## Abstract

We propose an accelerated CTMC simulation method that is exact in the sense that it produces all of the transitions involved. We call our method *Trajectory Sampling Simulation* as it samples from the distribution of state sequences and the distribution of time given some particular sequence. Sampling from the trajectory space rather than the transition space means that we need to generate fewer random numbers, which is an operation that is typically computationally expensive. Sampling from the time distribution involves approximating the exponential distributions that govern the sojourn times with a geometric distribution. A proper selection for the approximation parameters can ensure that the stochastic process simulated is almost identical to the simulation of the original Markov chain. Our approach does not depend on the properties of the system and it can be used as an alternative to more efficient approaches when those are not applicable.

*Keywords:* Markov chain, simulation, trajectory, random variable

---

## 1 Introduction

*Continuous Time Markov Chains* (CTMCs) have been used for many years for describing systems that exhibit stochastic behaviour. Stochastic simulation is a traditional approach for exploring the transient and steady-state properties of massive CTMCs, since it does not require an explicit representation of the state-space. There are models however, such as bio-chemical reaction networks, whose state-space is too large even for this kind of approach. The standard CTMC simulation approach is known as the *direct method* (DM) [9]. In the case of very large models, it has a high computational cost because it simulates every possible transition happening. Several accelerated methods have been proposed that are either exact or approximate. Exact methods typically involve optimisations over the standard algorithm, such as the *next reaction method* [8], the *optimised DM* [5], the *logarithmic*

DM [17] and *ER-leap* [19]. Most of these approaches involve the use of appropriate data structures in order to generate the simulation events efficiently. For example, the optimised DM makes use of a dependency graph to avoid recalculating rates that remain unchanged.

An approximate simulation method tries to skip some of the simulation events, resulting in a significantly faster process when compared to exact methods. For example,  $\tau$ -*leaping* [10] advances time by a pre-selected  $\tau$ , during which many transitions may occur. Similarly in *R-leaping* [1], stochastic simulation was accelerated by advancing by a predefined number of transition firings. *K-leap* [3] is an approach that also advances time by a specified number of events. All these methods assume that a single transition causes only small changes to the state of the system. Other approaches such as [20] and [4] make use of the notion of time-scale separation. It is assumed that the model can be partitioned to two sub-systems: slow and fast. The behaviour of the fast sub-system is approximated, while only the slow sub-system is simulated. Such assumptions may not always hold for arbitrary models, meaning that either significant error is introduced or the approximate method fails to accelerate the simulation process.

The *Trajectory Sampling Simulation* (TSS) algorithm that we propose is a modification of the DM that can be characterised as almost exact, in the sense that it can be arbitrarily precise. In the case of the DM, each step requires sampling from two distributions: the state distribution and the time distribution, both conditioned on the current state. In a similar way, TSS involves sampling from the distribution of state sequences. This reduces the number of random samples generated, a fact that implies a faster simulation algorithm. The algorithm is still exact, since no transitions are skipped. The same approach is extended to sample from the time distribution given some particular sequence. That is achieved by approximating the exponentially distributed sojourn times with a discrete random variable. Time discretisation allows us to consider the time distribution as a discrete state Markov chain, and therefore employ the TSS technique. This modification essentially renders our approach approximate, as part of the stochastic behaviour of the CTMC is suppressed. However, we have proved that our method in the limit converges to the solution of the original process, a fact that explains the term ‘almost exact’ used earlier in the paragraph. We show that an appropriate selection of the approximation parameters can result in a behaviour very close to the original CTMC, and in a reasonable speedup at the same time. Our implementation is based on the optimised DM (ODM), hence the ODM is used as a baseline for efficiency comparisons.

Our approach is related to *K-skip method I* in [2], or simply *K-skip*. While their strategy for sampling from the state sequence distribution is similar, their approach for sampling from the time distribution is different. In order to reduce the random samples that determine the sojourn times, they approximate the sum of  $k$  exponential random variables with a Gamma distribution, assuming that the exit rates are similar for subsequent states. This assumption is reasonable for many bio-chemical systems, however it may introduce errors for some models as we demonstrate in the experiments’ section, while our approach can be generalised for arbitrary models.

We have implemented K-skip following its description in the original paper, in order to produce some comparative results. The error parameter that we have used for K-skip is 0.01, which is the smallest value used in the original work. We also highlight some computational issues not considered in [2] that arise from the fact that one random number is used to produce an entire trajectory.

In Section 2, we introduce some concepts used throughout the paper. Sections 3 and 4 contain the theoretical details of our work. Some implementation issues are discussed in Section 5. Experimental results are presented in Section 6. Finally, we summarise the conclusions in Section 7.

