### **Abstract**

Efferocytosis, the process by which dying/dead cells are removed by phagocytosis, plays an important role in development, tissue homeostasis and innate immunity<sup>1</sup>. Efferocytosis is mediated, in part, by receptors that bind to exofacial phosphatidylserine (PS) on cells or cellular debris after loss of plasma membrane asymmetry. Here we show that a bacterial pathogen, *Listeria monocytogenes* (*Lm*), can exploit efferocytosis to promote cell-to-cell spread during infection. These bacteria can escape the phagosome in host cells using the pore-forming toxin Listeriolysin O (LLO) and two phospholipases C<sup>2</sup>. Expression of the cell surface protein ActA allows *Lm* to activate host actin regulatory factors and undergo actin-based motility in the cytosol, eventually leading to formation of actin-rich protrusions at the cell surface. We show that protrusion formation is associated with plasma membrane damage due to LLO's pore-forming activity. LLO also promotes the release of bacteria-containing protrusions from the host cell, generating membrane-derived vesicles with exofacial PS. The PS-binding receptor TIM-4 contributes to efficient cell-to-cell spread by *Lm* in macrophages *in vitro* and growth of these bacteria is impaired in TIM-4<sup>-/-</sup> mice. Thus, *Lm* promotes its dissemination in a host by exploiting efferocytosis. Our study suggests that PS-targeted therapeutics may be useful in the fight against infections by *Lm* and other bacteria that utilize similar strategies of cell-to-cell spread during infection.

**ONLINE CONTENT** Any additional Methods, Extended Data display items and Reagents are available in the online version of the paper; references unique to these sections appear only in the online paper.

**AUTHOR CONTRIBUTIONS** J.H.B., M.A.C., S.O. and D.E.H. designed the experiments and wrote the paper. M.A.C., R.F., J.V.R., V.A.C., and S.O. performed the experiments. A.M.M. and V.K.K. contributed reagents and consultations.

## Results and Discussion

The intermediate stages of cell-to-cell spread by *Lm* remain unclear. Based on observations with an *in vitro* infection model, Theriot and colleagues suggested that bacteria-containing protrusions are released from infected cells, prior to uptake of membrane vesicles containing bacteria by neighboring cells<sup>3</sup>. However, the mechanisms that mediate protrusion release and uptake of bacteria in vesicles are not known.

LLO is required for *Lm* cell-to-cell spread in some cell types, including macrophages<sup>4,5</sup>. LLO is a pore-forming toxin that is often referred to as a “phagosome-specific lysin”<sup>6</sup> because it has limited activity in the cytosol of host cells, due to its relatively low lytic activity<sup>7</sup> and stability<sup>8</sup> at neutral pH. Furthermore, LLO is degraded by the proteasome<sup>9</sup>. Despite these factors, it is now appreciated that LLO can damage the plasma membrane of host cells<sup>10</sup>. Host membrane repair pathways limit LLO-mediated membrane damage<sup>11</sup>, but the mechanisms by which they act remain unclear. LLO is essential for disruption of the outer membrane of spreading vacuoles<sup>4</sup>. Whether LLO contributes to other stages of cell-to-cell spread has not been tested.

We hypothesized that LLO-mediated damage to the plasma membrane may promote cell-to-cell spread. We used a propidium iodide (PI) assay to measure membrane damage induced during *Lm* infection (Fig. 1a). Repair of the plasma membrane is a Ca<sup>2+</sup>-dependent process<sup>12</sup>. Therefore, the absence of Ca<sup>2+</sup> in the medium provided a convenient method to inactivate endogenous repair mechanisms and visualize the full extent of membrane damage. HeLa cells were used for these studies since phagosome escape by *Lm* does not require LLO in this cell type<sup>13</sup>.

In the absence of extracellular Ca<sup>2+</sup>, infection of cells with wild type bacteria revealed an increase in membrane damage compared to uninfected cells (Fig. 1b,c). The number of PI<sup>+</sup> cells increased over time, indicating that membrane damage was an ongoing event during infection. Less damage was observed when Ca<sup>2+</sup> was present in the extracellular medium, indicating Ca<sup>2+</sup>-dependent repair pathways limit plasma membrane damage.

Caspase 7 promotes membrane repair during *Lm* infection of macrophages<sup>11</sup>. Consistent with this, we found that siRNA-mediated knockdown of Caspase 7 increased membrane damage induced by *Lm* (Extended Data Fig. 1a,b). However, this effect was minor, indicating other factors contribute to membrane repair. Annexins also play a role in membrane repair<sup>14</sup>. We found that siRNA-mediated knockdown of Annexins 1,2 and 6 lead to an increase in membrane damage (Extended Data Fig. 1a,b). We conclude that multiple host factors contribute to repair of the plasma membrane during *Lm* infection.

LLO damages host membranes during infection<sup>10,11</sup>. Consistent with this, a mutant lacking LLO (*hly*) was impaired in membrane damage and complementation with *hly* restored membrane damage (Fig. 1d, Extended Data Fig. 2a). Deletion of both PLCs had no effect on membrane damage in Ca<sup>2+</sup>-free media. However, PLCs were required for membrane damage in Ca<sup>2+</sup>-containing media, suggesting they may promote LLO activity and/or inhibit membrane repair mechanisms. We observed a decrease in membrane damage in cells infected with ActA-deficient (*actA*) bacteria. Treatment of cells with actin inhibitors

latrunculin B or cytochalasin D had a similar effect (Extended Data Fig. 2b). Thus, actin-based motility may promote membrane damage by LLO by allowing close apposition of bacteria to the plasma membrane.

Membrane damage is associated with the loss of membrane asymmetry and redistribution of phosphatidylserine (PS) to the outer leaflet of the plasma membrane<sup>15</sup>. Therefore, to visualize membrane damage induced by *Lm* we stained cells with a probe (Annexin V-Alexa 488) to label exofacial PS. In uninfected cells, low amounts of exofacial PS was detected (Extended Data Fig. 3). In contrast, treatment of cells with saponin led to staining of cells with Annexin V-Alexa 488.

