers of insulation sheets were cut to size as shown in

Figure 22.

Figure 22. Evaporator insulation L1 layer.
Multiple layers of insulation foam sheets were joined together with adhesive to form the insulation systems for the evaporator section, condenser section, and the adiabatic
section. Figure 23 and Figure 24 show the exploded view and a fully assembled configuration of the insulation system assembly.

Figure 23. Insulation system exploded view.

Figure 24. Insulated heat pipe assembly.

### 2.3.2 CFD Heat Loss Analysis

A CFD heat loss model was constructed in Comsol Multiphysics to understand the amount of heat loss present in the experiment. A range of constant temperature from -10 ${ }^{\circ} \mathrm{C}$ to $60^{\circ} \mathrm{C}$ was applied to the internal walls of the evaporator and adiabatic section of the insulation system in the CFD model. Heat loss from the chiller block section of the heat pipe assembly was not needed to be accounted for as it is located downstream of the condenser flange on the conduction path as shown in the resistance network in Figure 25. No boundary condition settings were applied on the internal walls of the condenser section. Volumetric flow rate of 40 CFM was applied to the inlet of the controlled volume with air at $20^{\circ} \mathrm{C}$. Volumetric flow rate setting of 40 CFM represents the inline fan operating without any back pressure. The inline fan operates at a lower volumetric
flow rate with the actual internal airflow impedance of the sheet metal enclosure which may lead to a slight overestimation of heat loss.

Figure 25. Thermal resistance network.

Figure 26 shows the internal surfaces where the temperature boundary condition is applied. Figure 27 shows the mesh element distribution used for the analysis. Figure 28 and Figure 29 show the temperature and air velocity pattern of the results.

Figure 26. Temperature boundary condition surfaces.

Figure 27. Mesh element distribution.

Figure 28. Temperature plot in kelvin.

Figure 29. Air velocity plot in m/s.
The total amount of heat loss increases as temperature of the heat pipe elevates from room temperature. CFD results show the maximum amount of heat loss of 10 W at $60^{\circ} \mathrm{C}$ and no heat loss at $20^{\circ} \mathrm{C}$, about $3 \%$ of total heat input of 300 W at $60^{\circ} \mathrm{C}$.

Table $\mathbf{3}$ and Figure 30 show the CFD heat loss analysis results. Equation 8 explains how a simplified thermal resistance, $R_{\text {loss }}$, is calculated by using evaporator temperature, adiabatic section temperature, ambient temperature, and the sum of heat loss from the evaporator and adiabatic section of the heat pipe, assuming the temperature difference between evaporator and adiabatic section is small.

$$
\begin{equation*}
R_{\text {loss }}=\frac{\frac{T_{\text {evaporator }}+T_{\text {adiabatic }}}{2}-T_{\text {ambient }}}{\dot{Q} \underset{\text { loss }}{\text { evaporator }}+\dot{Q} \underset{\text { adiabatic }}{\text { loss }}} \tag{8}
\end{equation*}
$$

Table 3. CFD Heat Loss Analysis Results

| Temperature $\left[{ }^{\circ} \mathrm{C}\right]$ | Heat Loss $[\mathrm{W}]$ | $R_{\text {loss }}\left[{ }^{\circ} \mathrm{C} / \mathrm{W}\right]$ |
| :---: | :---: | :---: |
| 60 | 10.2 | 3.92 |
| 50 | 7.7 | 3.90 |
| 40 | 5.1 | 3.92 |
| 30 | 2.6 | 3.85 |
| 20 | 0 | $\mathrm{~N} / \mathrm{A}$ |
| 10 | -2.6 | 3.85 |
| 0 | -5.2 | 3.85 |
| -10 | -7.7 | 3.90 |

Figure 30. CFD heat loss vs. temperature analysis results.

