# Beyond the Fokker–Planck equation: Pathwise control of noisy bistable systems

Nils Berglund and Barbara Gentz

## Abstract

We introduce a new method, allowing to describe slowly time-dependent Langevin equations through the behaviour of individual paths. This approach yields considerably more information than the computation of the probability density. The main idea is to show that for sufficiently small noise intensity and slow time dependence, the vast majority of paths remain in small space–time sets, typically in the neighbourhood of potential wells. The size of these sets often has a power-law dependence on the small parameters, with universal exponents. The overall probability of exceptional paths is exponentially small, with an exponent also showing power-law behaviour. The results cover time spans up to the maximal Kramers time of the system. We apply our method to three phenomena characteristic for bistable systems: stochastic resonance, dynamical hysteresis and bifurcation delay, where it yields precise bounds on transition probabilities, and the distribution of hysteresis areas and first-exit times. We also discuss the effect of coloured noise.

## 1 Introduction

Noise is often used to model the effect of fast degrees of freedom, which are too involved to describe otherwise. In statistical physics and solid state physics, for instance, the influence of a heat bath is represented by a stochastic Glauber dynamics or a Langevin equation. In meteorological and climate models, the effect of fast modes (e. g. short wavelength modes neglected in a Galerkin approximation) is often described by noise [Ha, Ar2]. As a consequence, stochastic differential equations are widely used to model systems of physical interest, including ferromagnets [Mar], lasers [Ri, HL, HN], neurons [Tu, Lo], glacial cycles [BPSV], oceanic circulation [Ce], biomolecules [SHD], and more.

Among the simpler stochastic models in use is the Langevin equation with additive white noise

$$dx_t = -\nabla V(x_t, \lambda) dt + \sigma G(\lambda) dW_t. \quad (1.1)$$

Here  $V$  is a potential,  $W_t$  denotes a standard vector-valued Wiener process (i. e., a Brownian motion), and  $\sigma$  measures the noise intensity. For now, we consider  $\lambda$  as a fixed parameter, but below we will be concerned with situations where  $\lambda$  varies slowly in time. Of course,

one may be interested in situations where noise enters in a different way, for instance  $G$  depending on  $\mathbf{x}$  as well, or coloured noise.

There exist different methods to characterize the dynamics of the Langevin equation (1.1). A popular approach is to determine the probability density  $p(\mathbf{x}, t)$  of  $\mathbf{x}_t$ , which gives all information on the instantaneous state of the system. For instance, the probability that  $\mathbf{x}_t$  belongs to a subset  $\mathcal{D}$  of phase space is given by the integral of  $p(\mathbf{x}, t)$  over  $\mathcal{D}$ . The density is given by the normalized solution of the Fokker–Planck equation

$$\frac{\partial}{\partial t} p(\mathbf{x}, t) = \nabla \cdot (\nabla V(\mathbf{x}, \lambda) p(\mathbf{x}, t)) + \nabla \cdot D(\lambda) \nabla p(\mathbf{x}, t), \quad (1.2)$$

where  $D = (\sigma^2/2)GG^T$  is the diffusion matrix. In particular, in the isotropic case  $GG^T = \mathbb{1}$ , (1.2) admits the stationary solution

$$p_0(\mathbf{x}) = \frac{1}{N} e^{-2V(\mathbf{x})/\sigma^2}, \quad (1.3)$$

where  $N$  is the normalization. For small  $\sigma$ , the stationary distribution is sharply peaked around the minima of the potential. For an arbitrary initial distribution, however, the Fokker–Planck equation cannot be solved in general, and one has to rely on spectral methods, WKB approximations and the like.

Even if we have obtained a solution of (1.2), this approach still has serious shortcomings. The reason is that the probability density only gives an instantaneous picture of the system. If, for instance, we want to compute correlation functions such as  $\mathbb{E}\{\mathbf{x}_s \mathbf{x}_t\}$  for  $0 < s < t$ , solving the Fokker–Planck equation with initial condition  $\mathbf{x}_0$  is not enough: We need to solve it for *all* initial conditions  $(\mathbf{x}_s, s)$ . Quantities such as the supremum of  $\|\mathbf{x}_t\|$  over some time interval are even harder to handle.

It is important to take into account that the stochastic differential equation (1.1) does not only induce a probability distribution of  $\mathbf{x}_t$ , but also generates a measure on the paths, which contains much more information. For almost any realization  $W_t(\omega)$  of the Brownian motion, and any deterministic initial condition  $\mathbf{x}_0$ , the solution  $\{\mathbf{x}_t(\omega)\}_{t \geq 0}$  of (1.1) is a continuous function of time (though not differentiable). The random variable  $\mathbf{x}_t(\omega)$  for fixed  $t$  is only one of many interesting random quantities which can be associated with the stochastic process.

First-exit times form an important class of such alternative random variables, and have been studied in detail. If  $\mathcal{D}$  is a (measurable) subset of phase space, the first-exit time of  $\mathbf{x}_t$  from  $\mathcal{D}$  is defined as

$$\tau_{\mathcal{D}} := \inf\{t > 0 : \mathbf{x}_t \notin \mathcal{D}\}. \quad (1.4)$$

For instance, if  $\mathcal{D}$  is a set of the form  $\{\mathbf{x} : V(\mathbf{x}) \leq V_1\}$ , containing a unique equilibrium point which is stable, then the distribution of  $\tau_{\mathcal{D}}$  is asymptotically exponential, with expectation behaving in the small-noise limit like Kramers' time

$$T_{\text{Kramers}} = e^{2(V_1 - V_0)/\sigma^2}, \quad \text{where } V_0 := \min_{\mathbf{x} \in \mathcal{D}} V(\mathbf{x}). \quad (1.5)$$

A mathematical theory allowing to estimate first-exit times for general  $n$ -dimensional systems (with a drift term not necessarily deriving from a potential) has been developed by Freidlin and Wentzell [FW]. In specific situations, more precise results are available, for instance the following. If  $\mathcal{D}$  contains a unique, stable equilibrium point, subexponential corrections to the asymptotic expression (1.5) are known, even for possibly time-dependent

drift terms [Az, FJ]. The case where  $\mathcal{D}$  contains a saddle as unique equilibrium point has been considered by Kifer in the seminal paper [Ki]. The situation where  $\mathcal{D}$  contains a stable equilibrium in its interior and a saddle on its boundary is dealt with in [MS1], employing the method of matched asymptotic expansions. The limiting behaviour of the distribution of the first-exit time from a neighbourhood of a unique stable equilibrium point as well as from a neighbourhood of a saddle point has been obtained by Day [Day1, Day2].

We remark that more recently, another approach has been introduced, which mimics concepts from the theory of dissipative dynamical systems [CF1, Schm, Ar1]. The main idea is that for a given realization of the noise (i. e., in a quenched picture), paths with different initial conditions may converge to an attractor, which has similar properties as deterministic attractors. Of course, in experiments, this random attractor is only visible if we manage to repeat the experiment many times with the same realization of noise.

The method of choice to study the Langevin equation (1.1) also depends on the time scale we are interested in. Consider for instance a one-dimensional double-well potential  $V(x) = -\frac{1}{2}ax^2 + \frac{1}{4}bx^4$ ,  $a, b > 0$ , with a barrier of height  $H = a^2/4b$ . Assume that  $x_0$  is concentrated at the bottom  $x = \sqrt{a/b}$  of the right-hand potential well. If the noise is sufficiently weak, paths are likely to stay in the right-hand well for a long time. The distribution of  $x_t$  will first approach a Gaussian in a time of order

$$T_{\text{relax}} = \frac{1}{c}, \quad (1.6)$$

where  $c = 2a$  is the curvature at the bottom of the well (the variance of the Gaussian is approximately  $\sigma^2/(2c)$ ). With overwhelming probability, paths will remain inside the same potential well, for all times significantly shorter than Kramers' time  $T_{\text{Kramers}} = e^{2H/\sigma^2}$ . Only on longer time scales will the density of  $x_t$  approach the bimodal stationary density (1.3). The dynamics will thus be very different on the time scales  $t \ll T_{\text{relax}}$ ,  $T_{\text{relax}} \ll t \ll T_{\text{Kramers}}$ , and  $t \gg T_{\text{Kramers}}$ . Random attractors can be reached only in the last regime. In particular, results in [CF2] stating that for the double-well potential  $V$ , the random attractor almost surely consists of one (random) point apply to the regime  $t \gg T_{\text{Kramers}}$ .

In the present work, we are interested in situations where the parameter  $\lambda$  varies slowly in time, that is, we consider stochastic differential equations (SDEs) of the form

$$dx_t = -\nabla V(x_t, \lambda(\varepsilon t)) dt + \sigma G(\lambda(\varepsilon t)) dW_t. \quad (1.7)$$

Such situations occur if the system under consideration is slowly forced, for instance by an external magnetic field, by climatic changes, or by a varying energy supply. Note that the probability density of  $x_t$  still obeys a Fokker–Planck equation, but there will be no stationary solution in general.

The main idea of our approach to equations of the form (1.7) is the following. For sufficiently small  $\varepsilon$  and  $\sigma$ , and on an appropriate time scale, we show that the paths  $\{x_t\}_{t \geq 0}$  can be divided into two classes. The first class consists of those paths which remain in certain space–time sets, typically in the neighbourhood of potential wells (but in some cases, they may switch potential wells). The geometry and size of these sets depends on noise intensity and shape of potential. The second class consists of the remaining paths, which we do not try to describe in detail, but whose overall probability is small, typically exponentially small in some combination of  $\varepsilon$  and  $\sigma$ . In this way, we obtain in particular concentration results on the density of  $x_t$  without solving the Fokker–Planck equation, but we also obtain global information on the stochastic process, including correlations, first-exit times, transition probabilities and, for instance, the shape of hysteresis cycles.

The slow time dependence of  $\lambda$  introduces a new time scale. If, for instance,  $\lambda$  is periodic with period 1, then (1.7) depends periodically on time with period  $T_{\text{forcing}} = 1/\varepsilon$ . Since the shape of the potential changes in time, the definitions (1.5) and (1.6) of the Kramers and relaxation times no longer make sense. We can, however, define these time scales by

$$T_{\text{Kramers}}^{(\text{max})} = e^{2H_{\text{max}}/\sigma^2} \quad \text{and} \quad T_{\text{relax}}^{(\text{min})} = \frac{1}{c_{\text{max}}}, \quad (1.8)$$

where  $H_{\text{max}}$  and  $c_{\text{max}}$  denote, respectively, the maximal values of barrier height and curvature of a potential well over one period. Our results typically apply to the regime

$$T_{\text{relax}}^{(\text{min})} \ll T_{\text{forcing}} \ll T_{\text{Kramers}}^{(\text{max})}, \quad (1.9)$$

that is, we require that  $\varepsilon \ll c_{\text{max}}$  and  $\sigma^2 \ll 2H_{\text{max}}/|\log \varepsilon|$ . The minimal curvature and barrier height, however, are allowed to become small, or even to vanish.

We can describe the paths' behaviour on time intervals including many periods of the forcing, as long as they are significantly shorter than the maximal Kramers time. We find it convenient to measure time in units of the forcing period. After scaling  $t$  by a factor  $\varepsilon$ , the relevant time scales become

$$T_{\text{relax}}^{(\text{min})} = \frac{\varepsilon}{c_{\text{max}}}, \quad T_{\text{forcing}} = 1, \quad T_{\text{Kramers}}^{(\text{max})} = \varepsilon e^{2H_{\text{max}}/\sigma^2}. \quad (1.10)$$

When scaling the Brownian motion, we should keep in mind its diffusive nature, which implies that in the new units, its standard deviation grows like  $\sqrt{t/\varepsilon}$ . Equation (1.7) thus becomes

$$d\mathbf{x}_t = -\frac{1}{\varepsilon} \nabla V(\mathbf{x}_t, \lambda(t)) dt + \frac{\sigma}{\sqrt{\varepsilon}} G(\lambda(t)) dW_t. \quad (1.11)$$

In the deterministic case  $\sigma = 0$ , we will sometimes write this equation in the form  $\varepsilon \dot{\mathbf{x}} = -\nabla V(\mathbf{x}, \lambda(t))$ , which is customary in singular perturbation theory. Throughout the paper, we will assume that  $V$ ,  $G$  and  $\lambda$  are smooth functions, that  $V(\mathbf{x}, \lambda)$  grows at least like  $\|\mathbf{x}\|^2$  for large  $\|\mathbf{x}\|$ , and that the matrix elements of  $G$ , as well as  $\lambda$ , have uniformly bounded absolute values. A large part of the paper is devoted to one-dimensional systems, and we come back to the multidimensional case in Section 6.

The aim of this paper is to illustrate our methods by applying them to a number of physically interesting examples. We thus emphasize the conceptual aspects, and refrain from giving mathematical details of the proofs, which will be presented elsewhere [BG1, BG2, BG3].

We start, in Section 2, by explaining the basic ideas in the simplest situation, where most paths remain concentrated near the bottom of a potential well. We also briefly describe the dynamics near a saddle. The three subsequent sections are devoted to more interesting cases in which paths may jump between the wells of a double-well potential. Note that we restrict our attention to double-well potentials only to keep the presentation simple, but the dynamics in more complicated multi-well potentials can be described by the same approach.

In Section 3, we discuss the phenomenon of stochastic resonance, where noise allows transitions between potential wells which would be impossible in the deterministic case. We compute the threshold noise intensity needed for transitions to be likely, and show that most paths are close, in a natural geometrical sense, to a periodic function. This provides an alternative quantitative measure of the signal's periodicity to the commonly used signal-to-noise ratio.

FIGURE 1. Example of a periodically forced double-well potential. In the limit of infinitely slow forcing, an overdamped particle tracks the bottom of potential wells. However, its position is not determined by the instantaneous value of the forcing alone. The system describes a hysteresis cycle, whose shape depends on the frequency of the forcing. Noise may kick the particle over the potential barrier, and thus influences the shape of the hysteresis cycle.

Section 4 is devoted to hysteresis, which is also characteristic for forced bistable systems. For sufficiently strong forcing, one of the two potential wells disappears, causing trajectories to switch between potential wells even when no noise is present (Figure 1). As a result, even in the adiabatic limit, the instantaneous value of the parameter  $\lambda$  does not suffice to determine the state of the system: Solutions follow hysteresis cycles. In absence of noise, their area is known to scale in a nontrivial way with the frequency of the forcing. Our methods allow us to characterize the distribution of the random hysteresis area for positive noise intensity. In particular, we show that for noise intensities above an amplitude-dependent threshold, the typical area no longer depends, to leading order, on amplitude or frequency of the forcing.

In Section 5, we consider the effect of additive noise on systems with spontaneous symmetry breaking, i. e., when the potential transforms from single to double well. In the deterministic case, solutions are known to track the saddle for a considerable time before falling into one of the potential wells, a phenomenon known as bifurcation delay. We characterize the effect of additive noise on this delay, and on the probability to choose one or the other potential well after the bifurcation. Furthermore, we give results on the concentration of paths near potential wells which allow, in particular, to determine the optimal relation between speed of parameter drift and noise intensity for an experimental determination of the bifurcation diagram.

Finally, Section 6 contains some generalizations. We first discuss analogous results to those of Section 2 for multidimensional potentials. This formalism allows us to treat the effect of the simplest kind of coloured noise, given by an Ornstein–Uhlenbeck process, in a natural way. We conclude by discussing the dependence of previously discussed phenomena on noise colour.

## 2 Near wells and saddles

We start by discussing situations in which the noise intensity is sufficiently small, compared to the depth of a given potential well, for paths to remain concentrated near the bottom of the well during a long time interval. In Section 2.1, the solvable linear case is used to compare the information provided by the Fokker–Planck equation and by the pathwise approach. In Section 2.2, we show that our method naturally extends to the nonlinear case. We briefly describe the dynamics near a saddle in Section 2.3.