In cells infected by wild type bacteria, we observed the formation of PS<sup>+</sup> structures at the cell surface (Fig. 2a, right panel; Extended Data Fig. 4). These structures colocalized with bacteria (visualized by red fluorescent protein (RFP) expression<sup>16</sup>) and were not associated with cellular blebbing, rounding, or nuclear condensation, indicating they were not the consequence of apoptosis. Extracellular bacteria did not label with Annexin V-Alexa 488 and bacteria present in PS<sup>+</sup> structures were not accessible to anti-*Lm* antibodies (Extended Data Fig. 5). This suggested PS<sup>+</sup> bacteria were present in a host-derived membrane structure. Correlative microscopy revealed that the PS<sup>+</sup> structures were associated with the surface of infected cells (Fig. 2a, left panel). Formation of PS<sup>+</sup> structures required LLO, consistent with a role for membrane damage in their formation (Fig. 2b,c). PS<sup>+</sup> structures were also observed in Henle-407 cells and murine bone marrow-derived macrophages (BMDM)(Extended Data Fig.6).

Several lines of evidence indicated that PS<sup>+</sup> structures are associated with protrusion formation. First, we observed filamentous PS<sup>+</sup> structures connected to bacteria that resembled protrusions (see arrowhead in Fig. 2b, upper panels). Second, *actA* mutants did not form these structures (Fig. 2b,c). Third, we observed that the kinetics of formation of PS<sup>+</sup> structures was similar to the kinetics of protrusion formation (marked by Ezrin<sup>17</sup>, Fig. 3a). Live cell imaging revealed that bacteria-containing protrusions (marked by LifeAct-RFP) rapidly recruited the exofacial PS probe, prior to rounding of the PS<sup>+</sup> protrusion into vesicles on the cell surface (Fig. 3b, Supp. Video 1). Recruitment of the exofacial PS probe was limited to protrusions and vesicles, indicating loss of membrane asymmetry was not the result of global cellular membrane damage. Annexin 2 was localized to PS<sup>+</sup> bacteria (Extended Data Fig. 1c), suggesting membrane repair pathways serve to locally restrict membrane damage.

Streptolysin O, a pore-forming toxin from Group A *Streptococcus*, has been shown to induce membrane blebbing and release of plasma membrane-derived vesicles<sup>18,19</sup>. Our studies indicated that *Lm* similarly induces the release of membrane vesicles through LLO. PS<sup>+</sup> structures containing bacteria were observed on coverslips with no connections to infected cells (Extended Data Fig. 7a). We also isolated these vesicles by centrifugation of the medium (Extended Data Fig. 7b). Our findings suggest bacteria-containing protrusions are released by infected host cells, giving rise to PS<sup>+</sup> vesicles in the medium and, in some cases, these vesicles remain associated with the cell surface of infected cells. Deletion of both PLCs caused an increase in the number of PS<sup>+</sup> structures associated with the surface of

infected cells (Fig. 2b,c). Thus, PLCs may promote bacterial escape from PS<sup>+</sup> structures after their release from infected cells and would be consistent with the role of PLCs in escape from vacuoles in secondarily infected cells<sup>4</sup>.

Efferocytosis receptors mediate uptake of PS<sup>+</sup> cells and cellular debris<sup>1</sup>. In macrophages, TIM-4 plays a key role in efferocytosis<sup>20,21</sup>. Since macrophages are a major target of *Lm* during systemic infection we examined the role of TIM-4 in cell-to-cell spread by these bacteria using an infection focus assay. Foci of infection in BMDM from TIM-4<sup>-/-</sup> mice contained fewer infected cells compared to control BMDM from C57BL/6 mice (Fig. 4a,b). Using live cell imaging we observed that infection foci were smaller in BMDM cultures from TIM-4<sup>-/-</sup> mice from 8-18 h p.i. (Fig. 4c,d). Bacterial replication within primarily infected TIM-4<sup>-/-</sup> BMDM at low cell density (minimizing cell-to-cell spread) was comparable to that of control BMDM (Extended Data Fig. 8). This indicated that deficient bacterial spread in TIM-4<sup>-/-</sup> BMDM cultures was not due to impaired bacterial replication in the cytosol of these cells. Blocking antibodies that targeted either TIM-4 or PS impaired bacterial spread in cultures of control but not TIM-4<sup>-/-</sup> BMDM (Fig. 4b), indicating that TIM-4 promotes bacterial cell-to-cell spread through its ability to bind PS<sup>+</sup> structures.

TIM-4 was previously shown to suppress pro-inflammatory cytokine production *in vivo*<sup>22</sup>. Therefore, we considered the possibility that TIM-4-deficiency impairs cell-to-cell spread by *Lm* indirectly, through enhanced pro-inflammatory cytokine production. However, in our *in vitro* experiments pro-inflammatory cytokine production was typically not observed until 18 h p.i. (after bacterial spread is initiated) and shared the same profile of expression in both control and TIM-4<sup>-/-</sup> BMDM cultures (Extended Data Fig. 9A). This suggested that TIM-4 acts in a cell autonomous manner to promote cell-to-cell spread by *Lm*.

To test this hypothesis, we used a cell-to-cell spread assay that measures the direct transmission of bacteria from primary infected cells to secondary cells (labeled with CellTracker™Blue). Primary cells were infected with a bacterial mutant lacking both PLCs ( *plcA plcB*) since this prevents bacterial escape from spreading vacuoles and avoids the confounding effect of rapid replication in the cytosol of secondary cells. Bacterial spread to secondary BMDM from TIM-4<sup>-/-</sup> mice was reduced compared to control mice (Fig. 4e). Microscopic analysis revealed higher numbers of actin<sup>+</sup> protrusions associated with secondary BMDM from control mice compared to TIM-4<sup>-/-</sup> mice (Fig. 4f,g). This suggests that TIM-4 may promote association/stability of protrusions as they project from infected cells towards/into adjacent cells. Together, our findings indicate a specific role for TIM-4 in mediating cell-to-cell spread by *L. monocytogenes*.

