Review

Introduction

Shoulder pain is a highly prevalent complaint and disorders of the rotator cuff are thought to be the most common cause [1]. Typically such disorders would initially be treated using conservative means, including physiotherapy, but if non-responsive then surgery may be considered [2]. There is evidence to suggest that the incidence of surgery to repair the rotator cuff is rising [3].

Surgical techniques to repair the rotator cuff have progressed over time. With the development of arthroscopic techniques, cuff repair has become less invasive, raising the possibility of more rapid patient recovery. Evolution of suture anchors and suture configurations have also resulted in more secure repairs [4]. Additionally, there has been a plethora of research relating to the effectiveness of surgical repair [5]. Despite all this, our understanding of the optimal approach to post-operative rehabilitation, a critical component of the recovery process, is not well developed [4]. Rehabilitation programmes have remained largely similar to those initially developed when surgical techniques were less robust [4]. Uncertainty currently appears to exist around two related parameters; 1) the period of post-surgical immobilisation; 2) the amount of early load permitted at the repair site [2]. In the context of this uncertainty a generally cautious approach to post-surgical rehabilitation seems to prevail including long periods of immobilisation and avoidance of active rehabilitation, largely due to apparent fear of contributing to failure or re-tear of the repair site. This is despite good clinical outcomes reported in the presence of re-tear [6,7], which for some raises questions about the mechanism of action of the surgery. In fact, excessive immobilisation not only has the potential to cause stiffness and delayed functional recovery, but might actually be detrimental to tendon healing. Improved clinical outcomes have been reported in other areas with early mobilisation [8].

Hence, the aim of this systematic review is to evaluate the effectiveness of rotator cuff repair rehabilitation programmes with a view to informing current clinical practice and also to develop a platform upon which future useful research might be conducted.

Methods

This systematic review was carried out using a predetermined protocol (http://www.crd.york.ac.uk/PROSPERO/display_record.asp?ID=CRD42014013215) in accordance with the PRISMA statement [9].

Data Sources & Search Strategy

An electronic search of the Cochrane Central Register of Controlled Trials (CENTRAL), MEDLINE and PEDro was undertaken from their inception to August 2014. The Cochrane highly sensitive search for identifying randomised trials was adopted [10]. The search terms used for the MEDLINE search are displayed in table 1.

1
2
3 The electronic search was complemented by hand searching the reference lists of
4 the articles found and previous systematic reviews. This process was undertaken by
5 one reviewer.
6

7 Study Selection

8
9 Studies had to meet the following criteria to be included:

10 **Participants**

11
12 Adult (> 18 years) patients who had undergone surgical repair of the rotator cuff.

13 **Interventions**

14
15 Any post-operative rehabilitation programme.

16 **Outcomes**

17
18 Any patient-reported outcome of pain and disability.

19 **Study design**

20
21 Randomised controlled trials (RCTs).

22 **Language**

23
24 English language.
25
26
27

28 Data Extraction

29
30 One reviewer extracted data in relation to study characteristics, participant
31 characteristics, interventions and results.
32

33 Quality Appraisal

34
35 Included studies were appraised for quality using the PEDro scale [11,12]. The
36 PEDro scale was developed to facilitate appraisal of clinical trials in terms of internal
37 validity and also the extent to which the statistical information provided makes their
38 results interpretable [11]. The 11 item scale has been widely adopted for use in
39 systematic reviews. The domains of the scale are detailed in table 2 where items 2 –
40 9 refer to the internal validity of a paper, and items 10 and 11 refer to the statistical
41 analysis, ensuring sufficient data to enable appropriate interpretation of the results.
42 Item 1 is related to the external validity and therefore not included in the total PEDro
43 score [13].
44

45
46 All included articles were already scored within the PEDro database, and these data
47 were extracted from the PEDro website with studies scoring ≥ 6 out of 10 considered
48 to be high quality [14].
49