The total power delivered from evaporator to condenser can be defined by subtracting heat loss from power input as described in Equation 9 and Equation 10.

$$
\begin{gather*}
\dot{Q}_{\text {input }}=P_{\text {input }}-\dot{Q} \underset{\text { evaporator }}{\text { loss }}-\dot{Q} \underset{\text { adiabatic }}{\text { loss }}  \tag{9}\\
\dot{Q}_{\text {input }}=P_{\text {input }}-R_{\text {loss }}\left[\frac{T_{\text {evaporator }}+T_{\text {adibatic }}}{2}-T_{\text {ambient }}\right] \tag{10}
\end{gather*}
$$

### 2.4 Physical Heat Loss Measurement

Physical heat loss measurements were conducted by elevating the evaporator and adiabatic section of the heat pipe assembly to match the temperature of the condenser to reach thermal equilibrium. The electrical power required for the heat pipe assembly to reach thermal equilibrium represents the total heat loss at the evaporator and adiabatic section. It is important to increase the electrical input power slowly over time to avoid any initiation of the boiling process inside the evaporator while elevating the temperature of the overall heat pipe assembly. A noticeable sudden temperature drop on the evaporator can be observed once the saturated liquid inside the evaporator begins to boil which is an indication of more than enough power is being applied to the heater block. Physical heat loss measurements were conducted from $30^{\circ} \mathrm{C}$ to $60^{\circ} \mathrm{C}$ in increments of $10^{\circ} \mathrm{C}$. Table 4 summarizes the amount of heat loss measured physically while Figure 31 compares the CFD heat loss results with the actual measurements. The results from
physical heat loss measurements align with the CFD heat loss analysis conducted in section 2.3.

Table 4. Physical Heat Loss Measurements

| Heat Pipe <br> Temperature <br> $\left[{ }^{\circ} \mathrm{C}\right]$ | Ambient <br> Temperature <br> $\left[{ }^{\circ} \mathrm{C}\right]$ | $\Delta \mathrm{T}$ <br> $\left[{ }^{\circ} \mathrm{C}\right]$ | Heat <br> Loss <br> $[\mathrm{W}]$ | $R_{\text {loss }}$ <br> $\left[{ }^{\circ} \mathrm{C} / \mathrm{W}\right]$ |
| :---: | :---: | :---: | :---: | :---: |
| 59.9 | 17.2 | 42.7 | 11.5 | 3.71 |
| 50.1 | 18.4 | 31.7 | 9.0 | 3.52 |
| 40.3 | 17.7 | 22.6 | 5.5 | 4.11 |
| 30.4 | 18.0 | 12.3 | 3.0 | 4.13 |

Figure 31. Physical vs. CFD heat loss comparison.

### 2.5 Nucleate Boiling Analysis

In order to initiate boiling of working fluid inside the evaporator, the internal heated surface temperature must be elevated above the saturation temperature of the working fluid. The rate of heat transfer of nucleate boiling is described in Equation 11 and the components used in the equation is explained in Table 5.

$$
\begin{equation*}
\dot{q}_{\text {nucleate }}=\mu_{l} h_{f g}\left[\frac{g\left(\rho_{l}-\rho_{v}\right)}{\sigma}\right]^{0.5}\left[\frac{C_{p l}\left(T_{s}-T_{s a t}\right)}{C_{s f} h_{f g} P r_{l}^{n}}\right]^{3} \tag{11}
\end{equation*}
$$