We observed decreased numbers of bacteria in the liver and spleen of TIM-4<sup>-/-</sup> mice compared to control mice (Fig. 4h). Similar numbers of *actA* mutant bacteria were observed in the liver of control and TIM-4<sup>-/-</sup> mice (Fig. 4i), indicating that TIM-4 is required for pathogenesis of motile bacteria in this organ and consistent with its role in promoting bacterial cell-to-cell spread. However, we observed a decrease in survival of *actA* mutant bacteria in spleens of infected TIM-4<sup>-/-</sup> mice. We also observed elevated basal levels of pro-inflammatory cytokines in spleens (and to a lesser extent the livers) of TIM-4<sup>-/-</sup> mice prior to infection (Extended Data Fig. 9b). Together, our findings suggest

that *Lm* exploits TIM-4 during systemic infection of mice by two mechanisms; directly, via uptake of PS<sup>+</sup> bacteria, and indirectly through the ability of TIM-4 to suppress pro-inflammatory cytokine production.

Behar and colleagues demonstrated that TIM-4 mediates clearance of apoptotic macrophages bearing *M. tuberculosis*<sup>23</sup>. Their study indicates an important role for efferocytosis in innate immunity. In contrast, our findings suggest that efferocytosis can be exploited by *Lm* to promote cell-to-cell spread. Other mechanisms also contribute to *Lm* dissemination in a host<sup>24-26</sup>. Viruses are known to exploit efferocytosis by incorporating PS into their viral membrane<sup>27,28</sup>. *Lm* does not incorporate PS into its cellular wall but rather exploits host membrane repair mechanisms to promote release of protrusion-associated membrane, giving rise to a PS<sup>+</sup> ‘cloak’ that can promote efferocytosis (see Model in Extended Data Fig. 10). Similar forms of non-lytic ejection of bacteria from host cells have been described for *M. marinum*<sup>29</sup> and *C. trachomatis*<sup>30</sup>, indicating that these (and likely other) pathogens may also exploit efferocytosis during infection. In summary, our study identifies a novel strategy used by pathogenic bacteria to promote their dissemination in a host and provides a remarkable example of how pathogens can exploit innate immune defenses during infection.

## Methods

### Bacterial strains

*Lm* were grown in brain-heart infusion (BHI) broth and the following strains were used: wild type 10403S<sup>31</sup>, DP-L2161 ( *hly*)<sup>32</sup>, DP-L4818 ( *hly* + *hly*)<sup>33</sup>, DP-L3078 ( *actA*)<sup>34</sup>, and DP-L1936 ( *plcA plcB*)<sup>35</sup>. Wild type *Lm* 10403S expressing TagRFP under the *actA* promoter (DP-L5538)<sup>16</sup> or expressing GFP under the *hly* promoter (DP-L1039) were previously described<sup>36</sup>.

### Antibodies, Constructs, and Reagents

Primary antibodies used were rabbit anti-Annexin A2 (#610068 from BD Biosciences), rabbit anti-GFP (#A11120 from Invitrogen), rabbit anti-Caspase 7 (#12827 from Cell Signaling), rabbit anti-*Listeria* (#B223021 from BD Biosciences), rabbit anti-*Lm* antibody (from Dr. Pascale Cossart, Institut Pasteur, France), mouse anti-phosphatidylserine (#18005 from Abcam) and mouse anti-ezrin (#35-7300 from Invitrogen). Rat anti-TIM4 blocking antibody was previously described<sup>37</sup>. Alexa Fluor 568 Phalloidin, Annexin V-Alexa Fluor-488 and -647 conjugates and all fluorescent secondary antibodies (AlexaFluor conjugates) were from Invitrogen. DAPI (#D1306 from Invitrogen) was used at 1:2500 dilution to stain the nuclei where indicated. Cytochalasin D (#2502555; 10 μM final) and Latrunculin B (#428020; 10 μg/mL final) were from Calbiochem. For transfection of HeLa cells, Xtreme Gene 9 (Roche) transfection reagent was used as per manufacturer’s protocols. LifeAct-mRFP<sup>38</sup> was a gift from Dr. Ray Truant (McMaster University, Canada). The following siRNAs were from Sigma: Annexin A1 (#00157996), Annexin A2 (#00246294), Annexin A6 (#00063383), Caspase 7 (#00128361).

## Cell Culture and Macrophage Generation

HeLa and Henle-407 cells were cultured in Dulbecco modified Eagle medium (Hyclone) supplemented with 10% heat-inactivated FBS (Wisent) without antibiotics at 37°C and 5% CO<sub>2</sub>.

All experimental protocols involving mice were approved by the Animal Care Committee of The Hospital for Sick Children. Mice were euthanized by cervical dislocation. Mouse bone marrow-derived macrophages (BMDMs) were obtained from the dissected femurs and tibias of 5-8 weeks old mice. Cells were washed with growth medium and plated on 70 cm<sup>2</sup> petri dishes. Medium was replaced every 2 days and after 7-9 days cells were used for experiments. Cells were maintained in high glucose RPMI-1640 medium (Wisent) containing 10% heat-inactivated FBS (Wisent), 1% sodium pyruvate (Wisent), 1% non-essential amino acids (Wisent), 0.5% 2-mercaptoethanol (Gibco), 1% penicillin and streptomycin (Invitrogen), and 10% L929 medium. L929-medium was generated by growing a confluent layer of L929 cells in 175 cm<sup>2</sup> flasks in DMEM supplemented with 10% heat-inactivated FBS. When cells reached confluency, growth medium was replaced by DMEM alone. After 7 days, supernatant was collected, centrifuged, filtered, and stored at -20°C.