### 2.1 Linear case

It is instructive to consider first the case of a linear force (that is, of a quadratic potential), which can be solved completely. A general one-dimensional, time-dependent quadratic potential can be written as

$$V(x, t) = \frac{1}{2}c(t)(x - x^*(t))^2, \quad (2.1)$$

where  $x^*(t)$  is the location of the potential minimum, and  $c(t)$  is the curvature of the potential. The SDE (1.7) takes the form

$$dx_t = \frac{1}{\varepsilon}a^*(t)(x_t - x^*(t)) dt + \frac{\sigma}{\sqrt{\varepsilon}}g(t) dW_t, \quad (2.2)$$

where  $a^*(t) = -c(t)$ . Throughout this paper, we will use  $a^*$  to denote the linearization of the force at an equilibrium point  $x^*$ , with  $a^* < 0$  if the equilibrium is stable, and  $a^* > 0$  if it is unstable. In this subsection and the following one, we consider the stable case, and assume that  $a^*(t) \leq -a_0$  for all  $t$  under consideration, where  $a_0$  is a positive constant. For simplicity, we shall assume that the functions  $x^*(t)$  and  $a^*(t)$ , as well as  $g(t)$ , are real-analytic.

Let us first investigate the probability density  $p(x, t)$  of  $x_t$ . The Fokker–Planck equation being linear, it can be easily solved. Assume for simplicity that the distribution of  $x_0$  is Gaussian, with expectation  $\mathbb{E}\{x_0\}$  and (possibly zero) variance  $\text{Var}\{x_0\}$ . (In addition, we always assume the initial distribution to be independent of the Brownian motion.) Then  $x_t$  has a Gaussian distribution for any  $t > 0$ , with density

$$p(x, t) = \frac{1}{\sqrt{2\pi \text{Var}\{x_t\}}} \exp\left\{-\frac{(x - \mathbb{E}\{x_t\})^2}{2 \text{Var}\{x_t\}}\right\}, \quad (2.3)$$

where expectation and variance of  $x_t$  obey the ODEs

$$\frac{d}{dt}\mathbb{E}\{x_t\} = \frac{1}{\varepsilon}a^*(t)(\mathbb{E}\{x_t\} - x^*(t)) \quad (2.4)$$

$$\frac{d}{dt}\text{Var}\{x_t\} = \frac{2}{\varepsilon}a^*(t)\text{Var}\{x_t\} + \frac{\sigma^2}{\varepsilon}g(t)^2. \quad (2.5)$$

Note that  $\mathbb{E}\{x_t\}$  coincides with the deterministic solution  $x_t^{\text{det}}$  of Equation (2.2) for  $\sigma = 0$ , with initial condition  $x_0^{\text{det}} = \mathbb{E}\{x_0\}$ :

$$\mathbb{E}\{x_t\} = x_t^{\text{det}} = x_0^{\text{det}} e^{\alpha^*(t)/\varepsilon} - \frac{1}{\varepsilon} \int_0^t e^{\alpha^*(t,s)/\varepsilon} a^*(s) x^*(s) ds, \quad (2.6)$$

where we use the notations

$$\alpha^*(t, s) = \int_s^t a^*(u) du, \quad \alpha^*(t) = \alpha^*(t, 0). \quad (2.7)$$

Our stability assumption  $a^*(t) \leq -a_0 \forall t$  implies that  $\alpha^*(t, s) \leq -a_0(t-s)$  for  $t > s$ . Hence the first term on the right-hand side of (2.6) decreases exponentially fast: It is at most of order  $\varepsilon$  after time  $\varepsilon|\log \varepsilon|/a_0$ , at most of order  $\varepsilon^2$  after time  $2\varepsilon|\log \varepsilon|/a_0$ , and so on.

We expect  $x_t^{\text{det}}$  to follow adiabatically the slowly drifting bottom of the potential well. To make this apparent, we evaluate the second term on the right-hand side of (2.6) by integration by parts:

$$-\frac{1}{\varepsilon} \int_0^t e^{\alpha^*(t,s)/\varepsilon} a^*(s) x^*(s) ds = x^*(t) - x^*(0) e^{\alpha^*(t)/\varepsilon} - \int_0^t e^{\alpha^*(t,s)/\varepsilon} \dot{x}^*(s) ds. \quad (2.8)$$

By successive integrations by parts, we find that the general solution of (2.4) can be written as

$$\mathbb{E}\{x_t\} = x_t^{\text{det}} = \bar{x}_t^{\text{det}} + (x_0^{\text{det}} - \bar{x}_0^{\text{det}}) e^{\alpha^*(t)/\varepsilon}, \quad (2.9)$$

where  $\bar{x}_t^{\text{det}}$  is a particular solution of (2.4), admitting the asymptotic expansion<sup>1</sup>

$$\bar{x}_t^{\text{det}} = x^*(t) + \varepsilon \frac{\dot{x}^*(t)}{a^*(t)} + \varepsilon^2 \frac{1}{a^*(t)} \frac{d}{dt} \left( \frac{\dot{x}^*(t)}{a^*(t)} \right) + \dots \quad (2.10)$$

Since  $a^*(t)$  is negative,  $\bar{x}_t^{\text{det}}$  tracks the bottom  $x^*(t)$  of the potential well with a small lag:  $\bar{x}_t^{\text{det}} < x^*(t)$  if  $x^*(t)$  moves to the right, and  $\bar{x}_t^{\text{det}} > x^*(t)$  if  $x^*(t)$  moves to the left. The particular solution (2.10) is called *adiabatic solution* or *slow solution*. Relation (2.9) expresses the fact that all solutions of (2.4) are attracted exponentially fast by the adiabatic solution  $\bar{x}_t^{\text{det}}$ .

The variance of  $x_t$  can be computed in a similar way. The solution of (2.5) is given by

$$\text{Var}\{x_t\} = \text{Var}\{x_0\} e^{2\alpha^*(t)/\varepsilon} + \frac{\sigma^2}{\varepsilon} \int_0^t e^{2\alpha^*(t,s)/\varepsilon} g(s)^2 ds. \quad (2.11)$$

The behaviour of the variance is very similar to the behaviour of the deterministic solution (2.6): The initial condition  $\text{Var}\{x_0\}$  is forgotten exponentially fast, and in analogy with (2.9) and (2.10), we can write

$$\text{Var}\{x_t\} = \bar{v}(t) + (\text{Var}\{x_0\} - \bar{v}(0)) e^{2\alpha^*(t)/\varepsilon}, \quad (2.12)$$

where  $\bar{v}(t)$  is a particular solution of (2.5), which admits the asymptotic expansion

$$\bar{v}(t) = \frac{\sigma^2}{2|a^*(t)|} \left[ g(t)^2 + \varepsilon \frac{d}{dt} \left( \frac{g(t)^2}{2a^*(t)} \right) + \dots \right]. \quad (2.13)$$

The fact that  $x_t$  has a Gaussian distribution implies in particular that for any  $t > 0$ ,

$$\mathbb{P}\left\{ |x_t - x_t^{\text{det}}| > h \sqrt{\text{Var}\{y_t\}} \right\} = 2 \int_{h\sqrt{\text{Var}\{y_t\}}}^{\infty} p(x_t^{\text{det}} + y, t) dy \leq e^{-h^2/2}. \quad (2.14)$$

---

<sup>1</sup>The asymptotic series does not converge in general, but it admits expansions to any order in  $\varepsilon$ , with a remainder which can be controlled.

Hence, the distribution of  $x_t$  is concentrated in an interval of width  $\sqrt{2 \operatorname{Var}\{y_t\}}$  around  $x_t^{\text{det}}$ , which behaves asymptotically like  $\sigma g(t)/\sqrt{|\alpha^*(t)|}$  by (2.12) and (2.13). In words, the spreading of  $x_t$  is proportional to the noise intensity and inversely proportional to the square root of the curvature of the potential: Flatter potentials give rise to a larger spreading of the distribution.

Up to now, we have only studied the probability density of  $x_t$ . However, even if the density is concentrated near the bottom of the well at all times, this does not exclude that the path  $\{x_s\}_{0 \leq s \leq t}$  makes occasional excursions away from  $x^*$ . From now on, we consider the initial condition  $x_0$  as deterministic, so that the path depends only on the realization of the Brownian motion. The solution of the SDE (2.2) can be written as

$$x_t = x_t^{\text{det}} + y_t, \quad y_t = \frac{\sigma}{\sqrt{\varepsilon}} \int_0^t e^{\alpha^*(t,s)/\varepsilon} g(s) dW_s. \quad (2.15)$$

The process  $y_t$  is a generalization of an Ornstein–Uhlenbeck process, with time-dependent damping and diffusion. Ideally, we would like to estimate the probability that the path leaves a strip of (time-dependent) width proportional to  $\sqrt{\operatorname{Var}\{x_t\}}$ , and centred at  $x_t^{\text{det}}$ . This turns out to be difficult because the variance may change quickly for  $t$  very close to 0, due to the first term on the right-hand side of (2.11). To avoid these technical complications, we use a strip of width proportional to  $\sqrt{\bar{v}(t)}$ , defined by

$$\mathcal{B}(h) = \{(x, t) : |x - x_t^{\text{det}}| < h\sqrt{\bar{v}(t)}\}. \quad (2.16)$$

Note that  $\mathcal{B}(h)$  coincides, up to order  $\varepsilon$ , with the set of points where  $V(x, t)$  is smaller than  $V(x_t^{\text{det}}, t) + (\frac{1}{2}h\sigma g(t))^2$ . Showing that the path  $\{x_s\}_{0 \leq s \leq t}$  is likely to remain in  $\mathcal{B}(h)$  is equivalent to showing that the *first-exit time* of  $x_s$  from  $\mathcal{B}(h)$ , defined by

$$\tau_{\mathcal{B}(h)} = \inf\{s \geq 0 : (x_s, s) \notin \mathcal{B}(h)\}, \quad (2.17)$$

is unlikely to be smaller than  $t$ . In fact, the following probabilities are equivalent (the superscripts refer to the initial condition):

$$\begin{aligned} \mathbb{P}^{0, x_0}\{\tau_{\mathcal{B}(h)} < t\} &= \mathbb{P}^{0, x_0}\{\exists s \in [0, t) : (x_s, s) \notin \mathcal{B}(h)\} \\ &= \mathbb{P}^{0, x_0}\left\{\sup_{0 \leq s < t} \frac{|x_s - x_s^{\text{det}}|}{\sqrt{\bar{v}(s)}} \geq h\right\}. \end{aligned} \quad (2.18)$$

The following result is a straightforward consequence of standard exponential bounds on the supremum of stochastic integrals, extended to integrals as appearing in (2.15). The proof, given in [BG1, Proposition 3.4] for constant  $g$ , also applies here.<sup>2</sup>

**Proposition 2.1.** *For all  $t$  and  $h > 0$ ,*

$$\mathbb{P}^{0, x_0}\{\tau_{\mathcal{B}(h)} < t\} \leq C(t, \varepsilon) e^{-\kappa h^2}, \quad (2.19)$$

where

$$C(t, \varepsilon) = \frac{|\alpha^*(t)|}{\varepsilon^2} + 2 \quad \text{and} \quad \kappa = \frac{1}{2} - \mathcal{O}(\varepsilon). \quad (2.20)$$

---

<sup>2</sup>The generalization of the proof to  $g$  bounded away from zero is trivial, but the result also holds if  $g$  vanishes. In fact, a sufficient condition is that  $\bar{v}(t)/\bar{v}(s) = 1 + \mathcal{O}(\varepsilon)$  whenever  $t - s = \mathcal{O}(\varepsilon^2)$ , which can be checked using the asymptotic expansion (2.13).

FIGURE 2. A sample path  $x_t$  of the linear equation (2.2) for  $a^*(t) = -4 + 2\sin(4\pi t)$ ,  $x^*(t) = \sin(2\pi t)$  and  $g(t) \equiv 1$ . Parameter values are  $\varepsilon = 0.04$  and  $\sigma = 0.025$ . The shaded region is the set  $\mathcal{B}(h)$  for  $h = 3$ , centred at the deterministic solution  $x_t^{\text{det}}$  starting at the same point as  $x_t$ . The width of  $\mathcal{B}(h)$  is of order  $h\sigma/\sqrt{a^*(t)}$ . Proposition 2.1 states that the probability of  $x_t$  leaving  $\mathcal{B}(h)$  before times of order 1 decays roughly like  $e^{-h^2/2}$ .

Note that only the prefactor  $C(t, \varepsilon)$  is time-dependent. The exponential factor  $e^{-\kappa h^2}$  is small as soon as  $h \gg 1$ , so that the paths  $\{x_s\}_{0 \leq s \leq t}$  are concentrated in a neighbourhood of order  $\sqrt{\bar{v}(s)}$  of the deterministic solution up to time  $t$  (see Figure 2). More precisely, paths are unlikely to leave the strip  $\mathcal{B}(h)$  of width  $h\sqrt{\bar{v}}$  before time  $t$  provided  $h^2 \gg \log C(t, \varepsilon)$ .

The bound (2.19) is useful for times significantly shorter than Kramers' time, which is of order  $\varepsilon e^{2H/\sigma^2}$  (to reach points where the potential has value  $H$ ). For longer times, the prefactor  $C(t, \varepsilon)$  becomes sufficiently large to counteract the term  $e^{-\kappa h^2}$  for any reasonable  $h$ , which is natural, as we cannot expect paths to remain concentrated near  $x_t^{\text{det}}$  on such long time scales. On polynomial time scales of order  $\sigma^{-k}$ , however, large excursions are very unlikely.

The estimate (2.19) has been designed to yield an optimal exponent for noise intensities scaling like a power of  $\varepsilon$ . We do not expect the prefactor  $C(t, \varepsilon)$  to be optimal, but for times and noise intensities polynomial in  $\varepsilon$ , it leads to subexponential corrections. However, if we do not care for the precise exponent, (2.20) can be replaced by

$$C(t, \varepsilon) = \frac{|\alpha^*(t)|}{\varepsilon} + 2 \quad \text{and} \quad \kappa > 0. \quad (2.21)$$

The denominator  $\varepsilon$  in  $C$  is due to the fact that we work in slow time.

## 2.2 Nonlinear case

We consider now the motion in a more general, nonlinear potential of the form

$$V(x, t) = \frac{1}{2}c(t)(x - x^*(t))^2 + \mathcal{O}((x - x^*(t))^3), \quad (2.22)$$

admitting a local minimum at  $x^*(t)$ . As before, we assume that the curvature  $c(t)$  is bounded below by a positive constant for all times  $t$ . We do not exclude, however, that  $V$  has other potential wells than the one at  $x^*(t)$ .

The probability density can no longer be computed exactly in general, although it seems plausible that a distribution initially concentrated near  $x^*(0)$  will remain concentrated near  $x^*(t)$ , on a certain time scale. In fact, Proposition 2.1 naturally extends to the nonlinear case.

Consider first the deterministic case  $\sigma = 0$ . A result due to Gradštein and Tihonov [Gr, Ti], which is related to the adiabatic theorem of quantum mechanics, states that

- there exists a particular solution  $\bar{x}_t^{\text{det}}$  of the deterministic equation  $\varepsilon \dot{x} = -\partial_x V(x, t)$  tracking the bottom of the potential well at a distance of order  $\varepsilon$ ;
- any solution  $x_t^{\text{det}}$  starting in a neighbourhood of  $x^*(0)$  (in fact, inside the potential well) approaches  $\bar{x}_t^{\text{det}}$  exponentially fast in  $t/\varepsilon$ .