## 2 Preliminaries

A CTMC can be represented as a triple  $(S, Q, \pi_0)$ , where  $S$  is a finite set of states,  $Q \in \mathbb{R}^{|S| \times |S|}$  is a generator matrix, and  $\pi_0$  is the initial probability distribution over  $S$ . Each  $s \in S$  is associated with an exponentially distributed random variable  $L_s \sim \text{Exp}(\lambda_s)$ , where  $\lambda_s = \sum_{s' \neq s} Q_{ss'}$  is the rate of exiting state  $s$ . The jump chain of a CTMC is discrete-time Markov with probability matrix  $P$  where:

$$P_{ss'} = \begin{cases} Q_{ss'}/Q_s, & s \neq s' \text{ and } Q_s \neq 0 \\ 0, & s \neq s' \text{ and } Q_s = 0 \\ 0, & s = s' \text{ and } Q_s \neq 0 \\ 1, & s = s' \text{ and } Q_s = 0 \end{cases}, \quad \text{where } Q_s = \sum_{s' \neq s} Q_{ss'} \quad (1)$$

A transition in a CTMC is associated with two random variables that depend on the current state  $s$ :  $X_s$  that determines the next state and  $L_s$  that determines the amount of time spent in  $s$ . The DM involves sampling from  $X_s$  and  $L_s$  to generate the next event. The distribution of  $X_s$  is categorical conditional on  $s$ , and its probability mass function is given by the  $s$ -th row of the jump matrix  $P$ . We assume an ordering of states such as  $s < s'$ , if  $s$  corresponds to a row of the transition matrix with a smaller index than  $s'$ . If  $s_{k-1}$  is the state of the system after  $k - 1$  transitions, sampling from  $X_{s_{k-1}}$  involves using a uniform sample  $U \sim \mathcal{U}(0, 1)$  and selecting the next state  $s_k$  with probability:

$$Pr(X_{s_{k-1}} = s_k) = Pr(a_{s_k} < U \leq b_{s_k}) \quad (2)$$

where  $b_{s_k}$  is the cumulative probability of state  $s_k$  given  $s_{k-1}$ , while  $a_{s_k}$  is the cumulative probability of the state that precedes  $s_k$  in the ordering:

$$a_{s_k} = \sum_{s_{k'}' < s_k} P_{s_{k-1}s_{k'}} \quad \text{and} \quad b_{s_k} = \sum_{s_{k'}' \leq s_k} P_{s_{k-1}s_{k'}} \quad (3)$$

In order to sample from  $L_{s_{k-1}}$ , we have to draw a new uniform sample  $U \sim \mathcal{U}(0, 1)$  and calculate the time  $t_{s_{k-1}}$  spent in  $s_{k-1}$  as follows:

$$t_{s_{k-1}} = -\frac{\ln(1 - U)}{\lambda_{s_{k-1}}} \quad (4)$$

From a trajectory point of view, the random variables are different. A CTMC trajectory involves a sequence of states and a sequence of positive numbers that represent the amount of time spent in each state. Let  $\mathcal{S}_k$  be a collection that stands for the family of state sequences of length  $k$ . Therefore, we define  $X_{\mathcal{S}_k}$  as the variable that represents the  $k$ -length sequence distribution. Given some particular sequence of states, namely  $s_{0:k}$ , its duration is represented by the  $L_{s_{0:k}}$  random variable. Ideally, we would like to directly sample from  $X_{\mathcal{S}_k}$  and  $L_{s_{0:k}}$  to determine the state history and the time of the system after  $k$  transitions. Exact stochastic simulation algorithms actually sample from those distributions implicitly by advancing by one state at each event. In the sections that follow, we discuss how we can directly sample from the trajectory-related distributions,  $X_{\mathcal{S}_k}$  and  $L_{s_{0:k}}$ .

### 3 Sampling from the State Sequence Distribution

The sampling from the state sequence distribution discussed in this section can be applied to both discrete and continuous time processes. Without loss of generality, we can assume that there is one initial state in some Markov chain. This will be the root of a tree whose paths represent all the possible state sequences. Each path of a tree with  $k$  levels corresponds to a sequence of  $k + 1$  states or  $k$  transitions. Then, the probability of a path can be defined as the product of the transitions involved:

$$Pr(X_{\mathcal{S}_k} = s_{0:k}) = \prod_{n=1}^k P_{s_{n-1}s_n} \quad (5)$$

In fact,  $X_{\mathcal{S}_k}$  follows a categorical distribution with  $|\mathcal{S}_k|$  parameters. Sampling from the sequence distribution requires us to compute its cumulative distribution function, which means that we have to define an ordering of the possible sequences.