Table 5. Nucleate Boiling Equation Components

| Terms | Description | Units |
| :---: | :---: | :---: |
| $\dot{q}_{\text {nucleate }}$ | Nucleate Boiling Heat Flux | $\mathrm{W} / \mathrm{m}^{2}$ |
| $\mu_{l}$ | Viscosity of the Liquid | $\mathrm{kg} / \mathrm{m} \cdot \mathrm{s}$ |
| $h_{f g}$ | Enthalpy of Vaporization | $\mathrm{J} / \mathrm{kg}$ |
| $g$ | Gravitational Acceleration | $\mathrm{m} / \mathrm{s}^{2}$ |
| $\rho_{l}$ | Density of the Liquid | $\mathrm{kg} / \mathrm{m}^{3}$ |
| $\rho_{v}$ | Density of the Vapor | $\mathrm{kg} / \mathrm{m}^{3}$ |
| $\sigma$ | Surface Tension of Liquid-Vapor |  |
| Interface | $\mathrm{N} / \mathrm{m}$ |  |
| $C_{p l}$ | Specific Heat of the Liquid | $\mathrm{J} / \mathrm{kg} \cdot{ }^{\circ} \mathrm{C}$ |
| $T_{\text {excess }}$ | Excess Temperature, $T_{s}-T_{s a t}$ | ${ }^{\circ} \mathrm{C}$ |
| $T_{s}$ | Temperature of the Heated Surface | ${ }^{\circ} \mathrm{C}$ |
| $T_{s a t}$ | Saturation Temperature of the Fluid | ${ }^{\circ} \mathrm{C}$ |
| $C_{s f}$ | Experimental Surface-Fluid Constant |  |
| $P r_{l}$ | Prandtl Number of the Liquid |  |
| $n$ | Experimental Fluid Constant |  |

Fluid properties used in Equation 11 are functions of temperature and pressure.
Temperature of the heated surface is a component of interest that was closely examined along with the start-up power requirement. Viscosity and surface tension of the working fluid are two major components which affects the heated surface excess temperature, $T_{s}-T_{\text {sat }}$. They both decrease as the saturation temperature increases. Figure 32 and Figure 33 show the relationship between liquid viscosity and surface tension of the working fluid over its operating temperature.

Figure 32. Ammonia NH3 liquid viscosity vs. saturation temperature [8].

Figure 33. Ammonia NH3 surface tension vs. saturation temperature [8].
The heated surface excess temperature increases marginally to offset for the difference caused by decrease in viscosity and surface tension to maintain a constant nucleate boiling heat flux in Equation 9 when the saturation temperature of the fluid increases. The heated surface temperature for a range of saturation temperatures from $20^{\circ} \mathrm{C}$ to $60^{\circ} \mathrm{C}$ in increments of $10^{\circ} \mathrm{C}$ were calculated by setting the nucleate boiling heat flux to a constant. Figure 34 shows the correlation of heated surface temperatures vs. fluid saturation temperatures.

Figure 34. Heated surface excess temperature vs. saturation temperature.

### 3.0 Experimental Work

### 3.1 Heater Block Assembly

The heater block provides and spreads the heating load applied to the heat pipe evaporator. It acts as a thermal mass to dampen any sudden changes in heat transfer rate to maintain an isothermal heat transfer surface for the heat pipe evaporator. The heater block is placed between the evaporator flange and the heating element. An array of resistance heating elements was selected to be able to provide 300 W of heating load for the heater block. Figure 35 shows a single resistance heating element.

Figure 35. Resistance heating element $40 \mathrm{~mm} \times 40 \mathrm{~mm} \times 2 \mathrm{~mm}$.
The heater block consisted of a fiberglass backing plate, a 0.75 " thick copper plate, resistance heating elements, thermal interface material, and mechanical fasteners to assemble the heater block together. Figure 36 shows the exploded view of the overall heater block design.

Figure 36. Heater block exploded view.

Silicone thermal interface material was used to conduct heat from the resistance heating elements to the copper plate. Thermocouples were installed between the thermal interface material and copper plate. Mechanical features were designed into the fiberglass backing plate to precisely control the positions of resistance heating elements and thermal interface material compression. Figure 37 and Figure 38 show the resistance heating element placement with thermocouple and thermal interface material installed on the fiberglass backing plate.

Figure 37. Resistance heater and TIM configuration.

Figure 38. Resistance heater array installed on backing plate.