Let us fix a deterministic initial condition  $x_0 = x_0^{\text{det}}$  such that  $x_t^{\text{det}}$  is attracted by  $\bar{x}_t^{\text{det}}$ . We introduce the notations

$$a(t) = -\frac{\partial^2 V}{\partial x^2}(x_t^{\text{det}}, t), \quad \alpha(t, s) = \int_s^t a(u) du \quad \text{and} \quad \alpha(t) = \alpha(t, 0) \quad (2.23)$$

for the curvature of the potential at  $x_t^{\text{det}}$  and the analogue quantities to (2.7). Note that Tihonov's result implies that  $a(t)$  asymptotically approaches  $-c(t) + \mathcal{O}(\varepsilon)$ . The difference  $y_t = x_t - x_t^{\text{det}}$  satisfies an SDE of the form

$$dy_t = \frac{1}{\varepsilon} [a(t)y_t + b(y_t, t)] dt + \frac{\sigma}{\sqrt{\varepsilon}} g(t) dW_t, \quad (2.24)$$

where  $b(y, t) = \mathcal{O}(y^2)$  describes the effect of nonlinearity. We define again a strip  $\mathcal{B}(h)$  as in (2.16), with

$$\bar{v}(t) = \bar{v}(0) e^{2\alpha(t)/\varepsilon} + \frac{\sigma^2}{\varepsilon} \int_0^t e^{2\alpha(t,s)/\varepsilon} g(s)^2 ds. \quad (2.25)$$

Our results work for any  $\bar{v}(0)$  larger than a positive constant independent of  $\varepsilon$ . A convenient choice is  $\bar{v}(0) = \sigma^2 g(0)^2 / (2|a^*(0)|)$ : Then the fact that  $x_t^{\text{det}}$  approaches exponentially fast a neighbourhood of order  $\varepsilon$  of  $x^*(t)$  implies that

$$\bar{v}(t) = \sigma^2 \left[ \frac{g(t)^2}{2|a^*(t)|} + \mathcal{O}(\varepsilon) + \mathcal{O}(|x_0 - x^*(0)| e^{-\text{const } t/\varepsilon}) \right]. \quad (2.26)$$

Proposition 2.1 generalizes to

**Theorem 2.2.** *There exists a constant  $h_0$ , independent of  $\sigma$  and  $\varepsilon$ , such that for all  $h \leq h_0/\sigma$ ,*

$$\mathbb{P}^{0, x_0} \{ \tau_{\mathcal{B}(h)} < t \} \leq C(t, \varepsilon) e^{-\kappa h^2}, \quad (2.27)$$

where

$$C(t, \varepsilon) = \frac{|\alpha(t)|}{\varepsilon^2} + 2 \quad \text{and} \quad \kappa = \frac{1}{2} - \mathcal{O}(\varepsilon) - \mathcal{O}(\sigma h). \quad (2.28)$$

The interpretation is the same as in the linear case: Paths are concentrated, for times significantly shorter than Kramers' time, in a strip of width proportional to  $\sqrt{\bar{v}(t)}$  around  $x_t^{\text{det}}$ .

The proof is identical to the one of [BG1, Theorem 2.4]. The main idea is to show that if the solution of the equation linearized around  $x_t^{\text{det}}$  remains in a strip  $\mathcal{B}(h)$ , then the solution of the nonlinear equation (2.24) almost surely remains in the slightly larger strip  $\mathcal{B}(h[1 + \mathcal{O}(\sigma h)])$ .

The main difference between the nonlinear and the linear case is the condition  $h \leq h_0/\sigma$ , which stems from the requirement that the linear term  $a(t)y_t$  in Equation (2.24) should dominate the nonlinear term  $b(y_t, t)$  for all  $(x_t, t) \in \mathcal{B}(h)$ . Because of this condition, the result (2.27) is useful for  $\sigma^2 \ll \kappa h_0^2 / \log C(t, \varepsilon)$ . It is, however, possible to derive bounds for larger deviations under additional assumptions on the potential:

**Proposition 2.3.** *Assume that there are constants  $L_0 > 0$ ,  $K > 0$  and  $n \geq 2$  such that*

$$x \frac{\partial V}{\partial x}(x, t) \geq K|x|^n \quad (2.29)$$

*whenever  $|x| \geq L_0$  and  $t \geq 0$ . Then there exist constants  $C, \kappa > 0$  such that*

$$\mathbb{P}^{0, x_0} \left\{ \sup_{0 \leq s \leq t} |x_s| \geq L \right\} \leq C \left( \frac{t}{\varepsilon} + 1 \right) e^{-\kappa L^n / \sigma^2} \quad (2.30)$$

*for all  $t \geq 0$ ,  $L \geq L_0$  and  $|x_0| \leq L_0/2$ .*

This result is a generalization of [BG3, Proposition 4.3], where the case  $n = 4$  was treated.

We remark in passing that the bounds (2.27) and (2.29) are sufficient to provide estimates on the moments of the distribution of  $x_t$ , without solving the Fokker–Planck equation (c. f. [BG3, Corollary 4.6]):

**Corollary 2.4.** *Assume that (2.29) holds for some  $n \geq 2$ . Then*

$$\mathbb{E}^{0, x_0} \{ |x_t - x_t^{\text{det}}|^{2k} \} \leq (2k - 1)!! M^k \bar{v}(t)^k \quad (2.31)$$

*for some constant  $M$ , all integers  $k$  and all  $t \geq 0$ , provided  $\sigma \leq c_0 / \log(1 + t/\varepsilon)$  for a sufficiently small constant  $c_0$ .*

Note that the Cauchy–Schwarz inequality immediately implies bounds on odd moments as well. The bounds on the moments are those of a Gaussian distribution with variance  $M\bar{v}(t)$ , even if the potential  $V$  has multiple wells. The reason is that on the time scale under consideration, solutions of the SDE do not have enough time to cross a potential barrier and reach another potential well.

### 2.3 Escape from a saddle

Assume now that the potential  $V(x, t)$  admits a saddle at  $x^*(t)$  for all times under consideration. In the deterministic case, a particular solution  $\hat{x}_t^{\text{det}}$  is known to track the saddle at a distance of order  $\varepsilon$ , separating the basins of attraction of two neighbouring potential wells. Trajectories starting near  $\hat{x}_t^{\text{det}}$  will depart from it exponentially fast, but if the initial separation  $|x_0 - \hat{x}_0^{\text{det}}|$  is exponentially small, the time required to reach a distance of order one from the saddle may be quite long.

Noise will help kicking  $x_t$  away from  $\hat{x}_t^{\text{det}}$ , and thus reduce the time necessary to leave a neighbourhood of the saddle. In order to describe this effect, we consider the deviation  $y_t = x_t - \hat{x}_t^{\text{det}}$ , which satisfies the SDE

$$dy_t = \frac{1}{\varepsilon} [\hat{a}(t)y_t + \hat{b}(y_t, t)] dt + \frac{\sigma}{\sqrt{\varepsilon}} g(t) dW_t, \quad (2.32)$$

where  $\hat{a}(t) \geq a_0 > 0$  is the curvature of the potential at  $\hat{x}_t^{\text{det}}$ , and  $\hat{b}(y, t) = \mathcal{O}(y^2)$ . We now describe the dynamics in a small neighbourhood of the adiabatic solution tracking the saddle, where diffusion prevails over drift<sup>3</sup>, defined by

$$\mathcal{B}(h) = \left\{ (x, t) : |x - \hat{x}_t^{\text{det}}| < \frac{h\sigma g(t)}{\sqrt{2\hat{a}(t)}} \right\}. \quad (2.33)$$

---

<sup>3</sup>A possible way to compare the influence of drift and noise is by Itô's formula, which yields, for  $\hat{b} = 0$ ,  $d(y_t^2) = (1/\varepsilon)[2\hat{a}(t)y_t^2 + \sigma^2 g(t)^2] dt + (2\sigma/\sqrt{\varepsilon})g(t)y_t dW_t$ . The expression in brackets is dominated by the noise term  $\sigma^2 g(t)^2$  for all  $(x_t, t)$  in  $\mathcal{B}(1)$ , while the deterministic term  $2\hat{a}(t)y_t^2$  prevails outside this domain.

The following result, which is proved in the same way as [BG1, Proposition 3.10], shows that the first-exit time  $\tau_{\mathcal{B}(h)}$  of  $x_t$  from  $\mathcal{B}(h)$  is likely to be small.

**Theorem 2.5.** *Assume that  $g$  is bounded below by  $L\varepsilon$  for a sufficiently large constant  $L$ . Then for all  $h \leq 1$  and all initial conditions  $(x_0, 0) \in \mathcal{B}(h)$ ,*

$$\mathbb{P}^{0, x_0} \{ \tau_{\mathcal{B}(h)} > t \} \leq C \exp \left\{ -\frac{\kappa}{h^2} \frac{1}{\varepsilon} \int_0^t \widehat{a}(s) \, ds \right\}, \quad (2.34)$$

where  $C, \kappa$  are positive constants.

This result shows that  $x_t$  will leave a neighbourhood of size  $\sigma g(t) / \sqrt{2\widehat{a}(t)}$  of  $\widehat{x}_t^{\text{det}}$  typically after a time of order  $\varepsilon / \widehat{a}(0)$ . Once this neighbourhood has been left, the drift term starts prevailing over the diffusion term, and one can show, (although this is not trivial,) that the typical time needed to leave a neighbourhood of order one of the saddle is of order  $\varepsilon |\log \sigma|$ . We will state a similar result in Section 5 when discussing the dynamics after passing through a pitchfork bifurcation point.

### 3 Stochastic resonance

Up to now, we have considered situations in which the potential has bounded curvature near its (isolated) extrema, so that for sufficiently small noise intensities and not too long time scales, most paths are concentrated near the bottom of the well they started in.

Not surprisingly, interesting phenomena occur when the condition on the curvature is violated. Two cases can be considered:

- *Avoided bifurcation:* The potential well becomes flatter, but the curvature does not vanish completely; sufficiently strong noise, however, may drive solutions to another potential well. This mechanism is responsible in particular for the phenomenon of *stochastic resonance*.
- *Bifurcation:* The curvature at the bottom of the well vanishes, say at time 0; for  $t > 0$ , new potential wells may be created (e. g. pitchfork bifurcation) or not (e. g. saddle–node bifurcation).

We will discuss the possible phenomena in the case of a Ginzburg–Landau potential

$$V(x, t) = \frac{1}{4}x^4 - \frac{1}{2}\mu(t)x^2 - \lambda(t)x. \quad (3.1)$$

However, the precise form of the potential and the fact that it has at most two wells are not essential.

The potential (3.1) has two wells if  $27\lambda^2 < 4\mu^3$  and one well if  $27\lambda^2 > 4\mu^3$ . Crossing the lines  $27\lambda^2 = 4\mu^3$ ,  $\mu > 0$ , corresponds to a saddle–node bifurcation, and crossing the point  $\lambda = \mu = 0$  corresponds to a pitchfork bifurcation. Equilibrium points are solutions of the equation  $x^3 - \mu(t)x - \lambda(t) = 0$ ; we will denote stable equilibria by  $x_{\pm}^*$ , and the saddle, when present, by  $x_0^*$ .

In this section, we investigate situations with avoided bifurcations, in which the potential always has two wells, but the barrier between them becomes low periodically. Bifurcation phenomena will be discussed in the next two sections.

FIGURE 3. A sample path of the equation of motion (3.2) in an asymmetrically perturbed double-well potential. Parameter values are  $\varepsilon = 0.0025$ ,  $a_0 = 0.005$  and  $\sigma = 0.065$ , which is just above the threshold for transitions to be likely. The upper and lower full curves show the locations of the potential wells, while the broken curve marks the location of the saddle.

### 3.1 The mechanism of stochastic resonance

Let us consider the case where  $\mu$  is a positive constant, say  $\mu = 1$ , and  $\lambda(t)$  varies periodically, say  $\lambda(t) = -A \cos(2\pi t)$ . If  $|\lambda| < \lambda_c = 2/(3\sqrt{3})$ , then  $V$  is a double-well potential. We thus assume that  $A < \lambda_c$ .

In the absence of noise, the existence of the potential barrier prevents the solutions from switching between potential wells. If noise is present, but there is no periodic driving ( $A = 0$ ), solutions will cross the potential barrier at random times, whose expectation is given by Kramers' time  $\varepsilon e^{2H/\sigma^2}$ , where  $H$  is the height of the barrier ( $H = 1/4$  in this case).

Interesting things happen when both noise and periodic driving  $\lambda(t)$  are present. Then the potential barrier will still be crossed at random times, but with a higher probability near the instants of minimal barrier height (i. e., when  $t$  is integer or half-integer). This phenomenon produces peaks in the power spectrum of the signal, hence the name *stochastic resonance* (SR).

If the noise intensity is sufficiently large compared to the minimal barrier height, transitions become likely twice per period (back and forth), so that the signal  $x_t$  is close, in some sense, to a periodic function (Figure 3). The amplitude of this oscillation may be considerably larger than the amplitude of the forcing  $\lambda(t)$ , so that the mechanism can be used to amplify weak periodic signals. This phenomenon is also known as *noise-induced synchronization* [SNA, NSAS]. Of course, too large noise intensities will spoil the quality of the signal.

The mechanism of stochastic resonance was originally introduced as a possible explanation of the close-to-periodic appearance of the major Ice Ages [BSV, BPSV]. Here the (quasi-)periodic forcing is caused by variations in the Earth's orbital parameters (Milankovich factors), and the additive noise models the fast unpredictable fluctuations caused by the weather. Meanwhile, SR has been detected in a large number of systems (see for instance [MW, WM, GHM] for reviews), including ring lasers, electronic devices, and even the sensory system of crayfish and paddlefish [N&].

Despite the many applications of SR, its mathematical description has remained in-

complete for two decades, although several limiting cases have been studied in detail. The first approaches considered either potentials that are piecewise constant in time [BSV], or two-level systems with discrete space [ET, McNW]. Continuous time equations have been mainly investigated through the Fokker–Planck equation, using methods from spectral theory [Fox, JH1] or linear response theory [JH2]. The main contribution of these approaches is an estimation of the signal-to-noise ratio (SNR) of the power spectrum, as a function of the noise intensity. The SNR is one of the possible quantitative measures of the signal’s periodicity, and behaves roughly like  $e^{-H/\sigma^2}/\sigma^4$ , which is maximal for  $\sigma^2 = H/2$ . In [MS2], an action functional is used to extend Kramers’ result to the case of small-amplitude forcing.

A description of individual paths has been given for the first time in Freidlin’s recent paper [Fr1]. His results apply to a general class of  $n$ -dimensional potentials, in the case where the period  $1/\varepsilon$  of the driving scales like Kramers’ time  $e^{2H/\sigma^2}$ . The fact that the minimal barrier height  $H$  is considered as constant while  $\sigma$  tends to zero, implies that the results only hold for exponentially long driving periods. As quantitative measure of the signal’s periodicity, the  $L^p$ -distance<sup>4</sup> between paths  $\{x_t\}_{t \geq 0}$  and a deterministic, periodic limit function  $\phi(t)$  is used. This limit function simply tracks the bottom of a potential well, and jumps to the deeper well each time the potential barrier becomes lowest. The  $L^p$ -distance is shown to converge to zero in probability as  $\sigma$  goes to zero. However, Freidlin’s techniques do not yield estimates on the speed of this convergence, or its dependence on  $p$ .

Our techniques allow us to provide such estimates for one-dimensional potentials, with a more natural distance than the  $L^p$ -distance: In fact, we simply use a geometrical distance between paths and the limit function, considered as curves in the  $(t, x)$ -plane. The analysis given below also includes situations in which the minimal barrier height becomes small in the small-noise limit.