**Definition 3.1** [Lexicographical Ordering of Sequences] Given an ordering of states, we define an ordering of sequences such as  $s_{0:k} < s_{0:k}'$  if one of the following holds:

- i.  $s_{0:k-1} < s_{0:k-1}'$  or
- ii.  $s_{0:k-1} = s_{0:k-1}'$  and  $s_k < s_k'$

Therefore, we can calculate the cumulative probabilities for the sequences. Given a uniform random variable  $U \sim \mathcal{U}(0, 1)$ , we can choose directly a sample from the sequence space. The relationship between  $U$  and  $X_{\mathcal{S}_k}$  is shown in the following equation:

$$Pr(X_{\mathcal{S}_k} = s_{0:k}) = Pr(a_{s_{0:k}} < U \leq b_{s_{0:k}}) \quad (6)$$

The term  $b_{s_{0:k}}$  is defined as the cumulative probability of the  $s_{0:k}$  sequence. In the same way,  $a_{s_{0:k}}$  will be the cumulative probability of the sequence that precedes  $s_{0:k}$

according to the ordering. More formally:

$$\begin{aligned}
 a_{s_{0:k}} &= \sum_{s_{0:k'} < s_{0:k}} Pr(s_{0:k'}) \\
 b_{s_{0:k}} &= \sum_{s_{0:k'} \leq s_{0:k}} Pr(s_{0:k'}) = a_{s_{0:k}} + Pr(s_{0:k})
 \end{aligned}
 \tag{7}$$

Although sampling from the sequence distribution is well-defined, it cannot be practically applied in its current form. The number of possible sequences grows exponentially as  $k$  increases, a fact that renders Equations (5) and (7) computationally expensive. What we can do instead, is to draw a sample from  $U \sim \mathcal{U}(0, 1)$  that determines the sequence, and recursively generate the transitions involved. A recursive definition for the cumulative sequence probabilities would be useful for this task. Using Definition 3.1, the cumulative probability of the sequence that precedes  $s_{0:k}$  can also be written recursively as follows:

$$a_{s_{0:k}} = Pr(s_{0:k-1}) \sum_{s_{k'} < s_k} P_{s_{k-1}s_{k'}} + a_{s_{0:k-1}}
 \tag{8}$$

Since the uniformly distributed sample  $U$  determines the entire  $k$ -length sequence, it follows that it also determines all of the  $k$  transitions involved. In the DM however, the sequence of the transitions would have been determined by a sequence of uniform samples  $U_n \sim \mathcal{U}(0, 1)$ , with  $0 \leq n \leq k$ . Thus, the sequence  $U_n$  is equivalent to the sample  $U$  for the state sequence. We shall next try to define the last sample  $U_k$  in terms of  $U$ , which gives rise to the following theorem:

**Theorem 3.2** *If  $U \sim \mathcal{U}(0, 1)$  is used to draw a state sequence sample  $s_{0:k}$ , then  $s_k$  is determined by:*

$$U_k = \frac{U - a_{s_{0:k-1}}}{b_{s_{0:k-1}} - a_{s_{0:k-1}}}
 \tag{9}$$

**Proof.** We have to show that  $a_{s_k} < U_k \leq b_{s_k}$ , which means that  $U_k$  will select the state  $s_k$ , according to Equation (2). Since  $s_{0:k}$  was selected, Equation (6) implies:

$$\begin{aligned}
 a_{s_{0:k}} < U \leq b_{s_{0:k}} &\Leftrightarrow \\
 U > Pr(s_{0:k-1}) \sum_{s_{k'} < s_k} P_{s_{k-1}s_{k'}} + a_{s_{0:k-1}} \\
 \text{and } U \leq Pr(s_{0:k-1}) \sum_{s_{k'} < s_k} P_{s_{k-1}s_{k'}} + a_{s_{0:k-1}} + Pr(s_{0:k})
 \end{aligned}$$

We subtract  $a_{s_{0:k-1}}$  from all terms, and divide everything by  $Pr(s_{0:k-1})$ :

$$\begin{aligned}
 Pr(s_{0:k-1}) \sum_{s_{k'} < s_k} P_{s_{k-1}s_{k'}} < U - a_{s_{0:k-1}} \leq Pr(s_{0:k-1}) \sum_{s_{k'} < s_k} P_{s_{k-1}s_{k'}} + Pr(s_{0:k}) \\
 \sum_{s_{k'} < s_k} P_{s_{k-1}s_{k'}} < \frac{U - a_{s_{0:k-1}}}{Pr(s_{0:k-1})} \leq \sum_{s_{k'} < s_k} P_{s_{k-1}s_{k'}} + \frac{Pr(s_{0:k})}{Pr(s_{0:k-1})}
 \end{aligned}$$