Stainless steel fasteners were used to evenly compress the thermal interface material across all the resistance heating elements. Figure 39 to Figure 41 show the assembled heater block, heater block assembled onto the evaporator assembly, and cross-sectional view of the evaporator assembly.

Figure 39. Assembled heater block.

Figure 40. Heat pipe evaporator assembly.

Figure 41. Evaporator assembly cross-sectional view.

### 3.2 Chiller Block

A chilled water cold plate was used to extract heat from the condenser. The cold plate was constructed entirely from T6-6061 aluminum. Temperature-controlled coolant was supplied to the cold plate at a volumetric flowrate of 5 GPM to provide an isothermal heat
transfer surface for the condenser flange. Figure 42 shows the cold plate assembly and Figure 43 shows the cross-sectional view of the cold plate assembly.

Figure 42. Chiller block assembly.

Figure 43. Chiller block cross-sectional view.

### 3.3 Mechanical Retention System

A mechanical retention system was designed to provide adequate compression force across the thermal interface material between the evaporator and condenser. The mechanical retention system consisted of aluminum plates, fiberglass plates, and mechanical fasteners. The aluminum plates provided mechanical structure to provide compression force. The fiberglass plates provided thermal insulation against the evaporator and condenser surfaces. Stainless steel mechanical hardware provided compression force against thermal interface material upon tightening. The identical mechanical retention system was used on the evaporator and condenser assembly of the thermosyphon. Figure 44 shows the exploded view of the mechanical retention system.

Figure 45 shows the mechanical retention system installed onto the condenser of the heat pipe assembly.

Figure 44. Evaporator and condenser mechanical retention system.

Figure 45. Mechanical retention system installed on condenser.

### 3.4 Thermal Interface Material

A silicone compound gap filler type thermal interface material was selected for its compressibility and thermal conductivity. It is important for thermal interface material to fill the gap between the heat pipe flanges, heater, and chiller blocks over a large surface area. The thermal interface material has a silicone compound composition with a thermal conductivity of $6 \mathrm{~W} / \mathrm{mk}$ and an initial thickness of 1 mm . It was expected to achieve $50 \%$ compression to reach a final thickness of 0.5 mm upon mechanical compression. A physical compressions test showed that the selected thermal interface material was able to evenly fill up the gap between the evaporator flanges and the heater and chiller blocks.

Figure 46 and Figure 47 show that the thermal interface material was evenly compressed by the mechanical retention system over the large heat transfer surface area.

Figure 46. Thermal interface material before compression.

Figure 47 . Evenly compressed thermal interface material.

### 3.5 DC Power Supply

The electrical power consumption of the electrical resistance heating element was measured for heat input calculation. Electrical energy is transformed into thermal energy at the resistive coils inside the resistance heating elements. Each individual heating resistance element has an electrical impedance of $6 \Omega$ at $20^{\circ} \mathrm{C}$, and they were configured in parallel. Figure 48 shows the electrical configuration of the resistance heating elements.

Figure 48. Heater block electrical impedance diagram.
DC power was selected to power the resistance heating elements. The DC power supply needed to deliver 20VDC of voltage and 14 A of current to provide 300 W of heat to the evaporator. A Chroma 62024P-80-60 DC programmable power supply was selected for its ability to deliver the required voltage and current. The selected power supply is also programmable. A series of power output can be preprogrammed into the power supply for test automation capabilities. Figure 49 and Figure 50 show the programmable DC power supply and the Chroma software interface.

Figure 49. Programmable DC power supply.

Figure 50. Chroma soft panel interface.
The DC voltage and current were distributed across each individual resistance heating
element using din rail terminal blocks. Electrical current supplied to the resistance
heating elements was measured with a shunt resistor wired in series with the DC power
supply. Voltage was measured at the din rail terminal blocks. Figure 51 shows the DIN rail electrical distribution unit.

Figure 51. DC electrical distribution terminal blocks.