### 3.2 Pathwise description

For the Ginzburg–Landau potential (3.1),  $\mu = 1$  and  $\lambda(t) = -A \cos(2\pi t)$ , the SDE takes the form

$$dx_t = \frac{1}{\varepsilon} [x_t - x_t^3 - A \cos(2\pi t)] dt + \frac{\sigma}{\sqrt{\varepsilon}} dW_t. \quad (3.2)$$

We assume that  $A < \lambda_c$ , so that there are always two stable equilibria at  $x_{\pm}^*(t)$  and a saddle at  $x_0^*(t)$ . We introduce a parameter  $a_0 = \lambda_c - A$  which measures the minimal barrier height: At  $t = 0$ , the barrier height is of order  $a_0^{3/2}$  for small  $a_0$ , and the distance between  $x_+^*$  and the saddle at  $x_0^*$  is of order  $\sqrt{a_0}$ . At  $t = \frac{1}{2}$ , the left-hand potential well at  $x_-^*$  is likewise close to the saddle. In order for transitions to become possible on a time scale which is not exponentially large, we allow  $a_0$  to become small with  $\varepsilon$ .

Assume that we start at time  $t_0 = -1/4$  in the basin of attraction of the right-hand potential well. Results from Section 2 show that transitions are unlikely for  $t \ll 0$ . Also, for  $0 \ll t \ll 1/2$ , paths will be concentrated either near  $x_+^*$  or near  $x_-^*$ . This allows us to define the *transition probability* as

$$P_{\text{trans}} = \mathbb{P}^{t_0, x_0} \{x_{t_1} < 0\}, \quad t_0 = -1/4, \quad t_1 = 1/4. \quad (3.3)$$

---

<sup>4</sup>The  $L^p$ -distance between  $x_t$  and  $\phi(t)$  is the integral of  $\|x_t - \phi(t)\|^p$  over a given time interval (raised to the power  $1/p$ ). Note that in contrast to a small supremum norm, a small  $L^p$ -norm of  $x_t - \phi(t)$  does not exclude that  $x_t$  makes large excursions away from  $\phi(t)$ , as long as these excursions are sufficiently short.

FIGURE 4. Sample paths of Equation (3.2) in a neighbourhood of time 0, when the barrier height is minimal, for two different noise intensities. Full curves mark the location  $x_+^*(t)$  of the right-hand potential well, broken curves the location  $x_0^*(t)$  of the saddle. Parameter values are  $\varepsilon = 0.0125$ ,  $a_0 = 0.002$  and (a)  $\sigma = 0.012$ , (b)  $\sigma = 0.07$ . In case (a), the path remains in the set  $\mathcal{B}(h)$ , shown here for  $h = 3$ , which is centred at the deterministic solution  $x_t^{\text{det}}$ . In case (b),  $x_t$  remains in  $\mathcal{B}(h)$  as long as the width of  $\mathcal{B}(h)$  is smaller than the distance between  $x_t^{\text{det}}$  and the saddle, that is, for  $t \ll -\sigma^2/3$ . The path jumps to the left-hand potential well during the time interval  $[-\sigma^2/3, \sigma^2/3]$ .

The properties of  $P_{\text{trans}}$  do not depend sensitively of the choices of  $t_0$  and  $t_1$ , as long as  $-1/2 \ll t_0 \ll 0 \ll t_1 \ll 1/2$ . Also the level 0 can be replaced by any level lying between  $x_-^*(t)$  and  $x_+^*(t)$  for all  $t$ . Denoting by  $a \vee b$  the maximum of two real numbers  $a$  and  $b$ , our main result can be formulated as follows.

**Theorem 3.1** ([BG2, Theorems 2.6 and 2.7]). *For the noise intensity, there is a threshold level  $\sigma_c = (a_0 \vee \varepsilon)^{3/4}$  with the following properties:*

1. If  $\sigma < \sigma_c$ , then

$$P_{\text{trans}} \leq \frac{C}{\varepsilon} e^{-\kappa \sigma^2 / \sigma^2} \quad (3.4)$$

for some  $C, \kappa > 0$ . Paths are concentrated in a strip of width  $\sigma / (\sqrt{|t|} \vee \sigma_c^{1/3})$  around the deterministic solution tracking  $x_+^*(t)$  (Figure 4a).

2. If  $\sigma > \sigma_c$ , then

$$P_{\text{trans}} \geq 1 - C e^{-\kappa \sigma^4 / (\varepsilon |\log \sigma|)} \quad (3.5)$$

for some  $C, \kappa > 0$ . Transitions are concentrated in the interval  $[-\sigma^2/3, \sigma^2/3]$ . Moreover, for  $t \leq -\sigma^2/3$ , paths are concentrated in a strip of width  $\sigma / \sqrt{|t|}$  around the deterministic solution tracking  $x_+^*(t)$ , while for  $t \geq \sigma^2/3$ , they are concentrated in a strip of width  $\sigma / \sqrt{t}$  around a deterministic solution tracking  $x_-^*(t)$  (Figure 4b).

The crossover is quite sharp: For  $\sigma \ll \sigma_c$ , transitions between potential wells are very unlikely, while for  $\sigma \gg \sigma_c$ , they are very likely. By ‘‘concentrated in a strip of width  $w$ ’’, we mean that the probability that a path leaves a strip of width  $hw$  decreases like  $e^{-\kappa h^2}$  for some  $\kappa > 0$ . The ‘‘typical width  $w$ ’’ is our measure of the deviation from the deterministic periodic function, which tracks one potential well in the small-noise case, and switches back and forth between the wells in the large-noise case.

Theorem 3.1 implies in particular that for the periodic signal’s amplification to be optimal, the noise intensity  $\sigma$  should exceed the threshold  $\sigma_c$ . Larger noise intensities will increase both spreading of paths (especially just before they cross the potential barrier) and size of transition window, and thus spoil the output’s periodicity.

It has been proposed to identify stochastic resonance and synchronization with a phase-locking mechanism [NSAS], but the definition of a phase remained problematic. The fact that the majority of paths are contained in small space–time sets makes it possible to associate a random phase with those paths. For instance, when  $\sigma > \sigma_c$ , most paths circle the origin of the  $(\lambda, x)$ -plane counterclockwise (see Figure 8c). For all paths not containing the origin, one can define a random phase  $\varphi_t$  by  $\tan(\varphi_t) = x_t/\lambda(t)$ . Although  $\varphi_t$  fluctuates, it is likely to increase at an average rate of  $2\pi$  per cycle.

Part of our results should appear quite natural. If  $a_0 > \varepsilon$ , the threshold noise level  $\sigma_c = a_0^{3/4}$  behaves like the square root of the minimal barrier height, which is consistent with the SNR being optimal for  $\sigma^2 = H/2$ . However,  $\sigma_c$  saturates at  $\varepsilon^{3/4}$  for all  $a_0 \leq \varepsilon$ . Hence, even driving amplitudes arbitrarily close to  $\lambda_c$  cannot increase the transition probability. This is a rather subtle dynamical effect, mainly due to the fact that even if the barrier vanishes at  $t = 0$ , it is lower than  $\varepsilon^{3/2}$  during too short a time interval for paths to take advantage. The situation is the same as if there were an “effective potential barrier” of height proportional to  $\sigma_c^2$ .

Another remarkable fact is that for  $\sigma > \sigma_c$ , neither the transition probability nor the width of the transition windows depend on the driving amplitude to leading order. In the remainder of this subsection, we are going to explain some ideas of the proof of Theorem 3.1, which will hopefully clarify some of the above surprising properties.

The first step is to understand the behaviour of the solutions of (3.2) in the deterministic case  $\sigma = 0$ . This problem belongs to the field of dynamical bifurcations, the theory of which is relatively well developed. We follow here a framework allowing to determine scaling laws of solutions near bifurcation points, which has been presented in [BK]. The main idea is that when approaching a bifurcation point  $(t^*, x^*)$ , the distance between the adiabatic solution and the static equilibrium branch scales like  $\varepsilon/|t - t^*|^\rho$  for  $t \leq t^* - \varepsilon^\nu$ , and like  $\varepsilon^\mu$  for  $|t - t^*| \leq \varepsilon^\nu$ . The rational numbers  $\rho, \nu$  and  $\mu = 1 - \rho\nu$  are universal exponents, which can be deduced from the Newton polygon of the bifurcation point.

Tihonov’s theorem implies that away from the avoided bifurcation point at  $t = 0$ , solutions  $x_t^{\text{det}}$  of the deterministic equation track the equilibrium branch  $x_+^*(t)$  adiabatically at a distance of order  $\varepsilon$ . It is thus sufficient to understand what happens in a small neighbourhood of the almost-bifurcation. Note that if  $\lambda = \lambda_c$ , the right-hand well and the saddle merge at  $x = 1/\sqrt{3}$ . It is thus helpful to consider the translated variable  $y_t^{\text{det}} = x_t^{\text{det}} - 1/\sqrt{3}$ , which obeys the differential equation

$$\varepsilon \dot{y} = ct^2 - \sqrt{3}y^2 + a_0 + \text{higher order terms}, \quad c = 2\pi^2\lambda_c. \quad (3.6)$$

Consider the “worst” case  $a_0 = 0$ . Then the right-hand side of (3.6) describes a transcritical bifurcation between the equilibria  $y_{+,0}^* = \pm\sqrt{c}3^{-1/4}|t| + \mathcal{O}(t^2)$ . One shows that the solution  $y_t^{\text{det}}$  tracks  $y_+^*(t)$  at a distance scaling like  $\varepsilon/|t|$  for  $|t| \geq \sqrt{\varepsilon}$ , and like  $\sqrt{\varepsilon}$  for  $|t| \leq \sqrt{\varepsilon}$ . In fact,  $y_t^{\text{det}}$  never approaches the saddle closer than a distance of order  $\sqrt{\varepsilon}$ , which is because the term  $-\sqrt{3}y^2$  only dominates during a short time interval of order  $\sqrt{\varepsilon}$ .

The same qualitative behaviour holds for  $0 < a_0 \leq \varepsilon$ . For  $a_0 > \varepsilon$ , one can show that  $x_t^{\text{det}}$  tracks  $x_+^*(t)$  at a distance never exceeding  $\mathcal{O}(\varepsilon/\sqrt{a_0})$ . Since  $x_+^*(0) - x_-^*(0)$  is of order  $\sqrt{a_0}$ ,  $x_t^{\text{det}}$  never approaches the saddle closer than a distance of order  $\sqrt{a_0}$ .

Let us now consider the random motion near  $x^{\text{det}}$  for  $\sigma > 0$ . We denote, as usual, by  $a(t)$  the curvature of the potential at the deterministic solution  $x_t^{\text{det}}$ . By (3.6),  $a(t)$  behaves, near  $t = 0$ , like  $-y_t^{\text{det}}$ , which we know to behave like  $-(|t| \vee \sqrt{a_0})$  for  $a_0 > \varepsilon$ , and like  $-(|t| \vee \sqrt{\varepsilon})$  for  $a_0 \leq \varepsilon$ . It turns out that Theorem 2.2 can be extended to the present situation, to show that paths are concentrated in a strip around  $x_t^{\text{det}}$ . The width of this strip is again related to the standard deviation of a linearized process, and behaves like

$$\frac{\sigma}{\sqrt{|a(t)|}} \asymp \frac{\sigma}{\sqrt{|t|} \vee \sigma_c^{1/3}}. \quad (3.7)$$

However, this property only holds under the condition that the spreading is always smaller than the distance between  $x_t^{\text{det}}$  and the saddle, which scales like  $|t| \vee \sigma_c^{2/3}$ . We thus have to require  $\sigma < |t|^{3/2} \vee \sigma_c$ , so that

- if  $\sigma < \sigma_c$ , the condition is always satisfied, and thus (3.4) follows from the generalization of Theorem 2.2 with  $h = \sigma_c/\sigma$  (Figure 4a);
- if  $\sigma > \sigma_c$ , the condition is only satisfied for  $t \leq -\sigma^{2/3}$  (Figure 4b).

It thus remains to understand what happens for  $t \geq -\sigma^{2/3}$  if  $\sigma > \sigma_c$ . Here the main idea is that during the time interval  $[-\sigma^{2/3}, \sigma^{2/3}]$ , the process  $x_t$  has a certain number of trials to reach the saddle. If  $x_t$  reaches the saddle, it has roughly probability 1/2 to move in each direction. If it moves far enough towards the left, it will most probably fall into the left-hand potential well, and is unlikely to come back for the remaining half-period. If it moves to the right, it has failed to overcome the barrier, but can try again during the next excursion.

One can define a typical time  $\Delta t$  for an excursion as the time needed for a path starting near  $x_{\pm}^*$  to reach and overcome the barrier with non-negligible probability, say with probability 1/3. One can show, by comparison with suitable linearized processes, that this typical time is determined by the condition

$$|\alpha(t, t + \Delta t)| = \int_t^{t+\Delta t} |a(s)| ds = \text{const } \varepsilon |\log \sigma|. \quad (3.8)$$

To obtain this, one first checks that the curvature of the potential is the same, up to sign reversal, at the adiabatic solutions tracking the bottom of the well and the saddle. To overcome the saddle, the integral in (3.8) must be of order  $\varepsilon$ , similarly as in Theorem 2.5. The factor  $|\log \sigma|$  is needed to reach a distance of order 1 from the saddle. Now the maximal number  $N$  of trials during the interval  $[-\sigma^{2/3}, \sigma^{2/3}]$  is given by

$$N = \text{const } \frac{|\alpha(\sigma^{2/3}, -\sigma^{2/3})|}{\varepsilon |\log \sigma|} \geq \text{const } \frac{\sigma^{4/3}}{\varepsilon |\log \sigma|}. \quad (3.9)$$

Finally, the Markov property implies that the probability *not* to overcome the saddle during  $N$  trials is bounded by

$$\left(\frac{2}{3}\right)^N = \exp\left\{-N \log\left(\frac{2}{3}\right)\right\} \leq \exp\left\{-\text{const } \frac{\sigma^{4/3}}{\varepsilon |\log \sigma|}\right\}, \quad (3.10)$$

which proves (3.5). An important point to note is that the transition probability is not determined by the curvature of the potential at the saddle, but by the curvature at the deterministic solution tracking the saddle, which may be larger for small  $a_0$ .

FIGURE 5. A sample path of the equation of motion (3.11) in a periodically modulated symmetric double-well potential. Parameter values are  $\varepsilon = 0.005$ ,  $a_0 = 0.005$  and  $\sigma = 0.075$ , which is above the threshold for transitions to occur with probability close to  $1/2$ . The upper and lower full curves show the locations of the potential wells, while the broken line marks the location of the saddle.

### 3.3 Symmetric potentials

Another case of interest is the Ginzburg–Landau potential (3.1) with  $\lambda \equiv 0$  and  $\mu(t) = a_0 + 1 - \cos(2\pi t)$ ,  $a_0 > 0$ . Then  $V(x, t)$  is always symmetric, with minima at  $x_{\pm}^*(t) = \pm\sqrt{\mu(t)}$  and a barrier height  $\frac{1}{4}\mu(t)^2$  becoming small at integer times. The associated SDE is

$$dx_t = \frac{1}{\varepsilon} [(a_0 + 1 - \cos(2\pi t))x_t - x_t^3] dt + \frac{\sigma}{\sqrt{\varepsilon}} dW_t. \quad (3.11)$$

As before, transitions between potential wells are most likely when the barrier is lowest. We can thus define a transition probability as in (3.3), with  $-1 \ll t_0 \ll 0 \ll t_1 \ll 1$ . We again assume that the process starts in the right-hand well. In this case, the result corresponding to Theorem 3.1 is

**Theorem 3.2** ([BG2, Theorems 2.2–2.4]). *There is a threshold noise level  $\sigma_c = a_0 \vee \varepsilon^{2/3}$  with the following properties:*

1. If  $\sigma < \sigma_c$ , then

$$P_{\text{trans}} \leq \frac{C}{\varepsilon} e^{-\kappa\sigma_c^2/\sigma^2} \quad (3.12)$$

for some  $C, \kappa > 0$ . Paths are concentrated in a strip of width  $\sigma/(|t| \vee \sqrt{\sigma_c})$  around the deterministic solution tracking  $x_+^*(t)$ .