We substitute  $\frac{Pr(s_{0:k})}{Pr(s_{0:k-1})}$  with  $P_{s_{k-1}s_k}$  and  $Pr(s_{0:k-1})$  with  $b_{s_{0:k-1}} - a_{s_{0:k-1}}$ :

$$\begin{aligned} \sum_{s_{k'} < s_k} P_{s_{k-1}s_{k'}} &< \frac{U - a_{s_{0:k-1}}}{b_{s_{0:k-1}} - a_{s_{0:k-1}}} \leq \sum_{s_{k'} < s_k} P_{s_{k-1}s_{k'}} + P_{s_{k-1}s_k} \\ \sum_{s_{k'} \leq s_k} P_{s_{k-1}s_{k'}} &< \frac{U - a_{s_{0:k-1}}}{b_{s_{0:k-1}} - a_{s_{0:k-1}}} \leq \sum_{s_{k'} \leq s_k} P_{s_{k-1}s_{k'}} \end{aligned}$$

which eventually yields:

$$a_{s_k} < U_k \leq b_{s_k}$$

□

Theorem 3.2 can be used to calculate any of the  $U_n$  samples that determine the transitions by simply considering  $k = n$ , with  $n > 1$ . For the special case where  $k = 1$ , the sequence probabilities will be equal to the transition probabilities of the first step. We could then calculate the uniform sample  $U_{k+1}$  needed for the next step and recursively update  $a_{s_{0:k+1}}$  and  $b_{s_{0:k+1}}$  to get the new cumulative sequence probabilities using Equation (8). This strategy might not be optimal though, as it requires keeping track of two cumulative probabilities. A cleaner and more efficient solution would be to write  $U_k$  in terms of the previous uniform sample  $U_{k-1}$ .

**Theorem 3.3** *If  $U_{k-1} \sim \mathcal{U}(0, 1)$  is used to draw a state sample  $s_{k-1}$ , then  $s_k$  is determined by*

$$U_k = \frac{U_{k-1} - a_{s_{k-1}}}{b_{s_{k-1}} - a_{s_{k-1}}} \tag{10}$$

**Proof.** Given a uniform sample  $U$  that determines the sequence, the samples  $U_k$  and  $U_{k-1}$  can be written as specified in (9). If we solve w.r.t.  $U$  in both cases, we obtain the following equality:

$$U_k Pr(s_{0:k-1}) + a_{s_{0:k-1}} = U_{k-1} Pr(s_{0:k-2}) + a_{s_{0:k-2}}$$

which yields:

$$U_k = \frac{U_{k-1} Pr(s_{0:k-2})}{Pr(s_{0:k-1})} - \frac{a_{s_{0:k-1}} - a_{s_{0:k-2}}}{Pr(s_{0:k-1})} \tag{11}$$

Using (8), the numerator of the second fraction above can be written as:

$$a_{s_{0:k-1}} - a_{s_{0:k-2}} = Pr(s_{0:k-2})a_{s_{k-1}} + a_{s_{0:k-2}} - Pr(s_{0:k-3})a_{s_{k-2}} - a_{s_{0:k-3}}$$

We also know that  $a_{s_{0:k-2}} = Pr(s_{0:k-3})a_{s_{k-2}} + a_{s_{0:k-3}}$  because of (8), so we can rewrite (11) as:

$$U_k = \frac{U_{k-1} Pr(s_{0:k-2})}{Pr(s_{0:k-1})} - \frac{a_{s_{k-1}} Pr(s_{0:k-2})}{Pr(s_{0:k-1})}$$

According to the definition of sequence probabilities in (5), we have  $Pr(s_{0:k-1}) = Pr(s_{0:k-2})P_{s_{k-2}s_{k-1}}$ , which implies:

$$U_k = \frac{U_{k-1} - a_{s_{k-1}}}{P_{s_{k-2}s_{k-1}}}$$

Finally, we can write  $P_{s_{k-2}s_{k-1}}$  as a difference of cumulative probabilities to obtain Equation (10). □

Starting from some initial transition, we can recursively generate an entire sequence of random samples that are uniformly distributed between 0 and 1. If the previous step utilised a sample  $U_{k-1} \sim \mathcal{U}(0, 1)$ , we know that  $a_{k-1} < U_{k-1} \leq b_{k-1}$ . If we define  $U_k$  according to (10), it is easy to show that  $0 < U_k \leq 1$ , which means that  $U_k \sim \mathcal{U}(0, 1)$ . Although this sequence is produced deterministically, we have shown that it corresponds to the uniform sample needed to sample from the sequence distribution.

Thus, assuming that the quantities  $a_{s_{k-1}}$  and  $b_{s_{k-1}} - a_{s_{k-1}}$  have to be calculated anyway, generating a sample at each step requires a subtraction followed by a division, as Equation (10) implies. This procedure is more efficient than most of the random generator algorithms, in particular the ones that produce high quality random numbers.