50 Data Synthesis

51
52
53
54
55
56
57
58
59
60

1
2
3 Due to the heterogeneity with regards to the patient reported outcomes a narrative
4 synthesis using a rating system for levels of evidence was used [15]. This rating
5 system, displayed in table 3, is used to summarise the results in which the quality
6 and outcomes of individual studies are taken into account.
7

8
9 To evaluate the effect of early versus delayed rehabilitation programmes in terms of
10 recurrent rotator cuff tendon re-tear, odds ratios (ORs) and 95% confidence intervals
11 were calculated. The data were pooled using a random effects model via
12 OpenMetaAnalyst software (http://www.cebm.brown.edu/open_meta). Statistical
13 heterogeneity was assessed using the I^2 statistic with $p < 0.05$ taken to indicate
14 statistical heterogeneity that would preclude data pooling.
15

16 **Results**

17 Study Selection

18
19 Figure 1 depicts the study selection process. The electronic search yielded a total of
20 1351 records. One additional source was retrieved through hand searching. The title
21 and abstracts of 1352 articles were screened with 14 potentially relevant studies
22 identified for full-text review. Of these 14, two did not report patient reported
23 outcomes of pain and disability leaving a total of 12 studies for inclusion.
24
25

26 Quality Appraisal Assessment

27
28 The results of the quality appraisal assessment are shown in table 2. Four of 12
29 (33%) studies were regarded as high quality clinical trials.
30
31

32 Study Characteristics

33
34 A summary of the characteristics of the 12 included studies (819 patients; mean age
35 58.1 years) along with the main results is shown in table 4.
36
37

38 Interventions

39
40 Seven of 12 studies [8,16–21] evaluated early versus delayed initiation of
41 rehabilitation. Typically this referred to initiation of passive ROM with the exception of
42 Klintberg et al [8] who commenced low-level active ROM from day two post-
43 operatively. There is strong evidence (consistent findings in multiple high quality
44 RCTs) that early initiation of rehabilitation does not adversely affect outcome in
45 terms of patient reported outcome of pain and disability in the short (3 months), mid
46 (6 months) or long term (≥ 12 months).
47

48
49 There is limited evidence (only one relevant low quality RCT) that early initiation of
50 rehabilitation might favourably affect outcome in terms of patient reported outcome of
51 pain and disability in the short term (≤ 4 months) [18].
52

53
54 Five of 12 studies [16,17,19–21] ($n = 469$) evaluated early versus delayed initiation
55 of rehabilitation and reported outcomes in terms of rate of tendon re-tear. The pooled
56 OR of tendon re-tear in the early rehabilitation group was 1.3 (95% CI 0.72 to 2.2; p
57 = 0.41).
58
59
60

1
2
3 There is moderate evidence (consistent findings among multiple lower quality RCTs
4 and/ or 1 higher quality RCT) that the means of initiating passive range of movement
5 (ROM); continuous passive movement, physiotherapist or patient directed, does not
6 affect outcome in terms of patient reported outcome of pain and disability or rate of
7 tendon re-tear in the short (3 months) or mid-term (6 months) [22–24]. Similarly,
8 there is limited evidence (only one relevant low quality RCT) that the nature of
9 exercise instruction; videotape or face to face, does not affect outcome in terms of
10 patient reported outcome of pain and disability in the short (3 months), mid (6
11 months), or long term (≥ 12 months).

12
13
14 There is strong evidence (consistent findings in multiple high quality RCTs) that
15 initiation of functional loading, for example active exercise, early in the rehabilitation
16 programme does not adversely affect outcome in terms of patient reported outcome
17 of pain and disability in the short (≤ 3 months), mid (6 months) or long term (≥ 12
18 months) [8,25].
19
20
21

22 **Discussion**

23
24 This systematic review summarises the results of twelve studies that have evaluated
25 the effectiveness of rehabilitation programmes following surgical repair of the rotator
26 cuff. It is suggested that concern about early initiation of rehabilitation and
27 introduction of functional load, in the form of patient directed active exercise,
28 following surgical repair of the rotator cuff might not be warranted in terms of adverse
29 patient reported outcome. Concern surrounding tendon re-tear as an adverse
30 outcome secondary to early initiation of rehabilitation programmes has been raised
31 by some, but this is not supported by this current review where a marginal increase
32 in tendon re-tear is evident but not statistically significant .
33
34