2. If  $\sigma > \sigma_c$ , then

$$P_{\text{trans}} \geq \frac{1}{2} - C e^{-\kappa\sigma^{3/2}/(\varepsilon|\log\sigma|)} \quad (3.13)$$

for some  $C, \kappa > 0$ . Transitions are concentrated in the interval  $[-\sqrt{\sigma}, \sqrt{\sigma}]$ . Moreover, for  $t \leq -\sqrt{\sigma}$ , paths are concentrated in a strip of width  $\sigma/|t|$  around the deterministic solution tracking  $x_+^*(t)$ , while for  $t \geq \sqrt{\sigma}$ , they are concentrated in a strip of width  $\sigma/t$  around a deterministic solution tracking either  $x_+^*(t)$  or  $x_-^*(t)$ .

The main difference with respect to the previous case is that due to the symmetry,  $P_{\text{trans}}$  can never exceed  $1/2$ . The limiting process obtained by letting  $\sigma$  go to zero but keeping  $\sigma > \sigma_c$  is no longer a deterministic function, but a “Bernoulli” process, choosing between the left and the right potential well with probability  $1/2$  at integer times (Figure 5).

Another difference lies in the distribution of barrier crossing times in the transition window. In the asymmetric case, paths may overcome the saddle as soon as  $t \geq -\sigma^{2/3}$ , and are unlikely to return to the shallower well. In the symmetric case, paths may jump back and forth between both wells up to time  $\sqrt{\sigma}$ , before settling for a potential well.

### 3.4 Modulated noise intensity

Other mechanisms leading to stochastic resonance have been examined, for instance periodic forcing which is not deterministic, but affects the noise intensity, a situation arising in power amplifiers [D&]. This case can be analyzed by the same method as the previous ones, but the results are quite different.

Let us consider the motion in a static symmetric double-well potential, described by the SDE

$$dx_t = \frac{1}{\varepsilon} [\mu_0 x_t - x_t^3] dt + \frac{\sigma}{\sqrt{\varepsilon}} g(t) dW_t, \quad (3.14)$$

where  $\mu_0 > 0$  is fixed and  $g(t)$  is periodic. We assume that  $g(t) \geq \varepsilon |\log \sigma| / \mu_0$  for all  $t$ . Theorem 2.2 shows that for sufficiently weak noise, paths starting at time  $t_0$  at the bottom  $\sqrt{\mu_0}$  of the right-hand potential well remain concentrated in a strip around  $\sqrt{\mu_0}$ , with width proportional to  $\sigma g(t) / (2\sqrt{\mu_0})$ . This holds as long as the spreading is smaller than a constant times the distance  $\sqrt{\mu_0}$  between well and saddle. The probability to cross the saddle before time  $t$  is bounded by

$$P(t) = C(t, \varepsilon) \exp \left\{ -\frac{\kappa}{\sigma^2} \left( \frac{2\mu_0}{\hat{g}(t)} \right)^2 \right\}, \quad \text{where} \quad \hat{g}(t) = \sup_{t_0 \leq s \leq t} g(s) \quad (3.15)$$

and  $\kappa > 0$ . Thus if  $g$  reaches its maximum  $\hat{g}(0)$  at time 0, the probability to see a transition during one period satisfies

$$P_{\text{trans}} \leq C(1, \varepsilon) e^{-\kappa \sigma_c^2 / \sigma^2} \quad \text{for} \quad \sigma \leq \sigma_c = \frac{2\mu_0}{\hat{g}(0)}. \quad (3.16)$$

Note that here, as the potential is static, the threshold value for the noise intensity can be guessed from Kramers' time, assuming constant  $g$ . Taking into account that  $g$  is *not* necessarily constant, we see that for  $\sigma > \sigma_c$ , transitions are likely to happen in the time interval during which  $\sigma g(t) \geq 2\mu_0$ . For instance, if  $g(t)$  behaves quadratically near its unique maximum, this transition window is given by

$$t^2 \leq \text{const } g(0) \left( 1 - \frac{\sigma_c}{\sigma} \right). \quad (3.17)$$

In contrast to the previous cases, however, the transition times are less concentrated, in the sense that for times  $t_0 < t_1 < t_2$  before the transition window,

$$P(t_1) \simeq P(t_2) (\hat{g}(t_2) / \hat{g}(t_1))^2. \quad (3.18)$$

A similar argument as in the previous cases shows that for  $\sigma > \sigma_c$ ,

$$P_{\text{trans}} \geq \frac{1}{2} - \text{const} \exp \left\{ -\kappa \frac{2\mu_0 \Delta}{\varepsilon |\log \sigma|} \right\}, \quad (3.19)$$

where  $\Delta$  is the length of the transition window.

If the potential is made asymmetric, so that a constant term  $\lambda_0 > 0$  is added to the drift term in (3.14), the critical noise intensities needed to reach the saddle from the shallower left-hand well and the deeper right-hand well will be different (one can check that their ratio is  $1 + \mathcal{O}(\lambda_0/\mu_0^{3/2})$ ). As a consequence, transitions from the shallower to the deeper well will be likely as soon as the noise intensity exceeds the smaller threshold, while transitions in both directions are likely when the noise intensity exceeds the larger threshold. When the noise intensity drops below the smaller threshold again,  $x_t$  will be in the deeper right-hand well with larger probability. The net effect is that  $x_t$  will visit both wells near integer times, but has only small probability to remain in the shallow well after the transition window. Thus the periodic signal is not amplified in the same way as discussed before, but nevertheless we observe an amplification mechanism which allows to read off at which times the threshold is exceeded.

## 4 Hysteresis

Hysteresis is another characteristic phenomenon of bistable systems. Let us consider again the motion in the Ginzburg–Landau potential (3.1) with  $\mu \equiv 1$  and  $\lambda(t) = -A \cos(2\pi t)$ , but without imposing the restriction  $A < \lambda_c$ . In the deterministic case  $\sigma = 0$  the equation of motion reads

$$\varepsilon \frac{dx_t}{dt} = x_t - x_t^3 + \lambda(t). \quad (4.1)$$

We may ask the question: How does  $x_t$  behave, as a function of  $\lambda(t)$ , in the adiabatic limit  $\varepsilon \rightarrow 0$ ? Intuitively,  $x_t$  will always track the bottom of a potential well. A naive way to see this is to set formally  $\varepsilon$  equal to zero in (4.1): We obtain the algebraic equation  $x - x^3 + \lambda = 0$ , which admits three branches of solutions (see Figure 6);  $X_+^*(\lambda)$  and  $X_-^*(\lambda)$  correspond to potential wells, and  $X_0^*(\lambda)$  to a saddle, which exists only for  $|\lambda| < \lambda_c$ .

If the amplitude  $A$  is smaller than the critical value  $\lambda_c$ , there are always two potential wells separated by a barrier. Hence  $x_t$  will always track the bottom of the same well in the limit  $\varepsilon \rightarrow 0$ , so that the instantaneous value of  $\lambda$  is sufficient to determine the state (provided we know in which potential well the process started).

If  $A$  is larger than  $\lambda_c$ , however, a saddle–node bifurcation point is crossed whenever  $|\lambda|$  reaches  $\lambda_c$  from below: The potential well tracked by  $x_t$  disappears, so that  $x_t$  jumps to the other well, which is unaffected by the bifurcation (Figure 1). As a result, the state  $x_t$  is not uniquely defined by the instantaneous value of  $\lambda$  if  $|\lambda| \leq \lambda_c$ :  $x_t$  tracks the bottom  $X_-^*(\lambda(t))$  of the left-hand well if  $\lambda$  increases, and the bottom  $X_+^*(\lambda(t))$  of the right-hand well if  $\lambda$  decreases. This phenomenon is called *hysteresis*. The hysteresis cycle consists of the branches  $X_\pm^*(\lambda)$ ,  $|\lambda| \leq A$ , and two vertical lines on which  $|\lambda| = \lambda_c$ . It encloses an area  $\mathcal{A}_0 = 3/2$ , called *static hysteresis area*. In many applications,  $x$  and  $\lambda$  are thermodynamically conjugated variables, and the hysteresis area represents the energy dissipation per cycle.

### 4.1 Dynamical hysteresis and scaling laws

Consider now what happens when  $\varepsilon$  is small but positive. The solutions of Equation (4.1) will not react instantaneously to changes in the potential, so that the shape of hysteresis cycles is modified. It is important to understand the  $\varepsilon$ -dependence of quantities such as the average of  $x_t$  over one period, the value of  $\lambda$  when  $x_t$  changes sign, and the area enclosed

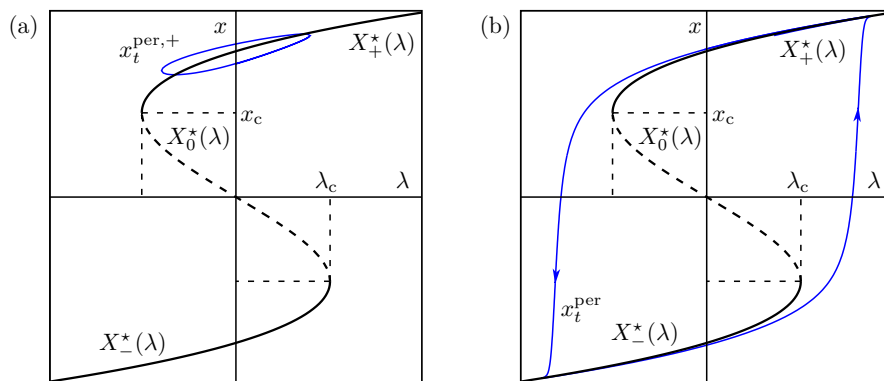

FIGURE 6. Periodic solutions of the deterministic equation (4.1), (a) in a case where the amplitude  $A$  of  $\lambda(t)$  is smaller than  $\lambda_c$ , and (b) in a case where it is larger than  $\lambda_c$ . The enclosed area scales like  $\varepsilon A$  in case (a), and like  $\mathcal{A}_0 + \varepsilon^{2/3}(A - \lambda_c)^{1/3}$  in case (b), where  $\mathcal{A}_0$  is the static hysteresis area. Potential wells  $X_{\pm}^*(\lambda)$  are displayed as full curves, the saddle  $X_0^*(\lambda)$  as a broken curve.

by the hysteresis cycle. It is known that there are constants  $\gamma_1 > \gamma_0 > 0$  such that the following properties hold:

- If  $A \leq \lambda_c + \gamma_0 \varepsilon$ , then  $x_t$  cannot change sign (except during the very first period, if the process does not start near the bottom of a well). There exist two stable periodic orbits, one tracking each potential well (Figure 6a). Each encloses an area  $\mathcal{A}$  satisfying

$$\mathcal{A} \asymp A\varepsilon, \quad (4.2)$$

and the average of  $x_t$  over each cycle is nonzero. The notation  $\asymp$  is a shorthand to indicate that  $c_- A\varepsilon \leq \mathcal{A} \leq c_+ A\varepsilon$  for some constants  $c_{\pm} > 0$  independent of  $\varepsilon$  and  $A$ .

- If  $A \geq \lambda_c + \gamma_1 \varepsilon$ , then  $x_t$  changes sign twice per period. All orbits are attracted by the same periodic orbit (Figure 6b), corresponding to a hysteresis cycle with zero average and area  $\mathcal{A}$  satisfying

$$\mathcal{A} - \mathcal{A}_0 \asymp \varepsilon^{2/3}(A - \lambda_c)^{1/3}. \quad (4.3)$$

When  $x_t$  changes sign, the parameter  $\lambda$  satisfies  $|\lambda| - \lambda_c \asymp \varepsilon^{2/3}(A - \lambda_c)^{1/3}$ .

- If  $\lambda_c + \gamma_0 \varepsilon < A < \lambda_c + \gamma_1 \varepsilon$ , several hysteresis cycles may coexist, some of them satisfying (4.2) and others satisfying (4.3).

The scaling law (4.3) was first derived in [JGRM] for  $A - \lambda_c$  of order 1, where Equation (4.1) was used to model a bistable laser. The case where  $A$  is close to  $\lambda_c$  has been analysed in [BK].

An equation qualitatively similar to (4.1) describes the dynamics of a Curie–Weiss model of a ferromagnet, subject to a periodic magnetic field  $\lambda(t)$ , in the limit of infinitely many spins [Mar]. The transition between the small and large amplitude regimes has been called “dynamic phase transition” in [TO].

The magnetization obeys a deterministic differential equation only in the limit of infinite system size. The effect of the number  $N$  of spins being finite can be modeled, in first approximation, by an additive white noise of intensity proportional to  $1/\sqrt{N}$  [Mar]. It is thus of major importance to understand the effect of additive noise on the properties of hysteresis cycles.

Langevin equations have already been studied for multi-dimensional Ginzburg–Landau potentials. Then, however, the mechanism leading to hysteresis is different, because there

is no potential barrier between stable states. Numerical simulations [RKP] suggested that the area of hysteresis cycles should follow the scaling law  $\mathcal{A} \asymp \varepsilon^{1/3} A^{2/3}$ , while various theoretical arguments indicate that  $\mathcal{A} \asymp \varepsilon^{1/2} A^{1/2}$  [DT, SD, ZZ]. It is not clear whether such a scaling law exists for the Ising model [SRN].

For clarity, we will keep interpreting  $x_t$  as magnetization and  $\lambda(t)$  as magnetic field. There exist, however, many other instances where the dynamics is described by a periodically forced Langevin equation. For instance, in models for the Atlantic thermohaline circulation,  $x_t$  represents the salinity difference between high and middle latitude, and  $\lambda(t)$  represents the atmospheric freshwater flux [St, Ra]. The effect of additive noise on this system has been investigated, for instance in [Ce], while the properties of hysteresis cycles were considered in particular in [Mo].

The fact that additive noise may create relaxation oscillations has been discussed in [Fr2], where the motion of a light particle in a randomly perturbed field is investigated with the help of large deviation theory.

## 4.2 The effect of additive noise

We consider the Langevin equation

$$dx_t = \frac{1}{\varepsilon} [x_t - x_t^3 - A \cos(2\pi t)] dt + \frac{\sigma}{\sqrt{\varepsilon}} dW_t, \quad (4.4)$$

where  $A > 0$ . We denote  $A - \lambda_c$  by  $a_0$ , but in contrast to Section 3 (where  $a_0$  had opposite sign), we do not impose that  $a_0$  is a small parameter, and we allow positive as well as negative  $a_0$ . Let us fix a deterministic initial condition ( $t_0 = -1/2, x_0 > 0$ ), such that the solution  $x_t^{\text{det}}$  of the deterministic equation (4.1) with  $x_{t_0}^{\text{det}} = x_0$  is attracted by the right-hand potential well.

We are interested in the quantity

$$\mathcal{A}(\varepsilon, \sigma) = - \int_{-1/2}^{1/2} x_t \lambda'(t) dt \quad (4.5)$$

measuring the area enclosed by  $x_t$  in the  $(\lambda, x)$ -plane during one period ( $x_t$  does not necessarily form a closed loop, but  $\mathcal{A}$  still represents the energy dissipation).  $\mathcal{A}(\varepsilon, 0)$  is the area enclosed by  $x_t^{\text{det}}$ , and behaves like (4.2) or (4.3). For positive  $\sigma$ ,  $\mathcal{A}(\varepsilon, \sigma)$  is a random variable, the distribution of which we want to characterize.