## 4 Sampling from the Time Distribution

### 4.1 Time Discretisation

If we select some particular sequence  $s_{0:k}$ , the duration of the total of the transitions involved is represented by a  $L_{s_{0:k}}$  random variable. In the case of CTMCs this will be the sum of  $k$  exponentially distributed independent random variables that determine the duration of each transition, or more formally:

$$L_{s_{0:k}} = \sum_{i=0}^k L_{s_i} \tag{12}$$

where  $L_{s_i} \sim Exp(\lambda_{s_i})$ . Therefore,  $L_{s_{0:k}}$  will follow hypo-exponential distribution with  $k$  parameters, or equivalently  $L_{s_{0:k}} \sim Hypo(\lambda_{s_0}, \dots, \lambda_{s_k})$ . To sample directly from  $L_{s_{0:k}}$  is only feasible for special cases such as the Erlang distribution, which is a hypo-exponential with  $k$  similar parameters. It is possible to transform  $L_{s_{0:k}}$  to an Erlang distributed variable by applying uniformisation [13]. This approach is problematic though, as the probability matrix of the embedded DTMC will contain self-loops, in contrast to the original jump chain as defined in (1). This means that the uniformised CTMC will involve a larger number of events, a fact that could actually slow the simulation down.

Our attempt of sampling from the hypo-exponential  $L_{s_{0:k}}$  efficiently will focus on approximating the exponentially distributed sojourn times with a discrete random variable. The use of a discrete distribution implies that we divide time into

intervals, since it involves discrete time-steps rather than continuous. Thus, while a continuous distribution indicates the probability of a transition happening up to a time  $t$ , a discrete one indicates the transition probability up to the  $n$ -th interval.

The geometric distribution seems to be a reasonable choice for the task, since it is the discrete analogue of the exponential. Given some exponential random variable  $L \sim \text{Exp}(\lambda)$ , this can be approximated by a geometrically distributed  $Y \sim G(p)$  that denotes the number of Bernoulli trials needed to fire a transition with probability  $p$ . The geometric distribution is supported in  $\mathbb{N}$  excluding zero. Given the length of intervals  $l$ , we can map a geometric random variable to  $\mathbb{R}^+$  by considering that it is supported in  $\{1l, 2l, \dots\}$ . Since  $Y$  is geometric, its expected value will be  $1/p$  intervals, or  $l/p$  in terms of time units. If we make  $L$  and  $Y$  correspond to the same expected value, that is  $1/\lambda = l/p$ , it is easy to show that the interval length will be:

$$l = \frac{p}{\lambda} \tag{13}$$

Therefore, to determine the amount of time spent in state  $s_k$  will involve two steps:

- (i) Sample from  $Y_{s_k} \sim G(p)$ . Using a uniform sample  $U \sim \mathcal{U}(0, 1)$ , we choose a  $n \in \mathbb{N}^*$  with probability:

$$\text{Pr}(Y_{s_k} = n) = \text{Pr}(a_{Y_{s_k}} < U \leq b_{Y_{s_k}}) \tag{14}$$

where  $b_{Y_{s_k}} = \text{Pr}(Y_{s_k} \leq n)$  and  $a_{Y_{s_k}} = \text{Pr}(Y_{s_k} \leq n - 1)$ .

- (ii) Calculate the time spent in state  $s_k$ :

$$t_{s_k} = n l_{s_k} = n \frac{p}{\lambda_{s_k}} \tag{15}$$

The advantage of time discretisation is that we can use the sequence sampling technique presented in Section 3, and therefore reduce the random samples generated. To illustrate how this is possible, let us consider the stochastic process  $\{Y_{s_k}\}_t$  that denotes the collection of geometrically distributed random variables used to approximate the sojourn times in some CTMC. If we set the same parameter  $p$  for these random variables, then they will be independent and identically distributed. We can easily verify that  $\{Y_{s_k}\}_t$  is essentially a Markov process, which means that it is possible to generate an entire state sequence using a single uniform sample, as demonstrated in the previous section. The time discretisation was necessary, otherwise it would not be possible to define the discrete state Markov chain  $\{Y_{s_k}\}_t$ , and therefore employ the trajectory sampling technique.

One desirable property of our approach is that it gives an estimation for the duration of all of the transitions involved in a trajectory. On the contrary, the Gamma sampling used in K-skip only produces the total duration of  $k$  transitions. While both approaches use a single random number to determine the duration of trajectories, K-skip is expected to be superior from a performance point of view. However, our method produces trajectories that are as detailed as the ones of the original Markov chain.

One other strength of our approach is that its applicability does not rely on particular model properties. The Gamma sampling used in K-skip assumes that exit rates do not change much during the  $k$  steps. This assumption, which is similar to the leap condition in  $\tau$ -leaping methods, may not hold for some models meaning that it could be an extra source of error. Our method is not exact however, due to the time discretisation employed. The quality of this approximation is discussed in the rest of this section.

#### 4.2 Quality of Approximation

Since the interval length  $l$  is dependent on the parameter  $p$  of the Geometric distribution, it is rather intuitive that smaller values for  $p$  result in better approximation, as  $l$  also tends to get smaller. We are going to characterise the quality of this approximation in a rigorous manner.