## Propidium Iodide Assay for Membrane Damage

HeLa cells were plated at  $5 \times 10^4$  cells per well in 24-well tissue culture plates ~18 h prior to infection. For siRNA treatments, the cells were plated at  $2.5 \times 10^4$  cells per well. siRNAs were applied after 18 h and the media was changed 24 h later. Infections were carried out 24 h later. All strains of *Lm* were infected at a multiplicity of infection (MOI) of 100. Bacteria were spun onto cells by centrifugation at 1500 rpm for 5 min. After 60 min of invasion at 37°C, cells were washed three times with phosphate buffered saline (PBS) with Calcium and Magnesium (Wisent #311-420-CL) followed by the addition of growth medium containing 50 µg/ml Gentamicin (Wisent #400-130-IG). At 6 h post infection, cells were washed two times with PBS without Calcium and Magnesium (Wisent #311-010-CL) and replaced with Tyrode's Buffer (10 mM HEPES, 10 mM Glucose, 5 mM Potassium chloride, 140 mM Sodium chloride, 1 mM EGTA, 1 mM Magnesium chloride, 2 mM Calcium chloride, pH 7.4) containing 0.5 mg/mL Propidium iodide (PI, Sigma #P4170). For Tyrode's Buffer lacking Calcium the 2 mM Calcium chloride was replaced with 2 mM Magnesium chloride. Cells were incubated in Tyrode's Buffer with PI for the indicated times and then fixed with 4% PFA (EM Sciences #15710). Samples were mounted on slides using fluorescence mounting medium (Dako). Quantifications were done using a Leica DMIRE2 epifluorescence microscope equipped with a 40x objective.

## Annexin V-Alexa 488 staining of exofacial PS

HeLa cells were plated at  $5 \times 10^4$  cells per well in 24-well tissue culture plates ~18 h prior to infection. All strains of *Lm* were infected at an MOI of 100 in DMEM. Bacteria were spun onto cells by centrifugation at 1500 rpm for 5 minutes. After 60 min of invasion at 37°C, cells were washed three times with phosphate buffered saline (PBS) with Calcium and Magnesium (Wisent #311-420-CL) followed by the addition of growth media containing 50 µg/ml Gentamicin (Wisent #400-130-IG). After indicated times of infection, cells were

cooled on ice and washed twice with chilled PBS with Calcium and Magnesium. Annexin V Alexa Fluor 488 Conjugate (Invitrogen) was diluted to 1% (v/v) in chilled PBS with Calcium and Magnesium and added onto the coverslips for 10 min on ice. Cells were washed twice with chilled PBS with Calcium and Magnesium and fixed with 2.5% PFA (EM Sciences #15710) for 30 min at 37°C. Samples were mounted on slides using fluorescence mounting medium (Dako).

### Immunofluorescence

Immunostaining was conducted as previously described<sup>39</sup>. Briefly, cells were permeabilized and blocked in PBS containing 0.2% saponin (Calbiochem) and 10% normal goat serum (SS-PBS) for 30 min. Subsequently cells were incubated for 1 h with primary antibodies in SS-PBS. Cells were washed three times with PBS and incubated with secondary AlexaFluor conjugated antibodies for 1 h. Cells were washed three times with PBS, mounted in fluorescence mounting medium (Dako), and analyzed using a Leica DMIRE2 epifluorescence microscope. Confocal pictures were taken using a Quorum spinning disk microscope (Leica DMIRE2 inverted fluorescence microscope equipped with a Hamamatsu back-thinned electron multiplying charge-coupled device camera, spinning disc head, and Volocity 4 software (Improvision). Confocal images were imported into Adobe Photoshop and assembled in Adobe Illustrator for labeling.

### Correlative Light-Scanning Electron Microscopy

HeLa cells were plated at  $5 \times 10^5$  cells per well in 6-well tissue culture plates with etched grid coverslips with imprinted numbers (BELLCO Biotechnology) 24 h prior to infection. Cells were infected with wild type *Lm* expressing RFP (DPL5538) at an MOI of 100 in DMEM. Bacteria were spun onto cells by centrifugation at 1500 rpm for 5 min. After 60 min of invasion at 37°C, cells were washed three times with phosphate buffered saline (PBS) with Calcium and Magnesium (Wisent #311-420-CL) followed by the addition of growth media containing 50 µg/ml Gentamicin (Wisent #400-130-IG). At 6 h post infection, cells were cooled on ice and washed twice with chilled PBS with Calcium and Magnesium. Annexin V Alexa Fluor 488 Conjugate (Invitrogen) was diluted to 1% (v/v) in chilled PBS with Calcium and Magnesium and added onto the coverslips for 10 min on ice. Cells were washed twice with chilled PBS with Calcium and Magnesium and fixed with 2.5% PFA (EM Sciences #15710) for 30 min at 37°C. Coverslips were imaged by fluorescence microscopy in PBS with Calcium and Magnesium. Subsequently, samples were fixed in 2% glutaraldehyde in cacodylate buffer, rinsed in buffer and dehydrated in a graded ethanol series. The samples were critical point dried in a Bal-tec CPD030 critical point dryer, mounted on aluminum stubs, gold coated in a Denton Desk II sputter coater and examined in an FEI XL30 SEM.

### Live cell imaging of PS<sup>+</sup> structure formation

HeLa cells were plated at  $2 \times 10^5$  cells per well in 6-well tissue culture plates with glass coverslips 48 h prior to infection. At 24 h prior to infection, cells were transfected with LifeAct-RFP. Cells were then infected with wild type *Lm* expressing GFP (DP-L1039) at an MOI of 100 in DMEM. After 60 min of invasion at 37°C, cells were washed three times

with phosphate buffered saline (PBS) with Calcium and Magnesium (Wisent #311-420-CL) followed by the addition of growth media containing 50 µg/ml Gentamicin (Wisent #400-130-IG). At 6 h post infection, coverslips were washed with PBS with Calcium and Magnesium (Wisent #311-420-CL) and transferred into spaceships and RPMI-1640 (Wisent #350-025-CL) with 10% heat-inactivated FBS (Wisent), 50 µg/ml Gentamicin, 2.5 mM CaCl<sub>2</sub> and 2% (v/v) Annexin V Alexa Fluor 647 Conjugate (Invitrogen). HeLa cells were maintained at 37°C during imaging. A Leica DMIRE2 inverted fluorescence microscope equipped with a Hamamatsu Back-Thinned EM-CCD camera and spinning disk confocal scan head with a 63X objective and LSM 510 software was used. Volocity software (Improvision) was used to acquire images.