Another random quantity of interest is the value  $\lambda^0$  of the magnetic field when  $x_t$  changes sign for the first time:

$$\lambda^0 = \lambda(\tau^0), \quad \tau^0 = \inf \{t > t_0 : x_t \leq 0\}. \quad (4.6)$$

Results from Section 3 already allow us to make some predictions for the case  $a_0 < 0$ . For  $\sigma \ll \sigma_c = (|a_0| \vee \varepsilon)^{3/4}$ ,  $x_t$  is unlikely to switch between potential wells, so that  $\mathcal{A}(\varepsilon, \sigma)$  will be concentrated near the deterministic value  $\mathcal{A}(\varepsilon, 0)$ , which is of order  $\varepsilon$  (Figure 8a). For  $\sigma \gg \sigma_c$ ,  $x_t$  is likely to cross the potential barrier at a random time  $\tau^0$  which behaves typically like  $-\sigma^{2/3}$ . The corresponding field  $\lambda^0$  behaves like  $\lambda_c - \sigma^{4/3}$  (Figure 8c). Thus additive noise of sufficient intensity will lead to a hysteresis area which is smaller, by an amount of order  $\sigma^{4/3}$ , than the static area  $\mathcal{A}_0$ .

The same behaviour can be shown to hold for positive  $a_0$  up to order  $\varepsilon$ . In this case, the potential barrier vanishes during a short time interval, which is too short, however,

FIGURE 7. Definition of the parameter regimes for hysteresis cycles, shown in the plane  $(a_0 = A - \lambda_c, \sigma)$  for a fixed value of  $\varepsilon$ . The behaviour of the hysteresis area  $\mathcal{A}(\varepsilon, \sigma)$  in each regime is described in Theorem 4.1. Typical hysteresis cycles are shown in Figure 8.

for  $x_t$  to notice. For  $a_0 > \varepsilon$ , there is a similar transition between a small-noise regime (Figure 8b), where  $x_t$  is likely to track the deterministic solution, and a large-noise regime, where it typically crosses the potential barrier some time before the barrier vanishes. The threshold value of  $\sigma$  delimiting both regimes is again deduced from the variance of the equation linearized around  $x^{\text{det}}$ , and turns out to be  $\sigma_c = (\varepsilon\sqrt{a_0})^{1/2}$ . For  $\sigma > \sigma_c$ , the typical value  $\lambda^0$  of the field when  $x_t$  changes sign is again found to behave like  $\lambda_c - \sigma^{4/3}$ .

We thus obtain the existence of three distinct parameter regimes, with qualitatively different behaviour of typical hysteresis cycles. We summarize the main results in the following theorem, and give some additional details afterwards. Many estimates contain logarithmic dependencies on  $a_0$ ,  $\sigma$  and  $\varepsilon$ . In order not to overburden notations, we will assume that  $\sigma$  and  $a_0$  behave like a power of  $\varepsilon$  ( $a_0$  may also be a constant), and denote  $|\log \varepsilon|$  by  $\ell_\varepsilon$ . The regimes are those indicated in Figure 7, but some results are only valid if we exclude a logarithmic layer near the boundary, for instance Case II corresponds to  $a_0 > \gamma_1 \varepsilon$  and  $\sigma \leq \text{const} (\varepsilon\sqrt{a_0})^{1/2}/\ell_\varepsilon$ .

**Theorem 4.1** ([BG3, Theorems 2.3–2.5]).

- **Case I: (Small-amplitude regime)**

The distribution of the random area  $\mathcal{A}(\varepsilon, \sigma)$  is concentrated near the deterministic value  $\mathcal{A}(\varepsilon, 0) \asymp A\varepsilon$ . There are two subcases to consider:

- In Case Ia,  $\mathcal{A}(\varepsilon, \sigma)$  can be written as the sum of a Gaussian random variable with variance of order  $\sigma^2\varepsilon$ , centred at  $\mathcal{A}(\varepsilon, 0)$ , and a random remainder. The remainder has expectation and standard deviation of order  $\sigma^2\ell_\varepsilon$  at most.
- In Case Ib, the distribution of  $\mathcal{A}(\varepsilon, \sigma)$  is more spread out. Expectation and standard deviation of  $\mathcal{A}(\varepsilon, \sigma) - \mathcal{A}(\varepsilon, 0)$  are at most of order  $\sigma^2\ell_\varepsilon$ , which may exceed  $\mathcal{A}(\varepsilon, 0)$ .

- **Case II: (Large-amplitude regime)**

The distribution of  $\mathcal{A}(\varepsilon, \sigma)$  is concentrated near the deterministic value  $\mathcal{A}(\varepsilon, 0)$  which satisfies (4.3).

- In Case IIa,  $\mathcal{A}(\varepsilon, \sigma)$  can be written as the sum of a Gaussian random variable with variance of order  $\sigma^2(\varepsilon\sqrt{a_0})^{1/3}$ , centred at  $\mathcal{A}(\varepsilon, 0)$ , and a random remainder.

FIGURE 8. Typical random hysteresis “cycles” in the three parameter regimes of Figure 7. Deterministic solutions are shown for comparison. (a) Case I, small-amplitude regime (here  $\varepsilon = 0.05$ ,  $a_0 = -0.1$ ,  $\sigma = 0.025$ ): Paths typically stay close to the deterministic cycle, which tracks a potential well. (b) Case II, large-amplitude regime (here  $\varepsilon = 0.02$ ,  $a_0 = 0.1$ ,  $\sigma = 0.05$ ): Typical paths are close to the deterministic cycle, which switches between potential wells. (c) Case III, large-noise regime (here  $\varepsilon = 0.001$ ,  $a_0 = 0$ ,  $\sigma = 0.16$ ): Paths are likely to cross the potential barrier when  $|\lambda|$  is of order  $\lambda_c - \sigma^{4/3}$ .

*The remainder has expectation and standard deviation of order  $\sigma^2 \ell_\varepsilon (\varepsilon \sqrt{a_0})^{-2/3}$  at most.*

- In Case IIb, we can only show that the distribution of  $\mathcal{A}(\varepsilon, \sigma)$  is concentrated in an interval of width  $(\varepsilon \sqrt{a_0})^{2/3} \ell_\varepsilon$  around  $\mathcal{A}(\varepsilon, 0)$ .

- **Case III: (Large-noise regime)**

*The distribution of  $\mathcal{A}(\varepsilon, \sigma)$  is concentrated near a (deterministic) reference area  $\hat{\mathcal{A}}$  satisfying  $\hat{\mathcal{A}} - \mathcal{A}_0 \asymp -\sigma^{4/3}$ . The standard deviation of  $\mathcal{A}(\varepsilon, \sigma)$  is at most of order  $\sigma^{4/3} \ell_\varepsilon^{2/3}$ , and its expectation belongs to an interval*

$$[\hat{\mathcal{A}} - \mathcal{O}(\sigma^{4/3} \ell_\varepsilon^{2/3}), \hat{\mathcal{A}} + \mathcal{O}(\sigma^2 \ell_\varepsilon^2) + \mathcal{O}(\varepsilon \ell_\varepsilon)]. \quad (4.7)$$

*In the case where  $a_0 \geq \varepsilon$  and  $\sigma \leq a_0^{3/4}$ , the term  $\mathcal{O}(\varepsilon \ell_\varepsilon)$  has to be replaced by  $\mathcal{O}(\varepsilon \sqrt{|a_0|} \ell_\varepsilon / \sigma^{2/3})$ . In both cases, the distribution decays faster to the right of  $\hat{\mathcal{A}}$  than to the left.*

In Regimes I and II, the main effect of additive noise is to broaden the distribution of the area, which remains concentrated, however, around the corresponding deterministic value. In Regime III, on the other hand, the hysteresis area obeys a completely new scaling law, which is determined by the noise intensity rather than by frequency and amplitude of the driving field.

The Gaussian behaviour of  $\mathcal{A}$  in Cases Ia and IIa is obtained in the following way. The deviation  $y_t = x_t - x_t^{\text{det}}$  from the deterministic solution satisfies an equation of the form (2.24) with  $g \equiv 1$ , whose solution obeys the integral equation

$$y_t = \frac{\sigma}{\sqrt{\varepsilon}} \int_{t_0}^t e^{\alpha(t,s)/\varepsilon} dW_s + \frac{1}{\varepsilon} \int_{t_0}^t e^{\alpha(t,s)/\varepsilon} b(y_s, s) ds, \quad (4.8)$$

where  $b(y, s) = \mathcal{O}(y^2)$ . For small values of  $y_t$ , the first term dominates the second one. Its

contribution to  $\mathcal{A}(\varepsilon, \sigma) - \mathcal{A}(\varepsilon, 0) = -\int y_u \lambda'(u) du$  can be written as

$$\frac{\sigma}{\sqrt{\varepsilon}} \int_{t_0}^{t_0+1} \gamma(t_0 + 1, s) dW_s, \quad \text{where} \quad \gamma(t, s) = -\int_s^t e^{\alpha(u,s)/\varepsilon} \lambda'(u) du. \quad (4.9)$$

The variance of this term is given by

$$\sigma^2 \varepsilon \Gamma(t_0 + 1, t_0), \quad \text{where} \quad \Gamma(t, t_0) = \frac{1}{\varepsilon^2} \int_{t_0}^t \gamma(t, s)^2 ds. \quad (4.10)$$

The integral  $\Gamma(t_0 + 1, t_0)$  depends only on properties of the deterministic solution  $x_t^{\text{det}}$  via the curvature  $a(t)$ . The auxiliary function  $\gamma(t, s)$  can be evaluated by partial integration, its leading term behaving like  $-\varepsilon \lambda'(s)/|a(s)|$ .

In Case I,  $\Gamma(t_0 + 1, t_0)$  is of order 1, and thus the contribution of the linear term to the variance of the area is of order  $\sigma^2 \varepsilon$ . In Case Ia, one can show that the Gaussian term dominates the distribution of  $\mathcal{A}(\varepsilon, \sigma)$  near  $\mathcal{A}(\varepsilon, 0)$ , in the sense that

$$\mathbb{P}\{|\mathcal{A}(\varepsilon, \sigma) - \mathcal{A}(\varepsilon, 0)| \geq H\} \leq \frac{C}{\varepsilon} e^{-\kappa H^2/(\sigma^2 \varepsilon)} \quad (4.11)$$

holds for some constants  $C, \kappa > 0$ , and for all  $H$  smaller than a constant times  $\sqrt{\varepsilon}(|a_0| \vee \varepsilon)^{4/3}$  if  $|a_0| \leq \varepsilon^{2/3}/\ell_\varepsilon^{4/3}$ , and all  $H$  smaller than  $\varepsilon/\ell_\varepsilon$  if  $|a_0| \geq \varepsilon^{2/3}/\ell_\varepsilon^{4/3}$ . Note that the upper bound (4.11) is exponentially small for the maximal value of  $H$ , except on the upper boundary of Region Ia.

In Case Ib, the Gaussian term no longer dominates, but one can still show that

$$\mathbb{P}\{|\mathcal{A}(\varepsilon, \sigma) - \mathcal{A}(\varepsilon, 0)| \geq H\} \leq \frac{C}{\varepsilon} e^{-\kappa H/(\sigma^2 \ell_\varepsilon)} \quad (4.12)$$

up to  $H = \text{const } |a_0|^{3/2} \ell_\varepsilon$ . Again, (4.12) is exponentially small except on the upper boundary of Region Ib.

Estimates (4.11) and (4.12) control the tails of the distribution of  $\mathcal{A}(\varepsilon, \sigma)$  in a neighbourhood of  $\mathcal{A}(\varepsilon, 0)$ . The quartic growth of the potential  $V(x, t)$  for large  $|x|$  implies, on the other hand, that

$$\mathbb{P}\{|\mathcal{A}(\varepsilon, \sigma) - \mathcal{A}(\varepsilon, 0)| \geq H\} \leq \frac{C}{\varepsilon} e^{-\kappa H^4/\sigma^2} \quad (4.13)$$

for all  $H$  larger than some constant (of order 1). In fact, this estimate holds in *all* parameter regimes, since it does not depend on the details of the potential near  $x = 0$ . This still leaves a gap between the domains of validity of (4.11) and (4.12), and of (4.13), which is due to the existence of a second potential well. In fact, the distribution of the hysteresis area will not be unimodal. Sample paths are unlikely to cross the potential barrier, but if they do so, then most probably near the instants of minimal barrier height, in which case they enclose an area of order 1. Hence the density of  $\mathcal{A}(\varepsilon, \sigma)$  will have a large peak near  $\mathcal{A}(\varepsilon, 0)$ , and a small peak near areas of order 1 (more precisely, near  $\int_{-A}^A (X_+^*(\lambda) - X_-^*(\lambda)) d\lambda$ ), see Figure 9.

In Case IIa, the distribution of  $\mathcal{A}(\varepsilon, \sigma)$  near  $\mathcal{A}(\varepsilon, 0)$  is again dominated by a Gaussian, stemming from the linearization of the SDE around  $x_t^{\text{det}}$ . The integral  $\Gamma(t_0 + 1, t_0)$  in (4.10) is found to behave like  $\varepsilon^{-2/3} a_0^{1/6}$ , leading to a variance of order  $\sigma^2 (\varepsilon \sqrt{a_0})^{1/3}$  and to the bound

$$\mathbb{P}\{|\mathcal{A}(\varepsilon, \sigma) - \mathcal{A}(\varepsilon, 0)| \geq H\} \leq \frac{C}{\varepsilon} e^{-\kappa H^2/(\sigma^2 (\varepsilon \sqrt{a_0})^{1/3})}, \quad (4.14)$$

FIGURE 9. Sketches of the distribution of the hysteresis area  $\mathcal{A}(\varepsilon, \sigma)$  in the different parameter regimes. Regime Ia: The area is concentrated near the deterministic area  $\mathcal{A}(\varepsilon, 0) \asymp \varepsilon A$ . There is a small probability to observe areas of order 1. Regime Ib: The distribution is more spread out. Regime IIa: The area is concentrated near the deterministic area  $\mathcal{A}(\varepsilon, 0)$  of order  $\mathcal{A}_0 + (\varepsilon\sqrt{a_0})^{2/3}$ . Regime IIb: The area is concentrated in an interval of width  $(\varepsilon\sqrt{a_0})^{2/3}$  around  $\mathcal{A}_0 + (\varepsilon\sqrt{a_0})^{2/3}$ , but we do not control the distribution in this interval. The broken curve shows an extrapolation of the estimates outside this interval. Regime III: The area is concentrated near  $\hat{\mathcal{A}}$ , which is of order  $\mathcal{A}_0 - \sigma^{4/3}$ . The distribution decays faster to the right than to the left.

valid for  $H$  smaller than a constant times  $\varepsilon\sqrt{a_0}$ .

Unfortunately, this estimate cannot be extended to Case IIb. The reason is that during the jump of  $x_t^{\text{det}}$  to the left-hand potential well, a zone of instability is crossed where paths are strongly dispersed. The maximal spreading of paths is of order  $\sigma(\varepsilon\sqrt{a_0})^{-5/6}$ , which is too large, in this regime, to allow for a precise control of the effect of nonlinear terms. This does not exclude the possibility that the bound (4.14) remains valid for larger  $\sigma$ .