**Theorem 4.1** *Let us consider some stochastic process that approximates some CTMC featuring the same state-space  $S$ , the same transition probability matrix  $P$ , and the same initial distribution  $\pi_0$ . The approximate process is only different in the sense that the sojourn times are determined by  $Y_{s_k} \sim G(p)$ , as described in (14) and (15). Then, the approximate process converges to the corresponding CTMC, as  $p \rightarrow 0$ .*

**Proof.** Let us define  $P(t)$  as the transition probability matrix of a CTMC at time  $t$ . Given an initial state distribution vector  $\pi_0$ , the distribution vector of the CTMC at time  $t$  will be:

$$\pi_t = \pi_0 P(t) \tag{16}$$

$P(t)$  can be calculated as a weighted sum of different powers of the probability matrix  $P$  of the underlying jump chain. The state distribution at  $t$  can then be rewritten as follows:

$$\pi_t = \pi_0 \sum_{k=0}^{\infty} P^k \times Pr(k \text{ steps until } t) \tag{17}$$

The modified stochastic process that resulted from this geometric approximation will have the same underlying jump chain as the original CTMC. The only term in (17) that is different in those two kinds of processes is the probability of  $k$  transitions happening until time  $t$ . This probability can be expressed as a sum of the probabilities of all sequences with duration less than or equal to  $t$ , weighted by the sequence probabilities:

$$Pr(k \text{ steps until } t) = \sum_{s_{0:k} \in \mathcal{S}_k} Pr(L_{s_{0:k}} \leq t) Pr(s_{0:k}) \tag{18}$$

In order to show that the behaviour of some CTMC as given in (17) is well approximated, it is sufficient (although not necessary) to show that the probability of  $k$  transitions until  $t$  is approximately the same for the two kinds of processes.

The modified process will have same sequence probabilities as its corresponding CTMC, since the jump process is the same. Thus, two corresponding processes are only different w.r.t the distribution of  $L_{s_0:k}$ . Therefore, it is sufficient (although not necessary again) to show that the cumulative distribution functions for the sojourn times are approximately the same:

$$\begin{aligned} Pr(L_{s_k} \leq t) \approx Pr(Y_{s_k} \leq n) &\Leftrightarrow 1 - e^{-\lambda t} \approx 1 - (1 - p)^n \\ &\Leftrightarrow e^{-\lambda t} \approx (1 - p)^n \end{aligned}$$

We can now plug in the equation the interval length  $l$  to our convenience:

$$e^{-\lambda t} \approx (1 - p)^{nl/l}$$

Since we are only interested for  $t$  such that  $t = nl$ , we can discard  $t$  and  $nl$ :

$$e^{-\lambda} \approx (1 - p)^{1/l}$$

We can also substitute the  $l$  on the exponent according to (13).

$$e^{-\lambda} \approx (1 - p)^{\lambda/p}$$

Finally, we can also discard  $\lambda$  in both sides to obtain:

$$1/e \approx (1 - p)^{1/p} \tag{19}$$

The last equation is valid for values of  $p$  close to zero, as it can be easily shown by the limit:

$$\lim_{p \rightarrow 0} (1 - p)^{1/p} = 1/e \tag{20}$$

□

The  $p$  parameter is a probability, so we have  $0 < p \leq 1$ . Equations (19) and (20) imply that smaller values of  $p$  result in much better approximation. However, a value for  $p$  that is too small can make the geometric sampling described by (14) inefficient, as the cumulative probabilities of the form  $Pr(Y_{s_k} \leq n)$  will involve too many terms. Hence, we need a trade-off between approximation quality and efficiency. In the experiments that follow, we use two different values:  $p = 1$  that implies deterministic time-steps that depend on the current state only, and  $p = 0.1$  which we think that it is a more appropriate choice, judging by the experimental results of Section 6.

## 5 Implementation Issues

Although sampling from the sequence distribution as discussed in Section 3 is theoretically correct, it gives rise to some computational issues. In most computer systems, the mantissa for the double-precision floating-point format contains 53 bits. That is why most random generators produce doubles of the form:  $m \times 2^{-53}$ ,

where  $m$  is a uniformly distributed integer. In other words, a random generator is capable of producing  $2^{53}$  different values. The TSS algorithm will have  $2^{53}$  different inputs resulting in  $2^{53}$  different trajectories at most. The number of the possible trajectories can easily exceed this value even for not so long simulation runs, since it grows exponentially with the number of simulation events. Therefore, it is inevitable that we will miss a significant number of possible state sequences.

This effect can be eliminated if we sample trajectories of some particular length  $k$ , such that the number of possible sequences are significantly smaller than the number of uniformly distributed doubles. A value  $k = 10$  is a reasonable choice that suits most of the models that we have encountered in practice. Given 53-bits of precision for the mantissa, we have  $2^{53} \approx 9 \times 10^{15}$  different possible random numbers. The largest model that we have tested is LacY [14] involving 21 biochemical reactions, which means that the maximum number of transitions available is also 21. If we set  $k = 10$ , we have  $21^k \approx 1.66 \times 10^{13} \ll 2^{53}$ .