## Animals

TIM-4<sup>-/-</sup> mice (on a C57BL/6 background) were previously characterized<sup>22</sup> and bred in house at the Hospital for Sick Children Animal Care Facility. C57BL/6 mice, originally from The Jackson Laboratory (Bar Harbor, ME), were also bred in house and used as controls. All experiments were performed with 7-9 week old female mice that were maintained on a 12-hour light-dark cycle, with food and water available *ad libitum*. Sample size was chosen based on litter size and where possible 5 mice were used per experiment per group and per bacterial strain. Experiments were not blinded and mice were not randomized. All experiments described in this study were carried out in accordance with the Guide for the Humane Use and Care of Laboratory Animals and were approved by the Hospital for Sick Children's Animal Care Committee (Toronto, ON, Canada).

## Infection Focus Assay

After 7–10 days of differentiation, BMDMs were washed twice and detached with ice-cold Versene buffer (0.8 mM EDTA, 1 mM glucose in PBS<sup>-/-</sup>) for 20 min at 4°C. BMDMs were then seeded onto coverslips in 24-well tissue culture plates at  $8.0 \times 10^5$  cells/well to generate a monolayer. After 18 h, the monolayer was infected with wild type *Lm* at an MOI of 0.01 in RPMI-1640. At 30 min p.i., cells were washed three times with PBS and cultured in RPMI-1640 medium containing 10% FBS. At 60 min p.i., cells were washed three times with PBS and RPMI-1640 containing 10% FBS, 10% L929 conditioned medium, and 50 µg ml<sup>-1</sup> gentamycin was added to the cultures. At 18 h p.i., cells were fixed with 2.5% paraformaldehyde for 30 min at 37°C and prepared for fluorescence microscopy. The number of infected cells per foci-of-infection was quantified using epifluorescence microscopy. Images for analysis were taken with a Hamamatsu Orca R2 camera and Nikon Ti-E microscope with 10X objective and Volocity software (Improvision).

## Live cell imaging of *Lm* cell-to-cell spread

BMDMs were plated as a monolayer at  $4 \times 10^6$  cells/well onto coverslips in a 6-well tissue culture plate. After 24 h, the monolayer was infected with *Lm* expressing RFP (DP-L5538) at an MOI of 0.01 for 1 h. Cells were washed three times with PBS and incubated at 37°C in RPMI containing 10% FBS, 10% L-929 conditioned medium and 50 µg/mL gentamycin. At 6 h post infection, the coverslips were imaged in 25 mM Hepes buffered RPMI containing 10% FBS and 50 µg/mL gentamycin using a Quorum spinning disk confocal microscope

(Leica DMIRE2 inverted fluorescence microscope equipped with a Hamamatsu back-thinned electron multiplying charge-coupled device camera, Yokogawa spinning disc head, and Volocity 6 software). Coverslips with BMDM from control and TIM4<sup>-/-</sup> mice were placed side by side on a dual chamber heated stage at 37°C. Over the course of 12 h, 36 μm z-stacks with a 2 μm step were taken every 15 min at ten foci of infection per coverslip. The channels for DIC and red fluorescence were acquired throughout the experiment. Image analysis was performed to measure the number of infected cells per infection foci during the course of the experiment.

### Cell-to-Cell spread assay

BMDM from C57BL/6 mice were seeded at a density of  $1 \times 10^6$  in 10 cm<sup>2</sup> petri dishes 16 h prior to experiments. Cultures of *plcA plcB* mutant bacteria were used to infect BMDM at an MOI of 10. At 60 min p.i., cells were washed three times with PBS and RPMI medium containing 10% FBS and 50 μg/mL gentamycin was added to the cultures. At 3 h p.i., cells were detached using CellStripper (Mediatech) containing 50 μg/mL gentamycin and counted.  $1 \times 10^5$  infected cells were then overlaid onto fresh cultures of CellTracker Blue-labeled BMDM from C57BL/6 or TIM4<sup>-/-</sup> mice. At 90 min post overlay, cells were fixed with 2.5% paraformaldehyde for 30 min at 37°C and prepared for fluorescence microscopy. The uptake of bacteria from infected primary cells (unlabeled) to secondary cells (CellTracker Blue-labelled) was determined by microscopic analysis.

Labeling of secondary host cells with CellTracker Blue (Invitrogen) was performed as follows. Secondary cells were plated onto coverslips in 24-well tissue culture plates  $1.5 \times 10^6$  cells/well. At 2 h prior to overlay, serum-free RPMI medium containing 20 μM CellTracker Blue was added to the culture. After 30 min incubation, cells were washed three times with PBS and RPMI medium containing 10% FBS was added.

### Macrophage Replication Assay

BMDMs were plated at  $3 \times 10^5$  cells per well in 24-well tissue culture plates 24 h prior to infection. Cells were then infected with *Lm* at an MOI of 1 in RPMI-1640. After 30 min of invasion at 37°C, cells were washed three times with phosphate-buffered saline (PBS) followed by the addition of RPMI-1640. At 60 min p.i., media was changed, and RPMI-1640 with 10% FBS containing 50 μg/ml gentamicin and 10% L929 was added. Cells were then lysed at 2, 4, 6, 8, 10, and 12 hr p.i. with 1% Triton X-100 in PBS. Serial dilutions of the lysates were plated on BHI-agar plates and incubated at 37°C for 16 h for subsequent quantification of intracellular CFUs.