However, the value  $\lambda^0$  of the magnetic field when  $x_t$  changes sign can be described in all of Regime II. One can show that

$$\mathbb{P}\{|\lambda^0| < \lambda_c - L\} \leq \frac{C}{\varepsilon} e^{-\kappa(|L|^{3/2} \vee \varepsilon\sqrt{a_0})/\sigma^2} \quad \text{for } -L_1(\varepsilon\sqrt{a_0})^{2/3} \leq L \leq L_0/\ell_\varepsilon \quad (4.15)$$

$$\mathbb{P}\{|\lambda^0| > \lambda_c + L\} \leq 3 e^{-\kappa L/(\sigma^2(\varepsilon\sqrt{a_0})^{3/2}\ell_\varepsilon)} \quad \text{for } L \geq L_2(\varepsilon\sqrt{a_0})^{2/3}. \quad (4.16)$$

Note that  $|\lambda^0|$  cannot exceed  $\lambda_c + a_0$ . These bounds mean that the distribution of  $\lambda^0$  is concentrated around the deterministic value of order  $\lambda_c + (\varepsilon\sqrt{a_0})^{2/3}$ , and decays faster to

the right than to the left. They can be used to show that in Case IIb,

$$\mathbb{P}\{\mathcal{A}(\varepsilon, \sigma) - \mathcal{A}(\varepsilon, 0) \leq -H\} \leq \frac{C}{\varepsilon} e^{-\kappa H^{3/2}/\sigma^2}, \quad (4.17)$$

$$\mathbb{P}\{\mathcal{A}(\varepsilon, \sigma) - \mathcal{A}(\varepsilon, 0) \geq +H\} \leq \frac{C}{\varepsilon} e^{-\kappa(\varepsilon\sqrt{a_0})^{1/3}H/(\sigma^2\ell_\varepsilon)} \quad (4.18)$$

for  $(\varepsilon\sqrt{a_0})^{2/3}\ell_\varepsilon \leq H \leq (\varepsilon\sqrt{a_0})^{1/3}\ell_\varepsilon$ . Thus the probability that  $\mathcal{A}(\varepsilon, \sigma) - \mathcal{A}(\varepsilon, 0)$  is outside an interval of size  $(\varepsilon\sqrt{a_0})^{2/3}\ell_\varepsilon$  is very small. We do not control, however, what happens inside this interval.

In Case III, the large-noise regime, most sample paths are driven over the potential barrier as soon as the magnetic field reaches a value of order  $\lambda_c - \sigma^{4/3}$ . Rather than comparing  $\mathcal{A}(\varepsilon, \sigma)$  to its deterministic value, we should compare it to a reference area  $\hat{\mathcal{A}}$  given by

$$\frac{1}{2}\hat{\mathcal{A}} = \int_{-1/4}^{t_1} x_s^{\text{det},+}(-\lambda'(s)) ds + \int_{t_1}^{1/4} x_s^{\text{det},-}(-\lambda'(s)) ds, \quad (4.19)$$

where  $x_s^{\text{det},\pm}$  are solutions tracking respectively the right and left potential well, and  $t_1 \asymp -\sigma^{2/3}$  is the typical jump time. Checking that  $\hat{\mathcal{A}} - \mathcal{A}_0$  scales like  $-\sigma^{4/3}$  is straightforward.

The probability of deviations of  $\mathcal{A}(\varepsilon, \sigma)$  from  $\hat{\mathcal{A}}$  can be estimated by bounding separately the integrals between  $-1/4$  and  $t_1$  and between  $t_1$  and  $1/4$ . The results differ slightly in two regimes. If  $a_0 \leq \varepsilon$  or  $\sigma > a_0^{3/4}$ , then

$$\mathbb{P}\{\mathcal{A}(\varepsilon, \sigma) - \hat{\mathcal{A}} \leq -H\} \leq \frac{C}{\varepsilon} e^{-\kappa H^{3/2}/\sigma^2} + \frac{3}{2} e^{-\kappa\sigma^{4/3}/(\varepsilon\ell_\varepsilon)} \quad (4.20)$$

$$\mathbb{P}\{\mathcal{A}(\varepsilon, \sigma) - \hat{\mathcal{A}} \geq +H\} \leq \frac{C}{\varepsilon} e^{-\kappa H/(\sigma^2\ell_\varepsilon)} + \frac{3}{2} e^{-\kappa H/(\varepsilon\ell_\varepsilon)} \quad (4.21)$$

holds for some  $C, \kappa > 0$  and all  $H$  up to a constant times  $\sigma^{2/3}\ell_\varepsilon$ . If  $a_0 \geq \varepsilon$  and  $\sigma \leq a_0^{3/4}$ , two exponents are modified:

$$\mathbb{P}\{\mathcal{A}(\varepsilon, \sigma) - \hat{\mathcal{A}} \leq -H\} \leq \frac{C}{\varepsilon} e^{-\kappa H^{3/2}/\sigma^2} + \frac{3}{2} e^{-\kappa\sigma^2/(\varepsilon\sqrt{a_0}\ell_\varepsilon)} \quad (4.22)$$

$$\mathbb{P}\{\mathcal{A}(\varepsilon, \sigma) - \hat{\mathcal{A}} \geq +H\} \leq \frac{C}{\varepsilon} e^{-\kappa H/(\sigma^2\ell_\varepsilon)} + \frac{3}{2} e^{-\kappa\sigma^{2/3}H/(\varepsilon\sqrt{a_0}\ell_\varepsilon)}. \quad (4.23)$$

Again, the distribution decays faster to the right of  $\hat{\mathcal{A}}$  than to the left, guaranteeing that  $\mathcal{A}(\varepsilon, \sigma)$  is likely to be smaller than the static hysteresis area  $\mathcal{A}_0$ . The second term on the right-hand sides of (4.20) and (4.22) does not depend on  $H$ : It bounds the probability that the paths do not cross the potential barrier, and enclose an area close to zero. The situation is opposite to Case I: The distribution of the hysteresis area has a large peak near  $\hat{\mathcal{A}}$  and a small peak near 0.

The qualitative behaviour of the distribution of  $\mathcal{A}(\varepsilon, \sigma)$  is sketched in Figure 9. When crossing the boundary between Regime I and Regime III, the probability of paths crossing the potential barrier increases, so that the peak near  $\mathcal{A}(\varepsilon, 0)$  shrinks while the peak near  $\mathcal{A}_0$  grows. When approaching the transition line between Regimes III and II, the distribution of the area  $\mathcal{A}(\varepsilon, \sigma)$  becomes more spread out and more symmetric, before concentrating again around the large-amplitude deterministic value of  $\mathcal{A}_0 + \mathcal{O}((\varepsilon\sqrt{a_0})^{2/3})$ .

## 5 Bifurcation delay

In the previous section, we had to deal in particular with the slow passage through a saddle–node bifurcation. This section is devoted to the slow passage through a (symmetric) pitchfork bifurcation.

We consider again the Ginzburg–Landau potential (3.1), but this time with  $\lambda \equiv 0$ , and a parameter  $\mu(t)$  increasing monotonously through zero. As  $\mu$  changes from negative to positive, the potential transforms from a single-well to a double-well potential, a scenario known as *spontaneous symmetry breaking*. In fact, the symmetry of the potential is not broken, but the symmetry of the state may be. Solutions tracking initially the potential well at  $x = 0$  will choose between one of the new potential wells, but which one of the wells is chosen, and at what time, depends strongly on the noise present in the system.

### 5.1 Dynamic pitchfork bifurcation

In the deterministic case  $\sigma = 0$ , the equation of motion reads

$$\varepsilon \frac{dx_t}{dt} = \mu(t)x_t - x_t^3. \quad (5.1)$$

Its solution  $x_t^{\text{det}}$  with initial condition  $x_{t_0}^{\text{det}} = x_0 > 0$  can be written in the form

$$x_t^{\text{det}} = c(x_0, t) e^{\alpha(t, t_0)/\varepsilon}, \quad \alpha(t, t_0) = \int_{t_0}^t \mu(s) ds, \quad (5.2)$$

where the function  $c(x_0, t)$  is found by substitution into (5.1). Its exact expression is of no importance here, it is sufficient to know that  $0 < c(x_0, t) \leq x_0$  for all  $t$ .

Assume that  $\mu(t)$  is negative for  $t < 0$  and positive for  $t > 0$ . If we start at a time  $t_0 < 0$ , the solution (5.2) will be attracted exponentially fast by the stable origin. The function  $\alpha(t, t_0)$  is negative and decreasing for  $t_0 < t < 0$ , which implies in particular that  $x_0^{\text{det}}$  is exponentially small. For  $t > 0$ , the function  $\alpha(t, t_0)$  is increasing, but it remains negative for some time. As a consequence,  $x_t^{\text{det}}$  remains close to the saddle up to the first time  $t = \Pi(t_0)$  for which  $\alpha(t, t_0)$  reaches 0 again (if such a time exists). Shortly after time  $\Pi(t_0)$ , the solution will jump to the potential well at  $+\sqrt{\mu(t)}$ , unless  $x_0$  is exponentially small.  $\Pi(t_0)$  is called *bifurcation delay*, and depends only on  $\mu$  and  $t_0$ . For instance, if  $\mu(t) = t$ , then  $\alpha(t, t_0) = \frac{1}{2}(t^2 - t_0^2)$  and  $\Pi(t_0) = |t_0|$ .

The existence of a bifurcation delay may have undesired consequences. Assume for instance that we want to determine the bifurcation diagram of  $\dot{x} = \mu x - x^3$  experimentally. Instead of measuring the asymptotic value of  $x_t$  for many different values of  $\mu$ , which is time-consuming (especially near  $\mu = 0$  where  $x_t$  decays only like  $1/\sqrt{t}$ ), one may be tempted to vary  $\mu$  slowly during the experiment. This, however, will fail to reveal part of the stable equilibrium branches because of the bifurcation delay. A similar phenomenon exists for the Hopf bifurcation [Ne1, Ne2].

The delay is due to the fact that  $x_t$  approaches the origin exponentially closely. Noise of sufficient intensity will help driving the particle away from the saddle, and should therefore reduce the bifurcation delay. The obvious question is thus: How does the delay depend on the noise intensity?

In the case of a quadratic potential  $V(x, t) = -\frac{1}{2}\mu(t)x^2$ , this question has been investigated and compared with experiments, with the result that the delay behaves like  $\sqrt{|\log \sigma|}$  [TM, SMC, SHA]. Similar results were obtained in [JL]. Our techniques allow us to derive rigorous bounds for the nonlinear equation.

## 5.2 Effect of additive noise

We consider the nonlinear SDE

$$dx_t = \frac{1}{\varepsilon} [\mu(t)x_t - x_t^3] dt + \frac{\sigma}{\sqrt{\varepsilon}} dW_t. \quad (5.3)$$

The results presented here are a particular case of those obtained in [BG1], which apply to more general nonlinearities. We assume that  $\mu(t) = t + \mathcal{O}(t^2)$  is monotonously increasing on an interval  $[t_0, T]$  or  $[t_0, \infty)$ ,  $t_0 < 0$ . We denote by  $x_t^{\text{det}}$  and  $x_t$  the solutions of the deterministic and stochastic equations with given initial condition  $x_0 > 0$ .

We already know that  $x_t^{\text{det}}$  decreases exponentially fast for  $t < 0$ . Results from Section 2 show that paths are concentrated in a neighbourhood of order  $\sigma$  of  $x_t^{\text{det}}$  on any time interval  $[t_0, t_1]$  bounded away from zero, so that we only need to worry about what happens after time  $t_1$ , when  $x^{\text{det}}$  is already exponentially small.

The dispersion of paths will be controlled by the variance-like function

$$\bar{v}(t) = \bar{v}_0 e^{2\alpha(t, t_1)/\varepsilon} + \frac{\sigma^2}{\varepsilon} \int_{t_1}^t e^{2\alpha(t, s)/\varepsilon} ds, \quad (5.4)$$

where  $\bar{v}_0$  is a positive constant. One can show that this function grows like  $\sigma^2/|\mu(t)|$  for  $t \leq -\sqrt{\varepsilon}$ , and remains of order  $\sigma^2/\sqrt{\varepsilon}$  up to time  $\sqrt{\varepsilon}$ . Only after time  $\sqrt{\varepsilon}$ ,  $\bar{v}(t)$  grows exponentially fast. In analogy with (2.16), we define a strip

$$\mathcal{B}(h) = \{(x, t) : t_1 \leq t \leq \sqrt{\varepsilon}, |x - x_t^{\text{det}}| < h\sqrt{\bar{v}(t)}\}. \quad (5.5)$$

In order to describe the behaviour for  $t \geq \sqrt{\varepsilon}$ , we further introduce the domain

$$\mathcal{D}(\varrho) = \{(x, t) : \sqrt{\varepsilon} \leq t \leq T, |x| \leq \sqrt{(1 - \varrho)\mu(t)}\}, \quad (5.6)$$

where  $\varrho$  is a parameter in  $[0, 2/3)$ . Note that  $\mathcal{D}(2/3)$  contains those points in space–time where the potential is concave, while  $\mathcal{D}(0)$  contains the points located between the bottoms of the wells.

**Theorem 5.1** ([BG1, Theorems 2.10–2.12]).

- There is a constant  $h_0 > 0$  such that for all  $h \leq h_0\sqrt{\varepsilon}/\sigma$ , the first-exit time  $\tau_{\mathcal{B}(h)}$  of  $x_t$  from  $\mathcal{B}(h)$  satisfies

$$\mathbb{P}^{t_1, x_{t_1}} \{\tau_{\mathcal{B}(h)} < \sqrt{\varepsilon}\} \leq C_\varepsilon e^{-\kappa h^2}, \quad (5.7)$$

where

$$C_\varepsilon = \frac{|\alpha(\sqrt{\varepsilon}, t_1)| + \mathcal{O}(\varepsilon)}{\varepsilon^2} \quad \text{and} \quad \kappa = \frac{1}{2} - \mathcal{O}(\sqrt{\varepsilon}) - \mathcal{O}\left(\frac{\sigma^2 h^2}{\varepsilon}\right). \quad (5.8)$$

- Assume that  $\sigma |\log \sigma|^{3/2} = \mathcal{O}(\sqrt{\varepsilon})$ . Then for any  $\varrho \in (0, 2/3)$ , the first-exit time  $\tau_{\mathcal{D}(\varrho)}$  of  $x_t$  from  $\mathcal{D}(\varrho)$  satisfies

$$\mathbb{P}^{\sqrt{\varepsilon}, x_{\sqrt{\varepsilon}}} \{\tau_{\mathcal{D}(\varrho)} \geq t\} \leq C(t, \varepsilon) \frac{|\log \sigma|}{\sigma} \frac{e^{-\varrho\alpha(t, \sqrt{\varepsilon})/\varepsilon}}{\sqrt{1 - e^{-2\varrho\alpha(t, \sqrt{\varepsilon})/\varepsilon}}}, \quad (5.9)$$

where

$$C(t, \varepsilon) = \text{const } \mu(t) \left(1 + \frac{\alpha(t, \sqrt{\varepsilon})}{\varepsilon}\right). \quad (5.10)$$

FIGURE 10. A sample path of the SDE (5.3) with  $\mu(t) = t$ , for  $\varepsilon = 0.01$  and  $\sigma = 0.015$ . A deterministic solution is shown for comparison. Up to time  $\sqrt{\varepsilon}$ , the path remains in the set  $\mathcal{B}(h)$  centred at  $x_t^{\text{det}}$ , shown here for  $h = 3$ . It then leaves the set  $\mathcal{D}(\varrho)$  (here  $\varrho = 2/3$ ) after a time of order  $\sqrt{\varepsilon}|\log \sigma|$ , after which it remains in a neighbourhood of the deterministic solution starting at the same time on the boundary of  $\mathcal{D}(\varrho)$ .

- Assume  $x_t$  leaves  $\mathcal{D}(\varrho)$  (with  $1/2 < \varrho < 2/3$ ) through its upper (lower) boundary. Let  $x_t^{\text{det},\tau}$  be the deterministic solution starting at time  $\tau = \tau_{\mathcal{D}(\varrho)}$  on the upper (lower) boundary of  $\mathcal{D}(\varrho)$ . Then  $x_t^{\text{det},\tau}$  approaches the equilibrium branch at  $\sqrt{\mu(t)}$  (resp.,  $-\sqrt{\mu(t)}$ ) like  $\varepsilon/\mu(t)^{3/2} + \sqrt{\mu(\tau)}e^{-\eta\alpha(t,\tau)/\varepsilon}$ , where  $\eta = 2 - 3\varrho$ . Moreover,  $x_t$  is likely to stay in a strip centred at  $x_t^{\text{det},\tau}$ , with width of order  $\sigma/\sqrt{\mu(t)}$ , at least up to times of order 1.