Each step in TSS consists of two actions: state sequence sampling as described in Section 3, and time sampling using geometric approximation. These concepts are summarised in Algorithm 1, which involves two parameters:  $p$  that controls the granularity of the geometric distribution and the length  $k$  of the trajectories to sample. In our implementation the probabilities of the geometric distribution have been pre-calculated for efficiency.

### Algorithm 1 Trajectory Sampling Simulation

---

```

1: Initialise system state and set  $0 < p \leq 1$  and  $k \geq 1$ 
2: Draw samples  $U_L \sim \mathcal{U}(0, 1)$  and  $U_X \sim \mathcal{U}(0, 1)$ 
3: while  $t < t_{final}$  do
4:   Given  $M$  transitions, calculate the transition rates  $\lambda_m, \forall m \in \{1, 2, \dots, M\}$ 
5:   Calculate  $\lambda = \sum_{m=1}^M \lambda_m$ , which is the rate of leaving the current state
6:   Using sample  $U_L$ , draw  $n$  from the geometric distribution  $G(p)$ 
7:   Using sample  $U_X$ , pick transition  $m$  with probability  $\lambda_m/\lambda$ 
8:   Update time:  $t = t + np/\lambda$ 
9:   Update state with effect of transition  $m$ 
10:  if iteration mod  $k \neq 0$  then
11:    Update  $U_L$  and  $U_X$  according to Equation (10)
12:  else
13:    Draw samples  $U_L \sim \mathcal{U}(0, 1)$  and  $U_X \sim \mathcal{U}(0, 1)$ 
14:  end if
15: end while

```

## 6 Experiments

The efficiency of our algorithm stems from the fact that it generates fewer random numbers. One of the most popular random generators in the literature is *Mersenne Twister* (MT) [18]. It produces high quality random numbers while it exhibits performance comparable to the most efficient algorithms of its kind, as can be seen in [15]. We have developed our algorithm in Java using a number of open-source libraries that contain implementations of MT, namely Apache Commons, CERN Colt, JAMES II [12] and SSJ [16]. The implementations used produce doubles whose mantissa precision is 53 bits.

We have applied our approach to simulate two different models of bio-chemical reaction networks. The first model is LacY, which involves 21 reactions and 22

species, as appeared in [14]. The second example is Goldbeter’s oscillatory model [11] as presented in [7], which involves 7 reactions and 6 species. Both models have been simulated using the ODM, K-skip, and TSS. The implementation of both K-skip and TSS is based on the ODM, hence any efficiency comparisons have ODM as a baseline.

Two different parameters were used for the geometric approximation:  $p = 1$  and  $p = 0.1$ . Table 1 contains the running times for different random generators. The experiments have been performed in an Intel® Xeon™ E5410 @ 2.33GHz PC running Scientific Linux 6. The results imply that TSS is about 15 ~ 20% faster than the ODM. A second observation is that using  $p = 1$  is not significantly faster than TSS using  $p = 0.1$  for the geometric distribution. This means that there is no need to use a value for  $p$  greater than 0.1, as this would not result in a significant improvement in efficiency.

Comparing running times for K-skip and TSS, we see that K-skip is clearly the most efficient of the two. This is because it determines the total duration of  $k$  events by sampling from a Gamma distribution, while we determine the duration of every single event happening. We note that the speedups observed for K-skip are smaller than the values reported in [2]. This is due to the MT random number generator, which is more efficient than the ran2 algorithm used in Cai & Wen paper, as pointed out in [15]. Because we are using a more efficient random generator there is less scope to deliver speedups over the ODM. If we consider this difference, the results we have found for K-skip seem to comply with the ones reported in the original work.

Table 1  
Execution times in seconds for  $10^5$  simulation runs

(a) LacY model,  $t_{final} = 1000$

	ODM	K-skip	TSS	
			$p = 1$	$p = 0.1$
Apache Commons	8759	5588	6930	6951
CERN Colt	9043	5568	6974	6915
JAMES II	9684	5490	7043	6944
SSJ	10452	5562	7248	7322

(b) Goldbeter’s model,  $t_{final} = 10$

	ODM	K-skip	TSS	
			$p = 1$	$p = 0.1$
Apache Commons	12264	9354	10678	10615
CERN Colt	12685	9514	10662	10658
JAMES II	13531	9857	10598	10596
SSJ	14636	9269	10719	10734

A second issue that has to be explored is whether the stochastic process described by Algorithm 1 is equivalent to the original Markov chain. The convergence is ensured as  $p \rightarrow 0$  when  $k = 1$ . The simulation will be still exact even if  $k > 1$  as implied by Theorems 3.2 and 3.3. However, the use of the geometric approximation means that we have a slightly altered process that approximates the original. To assess the quality of this approximation we construct the histograms for various rewards (i.e. species populations) in the models used, as it would have been im-

practical to compare the entire state-space distribution for models of that size. We then calculate the *histogram distance* [6], which is the euclidean distance between the histograms of the true and the approximate distribution.