### Mouse Infection and Tissue Collection

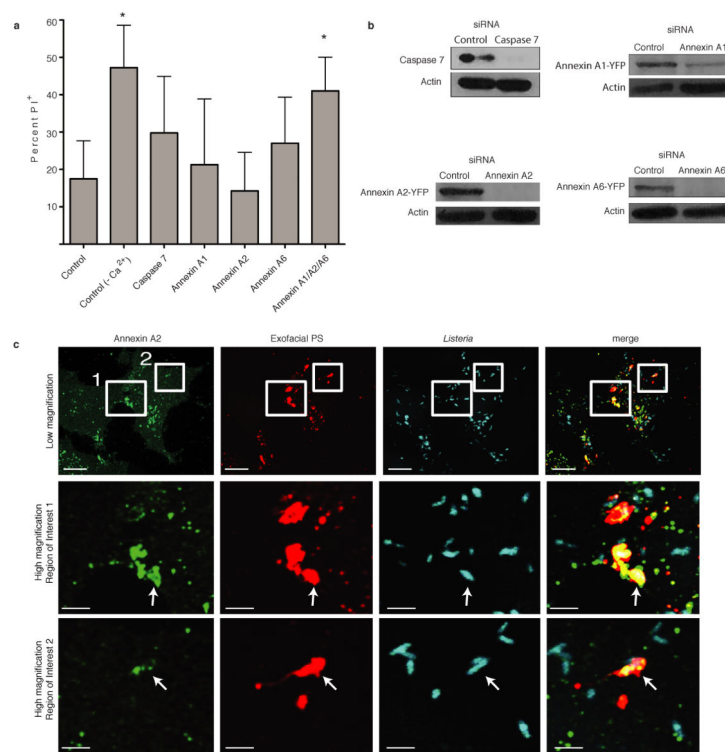

Mice were infected with  $5 \times 10^4$  CFU wild type or  $1 \times 10^7$  CFU *actA* mutant *Lm* (in 200 μl of PBS) via intravenous injection in the lateral tail vein. Liver and spleen were collected at 72 h post infection. Organs were placed in 1 ml of sterile PBS and homogenized. A dilution series was plated on BHI plates, grown overnight at 37°C and individual bacterial colonies were enumerated.

For cytokine analysis, cell culture supernatants and tissue homogenates were centrifuged (12,000 rpm for 12') and supernatants were collected and stored at  $-80^{\circ}\text{C}$ . Cytokines were measured using the mouse 7-plex pro-inflammatory kit from Meso Scale Discovery, according to manufacturer's instructions.

## Statistical Analysis

Statistical analyses were conducted using GraphPad Prism v4.0a. The average  $\pm$  s.d. is shown in figures, and  $p$  values were calculated as described in figure legends. A  $p$  value of less than 0.05 was considered statistically significant and is denoted by \*.  $p < 0.01$  is denoted by \*\* and  $p < 0.001$  by \*\*\*

## Extended Data

### Extended Data Figure 1. Annexins promote membrane repair during *Lm* infection

**A.** HeLa cells were treated with the indicated siRNA for 48 h and then infected with wild type *Lm* at an MOI of 100. At 6 h p.i., medium was switched to Tyrodes buffer containing 0.5 mg/mL propidium iodide (PI) with or without calcium. Cells were fixed at 60 min after PI addition and then stained for bacteria and DNA (DAPI). PI<sup>+</sup> cells were enumerated by microscopic analysis. Averages  $\pm$  s.d. for 3 independent experiments are shown.  $P$  values calculated using one-Way ANOVA. \* $P < 0.05$ . **B.** Knockdown of gene expression by siRNA was confirmed by western blotting. Images representative of 2 independent experiments. **C.** Recruitment of Annexin A2 to PS<sup>+</sup> structures containing bacteria. Boxes in low magnification image indicate areas enlarged in lower panels. Arrows indicate PS<sup>+</sup> structures

that colocalize with Annexin A2. Images representative of 3 independent experiments. Scale bars, 10  $\mu\text{m}$  for low magnification images, 2  $\mu\text{m}$  for enlarged regions of interest.

**Extended Data Figure 2. Actin-based motility promotes LLO-mediated membrane damage during *Lm* infection**

**A.** HeLa cells were infected with the indicated *Lm* strain. At 6 h p.i., medium was switched to Tyrodes buffer containing 0.5 mg/mL propidium iodide (PI) with or without calcium. Cells were fixed at 60 min after PI addition and then stained for bacteria and DNA (DAPI). Confocal images representative of 3 independent experiments are shown. PI<sup>+</sup> cells were enumerated and results are shown in Figure 1D. Where indicated, uninfected cells were treated with Saponin to permeabilize membranes and allow PI entry, serving as a positive control. Scale bars, 10  $\mu\text{m}$ . **B.** HeLa cells were infected with wild type *Lm* and subjected to membrane damage assay as in A in the presence of either DMSO or the actin cytoskeleton inhibitors Latrunculin B or Cytochalasin D. Averages  $\pm$  s.d. for 3 independent experiments are shown. P values were calculated using two-tailed Student's t test. \* $P < 0.05$ .

### Extended Data Figure 3. Annexin V-Alexa 488 as a probe to label PS

Live HeLa cells were cooled on ice and stained with a fluorescent probe (Annexin V-Alexa 488) for 10 min to label exofacial PS. Cells were then fixed and stained with phalloidin Alexa 568 to visualize F-actin. In uninfected control experiments, low amounts of exofacial PS was detected in the membranes of cells, due to asymmetry of PS distribution in the plasma membrane. In contrast, treatment of cells with the pore-forming surfactant saponin led to robust staining of cells with Annexin V-Alexa 488. Images representative of 3 independent experiments. Scale bars, 10  $\mu\text{m}$ .