The bound (5.7), which is proved in a similar way as Theorem 2.2, shows that paths are unlikely to leave the strip  $\mathcal{B}(h)$  if  $1 \ll h \leq h_0\sqrt{\varepsilon}/\sigma$ . If  $\sigma$  is smaller than  $\sqrt{\varepsilon}$ , paths remain concentrated in a neighbourhood of the origin up to time  $\sqrt{\varepsilon}$ , with a typical spreading growing like  $\sigma/\sqrt{|\mu(t)|}$  for  $t \leq -\sqrt{\varepsilon}$ , and remaining of order  $\sigma/\varepsilon^{1/4}$  for  $|t| \leq \sqrt{\varepsilon}$ . This is again a dynamical effect: Although there is a saddle at the origin for positive times, its curvature is so small that paths do not have time to escape before  $t = \sqrt{\varepsilon}$ , see Figure 10.

Relation (5.9) yields an upper bound on the typical time needed to leave  $\mathcal{D}(\varrho)$ , and thus enter a region where the potential is convex. Since  $\alpha(t, \sqrt{\varepsilon})$  grows like  $\frac{1}{2}t^2$  for small  $t$ , the probability not to leave  $\mathcal{D}(\varrho)$  before time  $t$  becomes small as soon as

$$t \gg \sqrt{\frac{2}{\varrho}\varepsilon|\log \sigma|}. \quad (5.11)$$

The last part of the theorem implies that another time span of the same order is needed for paths to concentrate again, around an adiabatic solution tracking the bottom of the well (at a distance of order  $\varepsilon/\mu(t)^{3/2}$ ). One can thus say that the typical bifurcation delay time of the dynamical pitchfork bifurcation with noise is of order  $\sqrt{\varepsilon}|\log \sigma|$ .

As a consequence, we can distinguish three parameter regimes (Figure 11):

FIGURE 11. Depending on the value of noise intensity  $\sigma$  and drift velocity  $\varepsilon$ , the random bifurcation delay has one of three qualitatively different behaviours. If  $\sigma$  is exponentially small in  $1/\varepsilon$ , the typical delay is macroscopic. For  $\sigma$  larger than  $\sqrt{\varepsilon}$ , there is no such delay, and paths make large excursions near the bifurcation point. In the intermediate regime, the typical delay is of order  $\sqrt{\varepsilon|\log \sigma|}$ .

- I. *Exponentially small noise:*  $\sigma \leq e^{-K/\varepsilon}$  for some  $K > 0$ .

At time  $\sqrt{\varepsilon}$ , the spreading of paths is still exponentially small. In fact, one can extend Relation (5.7) to all times for which  $\alpha(t, \sqrt{\varepsilon}) < K$ . If  $K$  is larger than  $\alpha(\Pi(t_0), 0)$ , where  $\Pi(t_0)$  is the deterministic bifurcation delay, most paths will track the deterministic solution and follow it into the right-hand potential well.

- II. *Moderate noise:*  $e^{-1/\varepsilon^p} \leq \sigma \ll \sqrt{\varepsilon}$  for some  $p > 1$ .

The bifurcation delay lies between  $\sqrt{\varepsilon}$  and a constant times  $\sqrt{\varepsilon|\log \sigma|} \leq \varepsilon^{(1-p)/2}$  with high probability. One can thus speak of a “microscopic” bifurcation delay.

- III. *Large noise:*  $\sigma \geq \sqrt{\varepsilon}$ .

The spreading of paths grows like  $\sigma/\sqrt{|\mu(t)|}$  at least up to time  $-\sigma$ . As  $t$  approaches the bifurcation time 0, the bottom of the potential well becomes so flat that the paths are no longer localized near the origin and may switch wells several times before eventually settling for a well. So for large noise intensities, the concept of bifurcation delay should be replaced by *two* variables, namely the first-exit time from a suitably chosen neighbourhood of the saddle and the time when the potential wells become attractive enough to counteract the diffusion.

One can also estimate the probability to reach the right-hand potential well rather than the left-hand potential well. Loosely speaking, if  $x_s$  reaches 0 before time  $t$ , it has equal probability to choose either potential well. It follows that

$$\mathbb{P}^{t_0, x_0} \{x_t \geq 0\} = \frac{1}{2} + \frac{1}{2} \mathbb{P}^{t_0, x_0} \{x_s > 0 \forall s \in [t_0, t]\}. \quad (5.12)$$

One can show that for  $t = 0$  the second term on the right-hand side is of order

$$\frac{x_0 \varepsilon^{1/4}}{\sigma} e^{-|\alpha(0, t_0)|/\varepsilon}, \quad (5.13)$$

and for larger  $t$ , this term will be even smaller. Thus in case II, paths will choose one potential well or the other with a probability exponentially close to  $1/2$ .

In the particular case where  $\mu(t) > \text{const } t$  for all  $t > 0$ , the height of the potential barrier grows without bound. This implies that once  $x_t$  has chosen a potential well, its probability *ever* to cross the saddle again is of order  $e^{-\text{const}/\sigma^2}$ .

The existence of three parameter regimes has some interesting consequences on the experimental determination of a bifurcation diagram. Assume we want to determine the stable equilibrium branches by sweeping the parameter with speed  $\varepsilon$ . Regime II is the most

favourable: In Regime I, part of the stable branches cannot be seen due to the bifurcation delay, while in Regime III, noise will blur the bifurcation diagram. For a given noise intensity  $\sigma$ , the sweeping rate  $\varepsilon$  should thus satisfy

$$\sigma^2 \ll \varepsilon \ll (1/|\log \sigma|)^{1/p} \quad (5.14)$$

in order to produce a good image of the stable equilibria. As long as  $\sigma^2 \ll 1/|\log \sigma|^{1/p}$ , increasing artificially the noise level allows to work with higher sweeping rates, but of course the image will be more and more blurred.

On the other hand, the relation between noise and delay can be used to measure the intensity of noise present in the system. If a bifurcation delay is observed for a sweeping rate  $\varepsilon_0$ , repeating the experiment with slower and slower sweeping rates should ultimately suppress the delay. If this happens for  $\varepsilon = \varepsilon_1$ , then the noise intensity is of order  $e^{-const/\varepsilon_1}$ .

## 6 Generalizations

### 6.1 Multidimensional systems

We now return to  $n$ -dimensional equations such as (1.11). As in Section 2, we start by examining the linear equation

$$dy_t = \frac{1}{\varepsilon} A(t)y_t dt + \frac{\sigma}{\sqrt{\varepsilon}} G(t) dW_t, \quad y_0 = 0, \quad (6.1)$$

obtained, for instance, by linearizing the equation around a given deterministic solution (in that case, the matrices  $A$  and  $G$  may depend on  $\varepsilon$ ). If the drift term derives from a potential, then  $A$  is necessarily symmetric, but we will not impose such a restriction here. We will assume, however, that we are in the stable case, that is, all eigenvalues of  $A(t)$  have real parts smaller than some constant  $-a_0 < 0$ .

The solution of (6.1) can be written as

$$y_t = \frac{\sigma}{\sqrt{\varepsilon}} \int_0^t U(t,s) G(s) dW_s, \quad (6.2)$$

where  $U(t,s) = U(t)U(s)^{-1}$  is the propagator of the deterministic equation  $\varepsilon \dot{y} = A(t)y$ , and we denote by  $U(t)$  its principal solution, i. e.,  $\varepsilon \dot{U}(t) = A(t)U(t)$  and  $U(0) = \mathbb{1}$ . The random variable  $y_t$  has a Gaussian distribution, with zero expectation and covariance matrix

$$\text{Cov}\{y_t\} = \frac{\sigma^2}{\varepsilon} \int_0^t U(t,s) G(s) G(s)^T U(t,s)^T ds. \quad (6.3)$$

In order to determine the asymptotic behaviour of the covariance matrix, we first note that it is a particular solution of the ODE

$$\varepsilon \frac{d}{dt} X(t) = A(t)X(t) + X(t)A(t)^T + \sigma^2 G(t)G(t)^T. \quad (6.4)$$

The general solution of (6.4) can be written as

$$X(t) = \bar{X}(t) + U(t)[X(0) - \bar{X}(0)]U(t)^T, \quad (6.5)$$

where  $\bar{X}(t)$  is a particular solution admitting an asymptotic expansion (c.f. [Wa])

$$\bar{X}(t) = \bar{X}_0(t) + \varepsilon \bar{X}_1(t) + \varepsilon^2 \bar{X}_2(t) + \dots \quad (6.6)$$

The terms of this expansion satisfy the Liapunov equations

$$A(t)\bar{X}_0(t) + \bar{X}_0(t)A(t)^T = -\sigma^2 G(t)G(t)^T \quad (6.7)$$

$$A(t)\bar{X}_n(t) + \bar{X}_n(t)A(t)^T = \frac{d}{dt}\bar{X}_{n-1}(t) \quad \forall n \geq 1. \quad (6.8)$$

The solution of (6.7) admits the integral representation (see for instance [Bell])

$$\bar{X}_0(t) = \sigma^2 \int_0^\infty e^{A(t)s} G(t)G(t)^T e^{A(t)^T s} ds, \quad (6.9)$$

and similarly for the solutions of (6.8). Note that  $\bar{X}_0$  corresponds to the asymptotic covariance matrix of (6.2) if  $A$  and  $G$  are constant in time

At any fixed time  $t$ , the distribution of  $y_t$  is concentrated in an ellipsoid of the form  $\langle y, \text{Cov}\{y_t\}^{-1}y \rangle \leq \text{const}$ , provided the (Gaussian) distribution of  $y_t$  is nondegenerate. Assume for the moment that  $G(t)G(t)^T$  is uniformly positive definite. Then  $\text{Cov}\{y_t\}^{-1}$  exists and so does  $\bar{X}(s)^{-1}$ . In addition, we find that  $\sigma^2 \bar{X}(s)^{-1}$  is bounded in norm. The following result, which generalizes Proposition 2.1 from the one-dimensional case, shows that the paths  $\{y_t\}_{t \geq 0}$  are concentrated in sets  $\{(t, y) : \langle y, \bar{X}(t)^{-1}y \rangle \leq \text{const}\}$ . The proof will be given in [BG4].

**Theorem 6.1.** *Assume that  $\sigma^2 \bar{X}(s)^{-1}$  is bounded in norm. Then for all  $t > 0$ ,  $h > 0$  and any  $\kappa \in (0, 1/2)$ ,*

$$\mathbb{P}^{0,0} \left\{ \sup_{0 \leq s \leq t} \langle y_s, \bar{X}(s)^{-1}y_s \rangle \geq h^2 \right\} \leq C_n(t, \varepsilon) e^{-\kappa h^2 (1 - \mathcal{O}(\varepsilon))}, \quad (6.10)$$

where

$$C_n(t, \varepsilon) = \left( \frac{t}{\varepsilon^2} + 1 \right) \left( \frac{1}{1 - 2\kappa} \right)^n. \quad (6.11)$$

The exponential growth of the prefactor as a function of the dimension implies that the estimate (6.10) is only useful for  $h > \sqrt{n}$ . This dependence, however, is to be expected as the tails of  $n$ -dimensional (standard) Gaussians only show their typical decay outside a ball of radius proportional to  $\sqrt{n}$ .

Under the condition that  $\sigma^{-2} \bar{X}(s)$  and  $\sigma^2 \bar{X}(s)^{-1}$  are bounded in norm, one can show that a bound similar to (6.10) holds if  $y_s$  obeys a nonlinear perturbation of Equation (6.1), for all  $h$  smaller than a constant times  $\sigma^{-1}$ .

## 6.2 Coloured noise

White noise has no time-correlations, and is thus appropriate to model the random influence of a “fast” environment on a “slow” system, if the relaxation time of the fast system is negligible. If the relaxation time is short but not negligible, one has to use coloured noise instead of white noise.

The simplest (still Markovian) model of coloured noise is the Ornstein–Uhlenbeck process

$$Z_t = \sigma \int_0^t e^{-\gamma(t-s)} dW_s, \quad (6.12)$$

whose autocorrelation function  $\mathbb{E}\{Z_s Z_t\} = (\sigma^2/2\gamma) e^{-\gamma(t-s)}[1 - e^{-2\gamma s}]$ ,  $s < t$ , decays exponentially in  $t - s$ .

Let us examine the influence of such coloured noise on a slowly time-dependent, one-dimensional, linear system, described by the SDE

$$dx_t = a(\varepsilon t)x_t dt + g(\varepsilon t) dZ_t. \quad (6.13)$$

We assume that  $a(\varepsilon t)$  is negative,  $g(\varepsilon t)$  is positive, and that both functions are uniformly bounded away from zero. Using the differential representation  $dZ_t = -\gamma Z_t dt + \sigma dW_t$  of the Ornstein–Uhlenbeck process (6.12), and scaling time by a factor  $\varepsilon$ , we obtain that the random variable  $y_t = (x_t, Z_t)$  obeys a two-dimensional linear SDE of the form (6.1), with

$$A(t) = \begin{pmatrix} a(t) & -\gamma g(t) \\ 0 & -\gamma \end{pmatrix} \quad \text{and} \quad G(t) = \begin{pmatrix} g(t) \\ 1 \end{pmatrix}. \quad (6.14)$$

For  $\gamma \rightarrow 0$ , we recover the white-noise case, while  $\sigma \rightarrow 0$  corresponds to the deterministic limit.

Theorem 6.1 shows that paths are concentrated in a tube  $\langle y_s, \bar{X}(s)^{-1} y_s \rangle \leq \text{const}$ , with covariance matrix  $\bar{X}(s)$  admitting the asymptotic series (6.6). The leading term  $\bar{X}_0(s)$  is found from (6.9) to be

$$\bar{X}_0(s) = \sigma^2 \begin{pmatrix} \frac{g(s)^2}{2(\gamma + |a(s)|)} & \frac{g(s)}{2(\gamma + |a(s)|)} \\ \frac{g(s)}{2(\gamma + |a(s)|)} & \frac{1}{2\gamma} \end{pmatrix}. \quad (6.15)$$

In particular, the paths  $\{x_s\}_{s \geq 0}$  are concentrated in a strip of width  $\sigma g(s)/\sqrt{2(\gamma + |a(s)|)}$ . The effect of coloured noise of the form (6.12) is thus to narrow the distribution of the paths, in the same way as if the curvature were increased by an amount  $\gamma$ .

This result allows us to make some predictions on the effect of noise colour on stochastic resonance. We have seen in Section 3.2 that in the standard case of the asymmetric double-well potential with additive periodic forcing and white noise, paths switch between potential wells when  $\sigma$  exceeds the threshold  $\sigma_c = (a_0 \vee \varepsilon)^{3/4}$ . This value was obtained by comparing the typical spreading of paths to the minimal distance between the deterministic solution and the saddle. Repeating this argument in the case of coloured noise given by (6.12), we thus expect the threshold noise intensity to be determined by

$$\sigma_c^2 = (a_0 \vee \varepsilon)(\gamma \vee (a_0 \vee \varepsilon)^{1/2}). \quad (6.16)$$

This shows in particular that shorter correlation times of the noise require larger noise intensities to enable transitions between the wells.

A similar stabilizing effect of noise colour can be expected when sweeping the bifurcation parameter through a pitchfork bifurcation as discussed in Section 5. The bifurcation delay will lie between the macroscopic delay of the deterministic case and the microscopic delay of the white-noise case. The shorter the correlation time of the noise, the larger will the delay be.