### 3.6 Water Chiller

The water chiller malfunctioned and failed to maintain a constant chilled water bath temperature due to electronic component failures in the control circuit. The original control circuit was not able to maintain the chilled water bath temperature at set point. It caused the chilled water supply temperature to fluctuate beyond acceptable range for the heat pipe testing processes to reach steady state. The water chiller's temperature stability was restored by replacing the control circuit and some corresponding electromechanical components. Installing a new temperature controller was considered instead of repairing the original control circuit. The new temperature controller improved the water chiller's
capabilities by adding remote controlled capabilities onto the water chiller. Figure 52 shows the malfunctioned control circuit.

Figure 52. Malfunctioned control circuit.
A temperature controller with serial communication feature was selected. An Omega
CNi 32 series PID temperature controller was installed to control the chilled water temperature by throttling the refrigerant solenoids. The controller has the capability to be programmed remotely with RS-232 or RS-485 communication protocols. Figure 53 shows the Omega CNi32 PID temperature controller.

Figure 53. Omega CNi32 PID temperature controller.

All the original electronic components were removed from the water chiller before the redesigned control circuit and temperature controller were installed. The redesigned control circuit consists of a 24VDC power supply, two DC solid state relays, an Atmel Atmega 328P microcontroller, a 24VDC to 5VDC DC-DC switching regulator, and two 24VDC refrigerant solenoids. The temperature controller has a DPST, double pole single throw relay which can be used to energize the two refrigerant solenoids. Instead of energizing the refrigerant solenoids directly with the DPST relay on the temperature controller, two solid state relays and a programmed microcontroller are used to energize the refrigerant solenoids to reduce wear and tear on the temperature controller's DPST relay. The microcontroller senses high and low signals from the temperature controller and sends digital signals to the solid-state relays for refrigeration solenoids throttling.

Figure 54 to Figure 56 show the new control circuit installed onto the water chiller.

Figure 54. Water chiller control circuit components.

Figure 55. New water chiller control circuit.

Figure 56. New water chiller circuit installed.
The temperature controller was programmed with a proportional gain value of 30, integral value of 0 , derivative value of 0 , and a cycle time of 3 seconds. It is able to maintain the chilled water bath within $+/-0.1^{\circ} \mathrm{C}$. Figure 57 shows the chilled water bath temperature response with a sudden drop of heat load from 275 W to 50 W over time.

Figure 57. Chilled water bath temperature response graph.

### 3.7 Thermocouple Locations

Type T thermocouples were used in this experiment. Thermocouples were instrumented throughout the body of the heat pipe. A total of 12 thermocouples were used for acquiring temperature readings on the heat pipe body. Heat loss is modeled with four thermocouples. Figure 58 shows the actual positions of the thermocouples mounted on the heat pipe during testing.

Figure 58. Locations of thermocoples on heat pipe assembly.

Channels 1 to 4 were mounted on the evaporator body to acquire evaporator readings. Channels 9 to 12 were mounted on the condenser body to acquire condenser readings. Figure 59 and Figure 60 show the location of thermocouples 1-4 and 9-12 on the evaporator and condenser body.

Figure 59. Locations of thermocoples on evaporator body.

Figure 60. Locations of thermocoples on condenser body.

### 3.8 Uncertainty Analysis

The total temperature uncertainty on a single channel of thermocouple temperature measurement can be defined as described in Equation 12 and Equation 13.

$$
\begin{gather*}
U_{\text {total }}=\sqrt{{U_{\text {bias }}}^{2}+U_{\text {random }}{ }^{2}}  \tag{12}\\
U_{\text {bias }}=\sqrt{\left(T_{\text {thermocouple }}-T_{\text {thermometer }}\right)^{2}} \tag{13}
\end{gather*}
$$

A hot plate with a magnetic stirrer was used to provide a constant temperature bath for determining the bias uncertainty and random uncertainty of the thermocouples. Random error of the new thermocouples was determined by taking 30 fast readings in an isothermal water bath. The standard deviation of the 30 readings was used to determine the random error. Figure 61 shows the temperature calibration setup.