It is important to note that the histogram distance will always be larger than zero, even if the simulation is exact, since the empirical distributions which result from simulation are always going to be different. In order to determine whether the distance calculated is significant, it has to be compared with the corresponding self-distance. The histogram self-distance depends on the number of samples drawn and the number of histogram intervals used. A value for the histogram distance that is smaller than the self-distance implies that the two distributions are practically identical for the given number of samples. According to [6], an upper bound for the average histogram self-distance given  $N$  samples is independent from the distribution and it can be calculated using  $\sqrt{(4K)/(\pi N)}$ , where  $K$  is the number of intervals in the histogram. For the examples that follow, we have considered  $K = 50$ .

Table 2 summarises the histogram distances for several species populations and time-points in the models considered. For TSS with  $p = 1$ , some of the distances are slightly larger than the self-distance (the values written in italics). This implies that we have a reasonably good approximation but the error introduced by using fixed times is observable for the number of samples considered. However, the approximation quality is better when using TSS with  $p = 0.1$ , as it was expected. The histogram distance from the true distribution is at the same level or smaller than the self-distance estimated almost in all cases. This means that the error observed is within the limits of the error inherently introduced by the simulation process. Those findings support the claim that TSS with parameter  $p = 0.1$  for the geometric approximation is an accelerated simulation approach that is almost exact.

While K-skip proved to be more efficient than our approach for the LacY and Goldbeter models, Table 2 suggests that it is not as accurate in some cases. Most of the histogram distances for the LacY model are greater than either the self-distance or the corresponding distances calculated for both versions of TSS. It seems that the assumption that the rates of subsequent states are similar might introduce some errors, a fact that renders K-skip less appropriate for some models. Our approach generalises to systems where this assumption is not valid. Moreover, our use of the geometric approximation specifies the duration of every single event happening, which can be important for some systems.

## 7 Conclusions

Trajectory sampling simulation requires fewer random samples to generate Markov chain trajectories. This is achieved by using a single random number to determine an entire sequence of transitions. We have proved that the random number required to select the next transition can be written in terms of the random number that selected the previous transition. This leads to a recursive update of a single random number

Table 2  
Histogram distances for  $10^6$  simulation runs (self-distance: 0.0080)

(a) LacY model

Time	K-skip			TSS ( $p = 1$ )			TSS ( $p = 0.1$ )		
	lactose	PLac	product	lactose	PLac	product	lactose	PLac	product
250	0.0070	<i>0.0090</i>	0.0064	0.0062	0.0005	0.0071	0.0045	0.0011	0.0054
500	0.0040	0.0074	<i>0.0087</i>	0.0042	0.0011	<i>0.0083</i>	0.0030	0.0004	0.0071
750	0.0041	0.0077	0.0074	0.0034	0.0004	<i>0.0086</i>	0.0050	0.0001	0.0076

(b) Goldbeter's model

Time	K-skip			TSS ( $p = 1$ )			TSS ( $p = 0.1$ )		
	active_M	active_X	C	active_M	active_X	C	active_M	active_X	C
2.5	0.0065	0.0068	0.0074	0.0071	0.0039	0.0039	0.0048	0.0040	0.0036
5.0	0.0067	0.0059	0.0055	0.0067	0.0066	0.0054	0.0066	0.0053	0.0052
7.5	0.0070	<i>0.0088</i>	0.0037	0.0068	<i>0.0082</i>	0.0054	0.0080	0.0079	0.0060
10.0	0.0071	0.0063	0.0067	0.0055	0.0048	<i>0.0081</i>	0.0041	0.0061	0.0062

that determines an entire state sequence. In the case of CTMCs a second random number is used to determine the length of this sequence. The same concept has been used by approximating the exponentially distributed times with a geometric distribution with parameter  $p$  that controls the quality of this approximation.

We have simulated two bio-chemical models of different nature to assess the efficiency and the accuracy of the our method. The experimental results show that our approach is about 15 ~ 20% faster than the ODM, while the errors observed were found to be negligible. K-skip method I, which is a similar approach, was found to be more efficient but in some cases less accurate. Thus, TSS can be thought of as an alternative to K-skip in cases where this is possibly inappropriate.

There are also some practical considerations with respect to the length  $k$  for the trajectories to be sampled. A too large value for  $k$  might result in missing possible state sequences, while a value too small will degenerate trajectory sampling simulation to the ODM. We have used  $k = 10$  for the experiments produced, but in the case of larger models we would have to set a smaller value for  $k$ . We think that  $k = 5$  is appropriate even for very large models. For example, given a model with 500 reactions we have:  $500^k \approx 3.125 \times 10^{13} \ll 2^{53}$ .