### Extended Data Figure 4. Formation of PS<sup>+</sup> structures during *Lm* infection

Low magnification images used to generate images shown in Figure 2a. HeLa cells were infected with wild type *Lm* expressing RFP for 6 h and then cooled on ice and stained with a fluorescent probe (Annexin V-Alexa 488) for 10 min to label exofacial PS. Cells were then fixed and analyzed by fluorescence microscopy to identify PS<sup>+</sup> structures and bacteria. Scanning electron microscopy (SEM) of the same cell revealed that PS<sup>+</sup> structures were associated with the dorsal surface of infected cells. Differential interference contrast (DIC) microscopy of cells was also performed to help identify cells for correlative imaging analysis. Images representative of 2 independent experiments. Scale bars, 20  $\mu\text{m}$ .

**Extended Data Figure 5. PS<sup>+</sup> bacteria are present with a host-derived membrane structure**

**A.** HeLa cells were infected with wild type *Lm* expressing RFP for 8 h and then labeled with a probe for exofacial PS (Annexin V-Alexa 488). Cells were then rapidly stained with anti-*Listeria* antibodies (5 min) to label extracellular bacteria. Cells were then fixed and analyzed by fluorescence microscopy to identify PS<sup>+</sup> structures and bacteria. Bacteria that colocalize with exofacial PS but are not labeled with anti-*Listeria* antibodies in the extracellular medium are indicated with arrows. Extracellular bacteria do not label with Annexin V-Alexa 488, indicating this probe does not bind non-specifically to bacteria. Box in low magnification image indicates area enlarged in lower panels. Images representative of 3 independent experiments. Scale bars, 10  $\mu\text{m}$  for low magnification, 2  $\mu\text{m}$  for high magnification. **B.** Cells were infected and stained as in A and analyzed by fluorescence microscopy. Bacteria that colocalize with exofacial PS were scored for their accessibility to anti-*Listeria* antibodies present in the extracellular medium. Data shows that the majority of PS<sup>+</sup> bacteria are not accessible to anti-*Listeria* antibodies. Averages  $\pm$  s.d. for two independent experiments are shown.

**Extended Data Figure 6. Formation of PS<sup>+</sup> structures during *Lm* infection of epithelial cells and macrophages**

**A.** Henle-407 human intestinal epithelial cells were infected with wild type *Lm* for 6 h and then incubated with a probe for exofacial PS (Annexin V-Alexa 488; green). Cells were then fixed and stained with phalloidin to visualize F-actin (red) and for bacteria (blue). Cells were analyzed by fluorescence microscopy to identify PS<sup>+</sup> structures and bacteria. Images representative of 3 independent experiments. **B.** Mouse bone marrow-derived macrophages (BMDM) from C57BL/6 mice were infected and stained as in A. Scale bars, 10 μm. Images representative of 3 independent experiments.

**Extended Data Figure 7. Release of PS<sup>+</sup> structures containing *Lm* from infected cells**

**A.** HeLa cells were infected with wild type *Lm* for 6 h and then incubated with a probe for exofacial PS (Annexin V-Alexa 488; green). Cells were then fixed and stained with phalloidin to visualize F-actin (red) and for bacteria (blue). Cells were analyzed by fluorescence microscopy to identify PS<sup>+</sup> structures and bacteria. Inset shows PS<sup>+</sup> bacteria that are not cell associated. Images representative of 3 independent experiments. **B.** HeLa cells were infected with *plcA plcB* mutant bacteria for 6 h. The supernatant from the infected cultures was then removed and centrifuged onto poly-L-Lysine coated coverslips. Bacteria associated with coverslips were then stained with a probe for exofacial PS (Annexin V-Alexa 488; green). Cells were then fixed and stained for bacteria (blue). Coverslips were analyzed by fluorescence microscopy to identify PS<sup>+</sup> bacteria. Inset shows

PS<sup>+</sup> bacteria. Scale bars, 10  $\mu$ m for low magnification images, 2  $\mu$ m for insets. Images representative of 3 independent experiments.

**Extended Data Figure 8. Growth of *Lm* in the cytosol of TIM-4<sup>-/-</sup> macrophages is not impaired**  
Gentamicin protection assay to measure intracellular bacterial growth. Bone marrow-derived macrophages were harvested from C57BL/6 or TIM-4<sup>-/-</sup> mice and seeded at a density of  $3 \times 10^5$  cells/well. Cells were then infected with wild type *Lm* in the presence of extracellular Gentamicin. At the indicated times, cell lysates were plated and intracellular bacterial numbers (CFU) were determined. Averages  $\pm$  s.d. for two independent experiments are shown.

### Extended Data Figure 9. Cytokine measurements

**A.** Measurement of cytokines following *in vitro* infection of bone marrow-derived macrophages from C57BL/6 or TIM4<sup>-/-</sup> mice with wild type *Lm* for the indicated time. Data from one of two independent experiments is shown. **B.** Measurement of basal cytokines in tissues of C57BL/6 or TIM4<sup>-/-</sup> mice without infection. Averages  $\pm$  s.d. for three independent experiments are shown. P values were calculated using one-Way ANOVA.

### Extended Data Figure 10. *Lm* exploits efferocytosis to promote cell-to-cell spread during infection

Model shows the steps that promote cell-to-cell spread by *L. monocytogenes*. **1.** Protrusion formation via actin-based motility. **2.** LLO-mediated damage to the plasma membrane leads to loss of membrane asymmetry and exofacial phosphatidylserine (PS) on protrusions. The exofacial exposure of PS promotes protrusion association with neighboring cells (right side). **3.** Loss of membrane asymmetry and PS exposure extends along length of protrusions. **4.** Calcium entry activates membrane repair pathways that promote scission of the protrusion. Bacteria are released from the cell in PS<sup>+</sup> vesicles. **5.** Macrophages mediate uptake of PS<sup>+</sup> vesicles containing bacteria via the PS-binding receptor TIM-4. PS<sup>+</sup> vesicles may be engulfed by neighboring cells either near the infected cell surface (left side) or within enclosed spaces that form as a result of protrusion penetration into the neighboring cell (right side). TIM-4 may also promote *Lm* infection indirectly, through its ability to suppress basal levels of pro-inflammatory cytokines as part of its homeostatic function in the immune system.