35 The recommendations from this current systematic review build upon previous
36 reviews which highlighted the limited nature of the evidence base and suggested
37 caution in relation to early initiation of rehabilitation and introduction of functional
38 load [2,26–28]. The strength of these current recommendations recognise
39 development of the evidence base in this area in terms of publication of further
40 related RCTs. But, although we conclude that there is no evidence to delay the
41 initiation of rehabilitation, this does not suggest that such approaches are superior to
42 existing, delayed protocols, based upon the available data. However, in the context
43 of the potential for superior short term outcomes, including return to work, and also
44 the potential to reduce the early morbidity enforced through sling immobilisation,
45 further high-quality studies are indicated to enhance our understanding.
46
47

48 The mean age of participants within the included studies was 58 years which
49 suggests that a significant proportion of patients undergoing surgical repair of the
50 rotator cuff will be engaged in gainful employment. Hence, greater understanding of
51 the short, mid and long-term implications of early initiation of rehabilitation and
52 introduction of functional load in terms of patient reported outcome and return to
53 work would be useful.
54

55 The size of the initial rotator cuff tendon tear has been cited by some as a means of
56 guiding post-operative rehabilitation where larger tears might indicate the need for a
57 more delayed and/ or relatively conservative rehabilitation protocol due to integrity of
58
59
60

1
2
3 the subsequent repair. However, the data presented from the included studies in this
4 review somewhat challenge that notion. Whereas some studies [18,25] appear to
5 make no attempt to quantify and include all rotator cuff tears irrespective of size;
6 some [19,20] quantify the size of tear and include patients diagnosed with small to
7 medium sized tears; others [23] include patients diagnosed with medium to large
8 sized tears. But, in doing so, all still report comparable outcomes between early
9 and/ or relatively aggressive rehabilitation protocols versus delayed and/ or relatively
10 conservative rehabilitation protocols. Hence, again, the data presented in this review
11 might serve to challenge a clinical reasoning approach based upon size of the rotator
12 cuff tear.
13

14
15 Following on from this point, in an attempt to offer a potential rationale for the idea
16 that the size of the initial rotator cuff tear might not be a useful basis upon which to
17 guide rehabilitation prescription, it is apparent that good patient reported outcomes
18 can still be achieved in the presence of re-tear [6,7]. Thus, it is plausible that the
19 primary mechanism of action of the surgery is not wholly biomechanical in terms of
20 structural repair but might be impacting in some other, currently unknown, way. So,
21 whether the tendon re-tears or not might not actually be the important factor and
22 probably should not be the primary concern of the patient or clinician.
23

24
25 One outcome not considered in this review is post-operative stiffness which has
26 been one of the suggested advantages of early versus delayed mobilisation.
27 Typically stiffness would be quantified in terms of shoulder ROM. However, due to
28 concerns about the level of reliability of ROM measurement and also concerns about
29 validity [29], i.e. apparent stiffness or loss of ROM not reflecting patient report of
30 disability, this outcome was omitted in preference for patient reported measures of
31 pain and disability, reflecting the wider movement in outcome measurement, and re-
32 tear rate. The former, an outcome important to the patient; and the latter
33 an outcome that appears to be important to many clinicians, particularly surgeons.
34

35 Implications for clinical practice and further research

36
37 From a clinical perspective, this review challenges the belief that a period of
38 enforced immobilisation and unloading is necessary to achieve a good outcome
39 following surgical repair of the rotator cuff. However, development of the evidence
40 base is indicated in terms of the need to evaluate both short and long term outcomes
41 of approaches to rehabilitation that foster early initiation of rehabilitation and gradual
42 introduction of functional load. Important outcomes include validated measures of
43 patient reported outcome, for example the Oxford Shoulder Score and Disabilities of
44 the Arm Shoulder & Hand, as well as return to work outcomes and associated
45 economic data.
46
47