Figure 61. Thermocouple calibration setup.

The bias uncertainty was determined to be $0.31^{\circ} \mathrm{C}$. The random error was analyzed to be $0.04^{\circ} \mathrm{C}$. The total temperature uncertainty was calculated to be $0.31^{\circ} \mathrm{C}$.

The Agilent data logger has a voltage measurement accuracy of $0.0026 \%$. The total power input, $P_{\text {input }}$ uncertainty was determined to be $0.0052 \%$. Physical heat loss uncertainty was calculated to be 1.2 W . Thermal conductivity uncertainty was calculated to be $0.44 \%$. The total heat transfer from evaporator to condenser, $\dot{Q}_{\text {input }}$ uncertainty is 1.2 W. Table 6 summarizes the experimental uncertainty findings.

Table 6. Experimental Uncertainty Table

| Measurement | Experimental <br> Uncertainty |
| :---: | :---: |
| Temperature | $0.31^{\circ} \mathrm{C}$ |
| $P_{\text {input }}$ | $0.01 \%$ |
| $\dot{Q}_{\text {loss }}$ | 1.2 W |
| $\dot{Q}_{\text {input }}$ | 1.2 W |
| $k$ | $0.44 \%$ |

### 4.0 Results and Discussion

Start-up tests were performed on the $S$ shaped thermosyphon heat pipe. The start-up tests were conducted from $20^{\circ} \mathrm{C}-60^{\circ} \mathrm{C}$ in a $10^{\circ} \mathrm{C}$ initial starting temperature with tilt angles of $0-90^{\circ}$ in increments of $10^{\circ}$. Temperature-controlled coolant was initially supplied to the condenser. Temperature readings of the heat pipe assembly were being constantly monitored during the test. A constant heat load was supplied to the evaporator once the whole heat pipe assembly reached the initial start-up temperature. Start-up was determined from a noticeable temperature decrease at the evaporator body which
indicates the initiation of nucleate boiling inside the evaporator. Figure 62 and Figure 63 show examples of the start-up temperature plots for a $70^{\circ}$ tilt angle at a $50^{\circ} \mathrm{C}$ starting temperature with 18W and 70W of heat input. Figure 62 shows a temperature decrease of $0.35^{\circ} \mathrm{C}$, just outside of the temperature uncertainty of $0.31^{\circ} \mathrm{C}$. All excess temperature measured at start-up except for three data points were greater than the temperature uncertainty.

Figure $62.18 \mathrm{~W} 50^{\circ} \mathrm{C} 70^{\circ}$ tilt start-up.

Figure $63.70 \mathrm{~W} 50^{\circ} \mathrm{C} 70^{\circ}$ tilt start-up.
The start-up characteristics of the evaporator were captured in the start-up examples in Figure 62 and Figure 63. Temperature of the evaporator began to elevate once electrical current was delivered to the resistance heating elements. A sudden drop of the evaporator body temperature was recorded as the evaporator's temperature was ramping up. The temperature difference recorded on the evaporator is the excess temperature in Equation 11. The excess temperature measured was different when compared between the 18 W and 70 W tests. The excess temperature measured in the 70 W start-up test was higher than the 14 W test. The excess temperature differences measured between the start-up examples conform to the definition of Equation 11. The 70W test yielded a higher heat flux while the 14 W test yielded a lower heat flux. Using the same set of fluid properties, solving Equation 11 returned a higher excess temperature for 70 W when
compared to 14 W . The remaining series of start-up tests were completed from $20^{\circ} \mathrm{C}$ $60^{\circ} \mathrm{C}$ in a $10^{\circ} \mathrm{C}$ initial starting temperature with tilt angles of $0-90^{\circ}$ in increments of $10^{\circ}$.