**Figure 1. Actin-based motility promotes LLO-mediated membrane damage**

**A.** Experimental design for membrane damage assay. **B.** Confocal images of HeLa cells infected as in A with wild type *Lm* at an MOI of 100. Scale bars, 10  $\mu$ m. Images representative of 3 independent experiments. **C.** Cells were infected as in A for the indicated time and PI<sup>+</sup> cells were enumerated. Averages  $\pm$  s.d. for 3 independent experiments. Asterisks indicate significantly different from uninfected cells. P values calculated using two-tailed Student's t test. **D.** Cells were infected with the indicated strain for 60 min. PI<sup>+</sup> cells were enumerated. Averages  $\pm$  s.d. for 3 independent experiments. P values calculated using one-Way ANOVA. \* $P < 0.05$  \*\* $P < 0.01$  \*\*\* $P < 0.001$ .

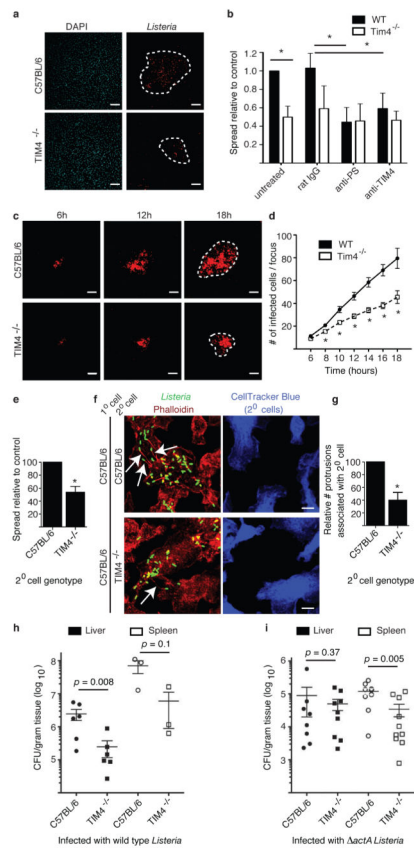

### Figure 2. Formation of PS<sup>+</sup> structures during *Lm* infection

**A.** HeLa cells were infected at an MOI of 100 with wild type *Lm* expressing RFP (red) for 6 h and then incubated with a probe for exofacial PS (Annexin V-Alexa 488; green). Cells were then fixed and analyzed by fluorescence microscopy to identify PS<sup>+</sup> structures and *Lm* (right panel). Scanning electron microscopy of the same cell shows PS<sup>+</sup> structures (left panel). Images representative of 2 independent experiments. Scale bars, 5  $\mu$ m. **B.** Confocal images of cells infected with the indicated strain for 6 h. Boxed areas in left hand low mag image (a 3 color merge, includes phalloidin stain for F-actin) are enlarged to right. Arrows indicate *Lm* that colocalize with PS and arrowhead indicates PS<sup>+</sup> filaments. Images representative of 3 independent experiments. Scale bars, 10  $\mu$ m for low mag merge, and 3  $\mu$ m for enlarged panels. **C.** Cells containing PS<sup>+</sup> bacteria enumerated for B. Averages  $\pm$  s.d. for 3 independent experiments. P values calculated using one-Way ANOVA. \*\* $P < 0.01$  \*\*\* $P < 0.001$ .

**Figure 3. Protrusions give rise to PS<sup>+</sup> vesicles containing *Lm***

**A.** PS<sup>+</sup> bacteria and ezrin<sup>+</sup> protrusions were enumerated in HeLa cells infected at an MOI of 100 with wild type *Lm* for the indicated time. Averages  $\pm$  s.d. for 3 independent experiments. **B.** Cells were transfected with LifeAct-RFP (F-actin probe) and then infected with wild type *Lm* expressing GFP for 6 h. Live infected cells were analyzed by spinning disk confocal microscopy with Annexin V-Alexa 647 in the medium to label exofacial PS (green). Successive frames are shown. Arrows indicates protrusion that acquires PS. Images representative of 4 independent experiments. Scale bar, 10  $\mu$ m.

**Figure 4. TIM-4 promotes *Lm* cell-to-cell spread in macrophages and growth in mice**

**A.** Infection focus assay for measuring cell-to-cell spread. BMDM were infected with *Lm* at an MOI of 0.01. Images representative of 3 independent experiments. Dotted lines delineate infection foci. Scale bars, 100  $\mu$ m. **B.** Infection foci from A were enumerated by fluorescence microscopy. A total of 100 infection foci were analyzed for each genotype/strain. Where indicated, cells were treated with anti-PS, anti-TIM-4 or non-specific rat IgG (control) during infection. Averages  $\pm$  s.d. for 3 independent experiments. P values calculated using two-way ANOVA with Bonferroni post test. **C.** Monolayers of control or TIM-4<sup>-/-</sup> BMDM were infected at an MOI of 0.01 with *Lm* expressing RFP and examined by live cell imaging. Images representative of 2 independent experiments. Dotted lines delineate infection foci. Scale bars, 100  $\mu$ m. **D.** The number of infected cells/focus for C. Averages  $\pm$  s.d. for 2 independent experiments. P values calculated using two-tailed Student's t test. **E.** Cell-to-cell spread assay. Averages  $\pm$  s.d. for 3 independent experiments. P values calculated using two-tailed Student's t test. **F.** Images from E. Arrows indicate actin<sup>+</sup> protrusions associated with secondary cells. Images representative of 4 independent experiments. Scale bars, 10  $\mu$ m. **G.** Actin<sup>+</sup> protrusions associated with secondary cells were enumerated. Averages  $\pm$  s.d. for 4 independent experiments. **H, I.** Mice were infected with  $5 \times 10^4$  CFU wild type (H) or  $1 \times 10^7$  CFU *actA* mutant (I) *Lm* by tail vein injection. Mice were sacrificed and livers and spleen were harvested at 72 h p.i. for quantification of

bacterial load (CFU/gram tissue). Data are expressed as Mean  $\pm$  s.e.m.. P values calculated using one-tailed Mann Whitney test.