48 Limitations

49
50 The twelve RCTs included in this systematic review comprised an average of 68
51 participants. Hence, one potential caveat to consider alongside the
52 recommendations from this review is the potential for Type II error. Although the
53 findings are reasonably consistent across studies the relatively small mean number
54 of included participants per trial might indicate that any true differences between
55 interventions could have been missed.
56
57
58
59
60

1
2
3 For pragmatic reasons one reviewer identified relevant studies, extracted data and
4 synthesised the findings. This approach somewhat challenges traditional systematic
5 review guidance where it is frequently suggested that multiple reviewers should be
6 involved at each stage [30]. However, it is interesting to note that there is movement
7 in the field of systematic review methodology towards an appreciation of rapid
8 reviews [31]. Frequently such reviews use one reviewer at the various stages for
9 pragmatic reasons and although it is recognised that the potential for error might be
10 higher, it is generally suggested that most errors or omissions do not lead to
11 substantial changes in any conclusion [32] while delivering in a timely manner.
12
13

14 15 **Conclusion**

16
17 Concern about early initiation of rehabilitation and introduction of gradual functional
18 load, in the form of patient directed active exercise, following surgical repair of the
19 rotator cuff might not be warranted in terms of adverse patient reported outcome or
20 tendon re-tear. Although the evidence base relating to rehabilitation of the rotator
21 cuff following surgical repair has developed, these conclusions are offered with the
22 caveat of the potential for Type II error and hence there is further need to evaluate
23 approaches that foster early initiation of rehabilitation and gradual introduction of
24 functional load both in the short and long term using high-quality, adequately
25 powered, trials.

Table 2 Completed PEDro quality appraisal (1. Eligibility criteria were specified ; 2. Subjects were randomly allocated to groups; 3. Allocation was concealed; 4. Groups were similar at baseline regarding the most important prognostic indicators; 5. There was blinding of all subjects ; 6. There was blinding of all therapists who administered the therapy; 7. There was blinding of all assessors who measured at least one key outcome; 8. Measures of at least one key outcome were obtained from more than 85% of the subjects initially allocated to groups; 9. All subjects for whom outcome measures were available received the treatment or control condition as allocated or, where this was not the case data for at least one key outcome was analysed by "intention to treat"; 10. The results of between-group statistical comparisons are reported for at least one key outcome; 11. The study provides both point measures and measures of variability for at least one key outcome)

Peer Review

Strong Evidence	Consistent findings in multiple high quality RCTs (n> 2)
Moderate Evidence	Consistent findings among multiple lower quality RCTs and/ or 1 higher quality RCT
Limited Evidence	Only one relevant low quality RCT
Conflicting evidence	Inconsistent findings amongst multiple RCTs
No evidence from trials	No RCTs