As the tilt angle decreased beyond $60^{\circ}$, the evaporator started boiling immediately once the heating elements were powered on. Start-up power no longer exists as the tilt angle decreased beyond $60^{\circ}$, which could be due to a partially flooded evaporator. The evaporator boiling surface area decreases as the evaporator becomes partially flooded. The heat flux on the internal boiling surface area increased as the internal boiling surface area decreases. This data trend indicates that the tilt angle slightly affects the excess temperature. However, its effect is not as noticeable when compared to adjustments in saturation temperature. The static pressure acting on the boiling surface area decreases as tilt angle decreases. Figure 19 from Section 2.1 shows the amount of fluid column height difference between tilt angles. Equation 11 suggests that the excess temperature slightly lowers as tilt angle decreases. Figure 64 shows the minimum amount of power that was required to initiate boiling inside the evaporator. Figure 65 shows the excess temperatures that were required to initiate boiling inside the evaporator.

Figure 64. Evaporator start-up power requirement vs. saturation temperature.

Figure 65. Evaporator excess temperature vs. saturation temperature.

The evaporator excess temperatures found to be required to initiate start-up presented in Figure 65 aligned with the data from Figure 34 generated from Equation 11 using ammonia, the working fluid's properties over the range of operating temperatures. The majority of the variables in Equation 11 decreased as saturation temperature increases. A higher excess temperature on the heated surface was required to maintain a constant heat input requirement presented in Figure 34 to initiate the start-up boiling process inside the evaporator as the saturation temperature increased. Figure 66 shows the data presented in Figure 65 overlaying with the data from Figure 34.

Figure 66. Evaporator excess temperature vs. saturation temperature.
A thermal conductivity test was conducted with a constant heat load of 200 W from $0^{\circ}-90^{\circ}$ tilt angle at $20^{\circ} \mathrm{C}$ saturation temperature to understand the effect of tilt angle on thermal conductivity. Thermal conductivity gradually decreases as the tilt angle decreases from $90^{\circ}$ to $0^{\circ}$. The evaporator becomes less flooded as tilt angle decreases
which leads to a smaller boiling surface area. As boiling surface area decreases, heat flux increases which results a higher excess temperature in Equation 11. The evaporator temperature in Equation 7 is directly proportional to the excess temperature in Equation 11. As a result, thermal conductivity decreases as tilt angle decreases. Figure 67 shows the relationship between thermal conductivity and tilt angle.

Figure 67. Effective thermal conductivity vs. tilt angle.

### 5.0 Conclusion and Future Work

Minimum start-up power requirements were found for tilt angles of $90^{\circ}, 80^{\circ}, 70^{\circ}$, and $60^{\circ}$ at $20^{\circ} \mathrm{C}, 30^{\circ} \mathrm{C}, 40^{\circ} \mathrm{C}, 50^{\circ} \mathrm{C}$, and $60^{\circ} \mathrm{C}$ saturation temperatures. Results show the minimum start-up power requirements at different tilt angles and saturation temperature were between 2 W and 3.6 W . There might be a small correlation between the minimum start-up power and tilt angles and saturation temperatures, but the power difference might be too small for this experiment setup to capture. The excess temperature required to
initiate the start-up boiling process in the evaporator was found to increase as the working fluid's saturation temperature increased. The relationship between the excess temperature and the working fluid's saturation temperature aligns with the nucleate boiling equation. The excess temperature of a heated surface increases as the surface tension of a working fluid decreases if the heat input is to remain constant. The $S$ shaped thermosyphon heat pipe was able to initiate start-up with a smaller excess temperature as the saturation temperature decreased. When the tilt angle decreased to an angle where the evaporator is no longer flooded, no signs of start-up behavior were noticed.

A better heat loss model could help to further improve the results of this experiment. This could better quantify the total amount of heat delivered from the evaporator to the condenser by better insulating the experiment and quantifying heat loss.