<p>RCT comparing early loading versus delayed loading</p> <p>Conducted in Sweden</p>	<p>64% male)</p> <p>Main inclusion criteria: a. Diagnosis of full-thickness tear repaired surgically</p>	<p>day from day 2 post-operatively supplemented by passive ROM directed by the physiotherapist. Load was progressed from day 28 post-operatively when sling immobilisation was ceased.</p> <p>2. n = 7; 6 weeks of sling immobilisation supplemented by passive ROM</p>	<p>Constant score at 6, 12 and 24 months:</p> <p>Between group difference inadequately reported; reported as no difference in adverse effects but statistical significance unclear</p>
<p><u>Koh et al [21]</u></p> <p>RCT comparing immobilisation for four versus eight weeks</p> <p>Conducted in South Korea</p>	<p>100 patients (mean age 59.9 years/ 50% male)</p> <p>a. Diagnosis of full-thickness tear, 2 to 4cm in size, repaired arthroscopically</p>	<p>1. n = 47; 4 weeks of immobilisation without passive ROM</p> <p>2. n = 53; 8 weeks of immobilisation without passive ROM</p>	<p>Main outcomes assessed using Constant score and ASES at 6 and 24 months:</p> <p>No statistically significant differences between groups including re-tear rate (5/40 versus 4/48; p = 0.73)</p>
<p>Lastayo et al [22]</p> <p>RCT comparing continuous passive motion versus manual passive ROM exercises</p> <p>Conducted in USA</p>	<p>31 patients (mean age 63.3 years/ 44% male)</p> <p>a. Rotator cuff tear repaired surgically</p>	<p>1. n = 17; home continuous passive motion for 4 hours per day after discharge from hospital for 4 weeks, supplemented by daily pendular exercises</p> <p>2. n = 15; manual passive ROM exercises three times per day performed by carer or similar for 4 weeks supplemented by daily pendular exercises</p>	<p>Main outcomes assessed using Shoulder Pain and Disability Index at unclear time point:</p> <p>No statistically significant (p > 0.05) differences between groups</p>
<p>Lee et al [23]</p> <p>RCT comparing aggressive versus limited passive exercises</p> <p>Conducted in South Korea</p>	<p>64 shoulders (mean age 54.9 years/ 64% male)</p> <p>a. Diagnosis of medium- or large-sized full-thickness rotator cuff tear repaired arthroscopically</p>	<p>1. n = 30; immediate passive ROM x 2/day without limit on ROM supplemented by daily pendular exercises with shoulder brace maintained in situ for 6 weeks</p> <p>2. n = 34; continuous passive movement limited to 90° x 2/ day</p>	<p>Main outcomes assessed using University of California Los Angeles shoulder rating scale at 3 and 6 months:</p> <p>Statistically significant (p < 0.01) difference in favour of aggressive exercise at 3 months but unknown if</p>

		and passive ROM with shoulder brace maintained in situ for 6 weeks	<p>difference of 2.9 points is clinically significant. No statistically significant difference by 6 months ($p = 0.16$).</p> <p>No statistically significant difference between groups in terms of re-tear rate (7/30 versus 3/34; $p = 0.11$)</p>
<p>Raab et al [24]</p> <p>RCT comparing physiotherapy versus physiotherapy with continuous passive motion</p> <p>Conducted in USA</p>	<p>26 patients (mean age 55.8 years/ 69% male)</p> <p>a. Rotator cuff tear repaired surgically</p>	<p>1. $n = 12$; physiotherapy (no further description)</p> <p>2. $n = 14$; physiotherapy with continuous passive movement commencing in the recovery room, progressed within pain-free limits, and continuing for 8 hours/ day for 3 weeks limited to $90^\circ \times 2/$ day and passive ROM with shoulder brace maintained in situ for 6 weeks</p>	<p>Main outcomes assessed using an author generated patient-reported shoulder score at 3 months:</p> <p>No statistically significant difference between groups ($p =$ not reported)</p>
<p>Roddey et al [33]</p> <p>RCT comparing two approaches to home exercise instruction</p> <p>Conducted in USA</p>	<p>108 patients (mean age 58 years/ 64% male)</p> <p>a. Diagnosis of full-thickness tear repaired arthroscopically</p>	<p>1. $n = 54$; videotape based home exercise instruction while sling remained in situ for 6 weeks. Passive exercise for 4 to 6 weeks, followed by active exercise between 6 to 12 weeks and then strengthening exercises > 3 months</p> <p>2. $n = 54$; personal PT instruction while sling remained in situ for 6 weeks. Principles of exercise progression as group 1</p>	<p>Main outcomes assessed using Shoulder Pain & Disability Index at 3, 6 and 12 months:</p> <p>No statistically significant difference between groups ($p = 0.17, 0.40, 0.99$ respectively)</p>

Table 4 Summary of the characteristics of the included studies along with main results (*RCT* = randomised controlled trial; *ROM* = range of motion; *PT* = physiotherapist/ physical therapist; *MT* = manual therapy; *ET* = electrotherapy including heat and ice)
