Abstract

In this paper an experimental and numerical work is reported concerning the process of perforation of thin steel plates using different projectile nose shapes. The main goal is to analyze how the projectile shape may change the ballistic properties of materials. A wide range of impact velocities from 35 to 180 m/s has been covered during the tests. All the projectiles were 13mm in diameter and the targets were 1mm thick, as such the projectile can be regarded as rigid and the target sheets were of interstitial-free (IF) steel. The mass ratio (projectile mass/steel sheet mass) and the ratio between the span of the steel sheet and the diameter of the projectile were kept constant, equal to 0.38 and 3.85 respectively. To define the thermoviscoplastic behaviour of the target material, the Rusinek-Klepaczko (RK) constitutive model [1] was used. The complete identification of the material constants was done based on a rigorous material characterization. Numerical simulations of some experimental tests were carried out using a non-linear finite element code ABAQUS/Explicit. It was found that the numerical models are able to describe the physical mechanisms in the perforation process with a good accuracy.

Keywords: perforation, failure, impact, ballistic properties

1. Introduction

Structural impact has been studied for a long time, and such a problem is known to be complex, both from experimental, analytical and numerical points of view. The most important parameters affecting the ballistic capacity of a target plate are the projectile (size, shape, density and hardness), the target plate (hardness/strength, ductility, microstructure and thickness) and the actual impact conditions (such as

impact velocity and projectile incidence angle). This paper concentrates on the ballistic capacity of targets, with the varying factors will being the nose shape of the projectile and the normal impact velocity.

The nose shape of hard projectiles has a strong influence on the failure mode and the ballistic limit of a target [2–4]. Corran et al. [5] investigated the effect of projectile mass, nose shape and hardness on the penetration of steel and aluminum alloy plates. Blunt and conical projectiles of 12.5 mm diameter were impacted on plates 1.3 to 5.9 mm thick and considering a velocity ranging from 50 to 250 m/s. The mass of the projectile varied from 15 to 100 g. They observed that the ballistic limit of the plate changes with projectile mass and nose shape. Goldsmith et al. [6] experimentally investigated normal impact of cylindro-conical and blunt projectiles into aluminum and steel sheet targets. The thickness of aluminum targets varied from 1.78 mm to 25.4 mm and that of steel plates varies from 1 mm to 19 mm. It was observed that the nose shape of projectile had insignificant effect on the ballistic limit. Ipson and Recht [7] found that conical projectiles penetrated the target in a less efficient way than blunt projectiles when the target thickness was moderate. However, for a thin and thick target, an opposite trend was observed by the authors. This is due to the different modes of failure involved. Experiments investigation carried out by Zukas et al. [8] showed that the projectile with blunt nose shape has higher ballistic limit velocity. A more recent work done by Kpenyigba et al. [9] on the impact of blunt, conical and hemispherical shape projectiles on 1mm thick mild steel sheets indicated that the ballistic limit is higher for hemispherical shape projectile, followed by conical and blunt respectively. The authors also showed that the blunt projectile failed the target by plug ejection due to a process of high speed shearing, the conical projectile caused failure by petaling due to a process of piercing and the hemispherical shape projectile led to radial hole expansion inducing necking and radial cracks. Backman and Goldsmith [3] concluded that blunt shape projectiles caused failure through plugging, wedge projectiles by ductile hole enlargement and sharp nosed projectiles by petaling. Borvik et al. [2,10] studied experimentally and numerically the perforation of 12 mm thick Weldox 460 E steel plates and showed that the blunt projectiles caused failure by plugging, which was dominated by shear banding, while hemispherical and conical projectiles penetrated the target mainly by pushing the material in front of the projectile aside. Gupta et al. [11] reported that the failure in thin ductile targets occurred through shear plugging by blunt projectiles, petal forming by ogive nosed projectiles and tensile stretching by hemispherical projectiles. **The high velocity impacts of the high strength projectiles into monolith 6 mm and sandwiched plates 2x6 mm of 45 and of Q235 steels were investigated [12]. The results present the nose shape (ogival or blunt) influence on the ballistic resistance of the structure. The authors also present the influence of the order of the material in sandwiched structures.** The available experimental and numerical investigations on the perforation and penetration of ductile metal targets by rigid projectiles are mostly restricted to a few specific nose shapes such as hemispherical, conical, ogival and blunt. In this work, some experimental tests were carried out on thin IF steel targets in order to study in detail the effect of projectile nose shape in structural

impact at sub-ordnance velocities. Moreover, an additional investigation was made to study the influence of a double-nosed stepped cylindrical projectile. Based on the experimental results, the ballistic curves were plotted for each projectile shape. Numerical simulations using a finite element code ABAQUS/Explicit were performed and the results obtained allow prediction properly the complete process of perforation.

2. Experimental material behavior description

The material studied is a 1 mm thick sheet of a deep-drawing quality IF steel. The IF steel was developed to obtain an optimized compromise between the mechanical strength and the formability due to specific metallurgy without interstitial elements (interstitial-free). It is mainly used for structural components subject to fatigue impact loading. The chemical composition of the material (in weight %) is given in Table 1. This steel has a ferritic structure with more or less equiaxial grains about 25 μ m in diameter.

Table 1. Chemical composition of the IF steel (weight %).

C	S	Mn	P	Si	Cu	Ni	Cr	Al	V	Sn
0,0018	0,007	0,095	0,009	0,006	0,026	0,015	0,023	0,06	0,001	0,003

Quasi-static tensile tests were conducted on a universal test machine (eg. Instron) and dynamic tensile tests were performed on a fast servo-hydraulic universal machine (eg. Zwick). A wide range of strain rates was covered at room temperature, $10^{-4} s^{-1} \leq \dot{\epsilon} \leq 250 s^{-1}$. The geometry and dimensions of the tensile specimens used in the characterization are given in Fig. 1. The thickness of the specimens is $t = 1 mm$. To analyze the possible anisotropy of the material in the plane of the sheet, the tension tests were performed in two directions complementary to the rolling direction: $\varphi_1 = 45^\circ$ and $\varphi_2 = 90^\circ$.

Fig. 1. Geometry and dimensions of the tensile specimens, Rusinek et al. [13].

Rusinek et al. [13,14] showed that these dimensions of the tensile specimens (*Fig. 1*) are optimum, which allows to achieve a proper level of stress coupled with sufficient ductility. The authors highlighted that this specimen design allows to avoid geometrical disturbances that frequently take place when small samples are used to reach very high strain rates during testing. For all tests performed, the true stress-strain curves were obtained up to incipient necking.

The curves in the *Fig. 2* show that the effect of rolling direction is not insignificant on the macroscopic behavior of the steel sheet. According to this result coupled to the microscopic observation, the isotropy is assumed in the description of the material behavior.

Fig. 2. Comparison of quasi-static tensile flow curves in three directions: 0° as well as 45° and 90° .

The true stress-strain curves at different strain rates are shown in *Fig. 3*. The first observation is an increase of the flow stress and the yield stress as the strain rate increase. For a high strain rate, the curves change shapes particularly by the presence of a thermal softening due to local temperature elevation during the tests. The loading time is short and the temperature does not have time to dissipate through the specimen. During these tests, necking which diffuses into the specimen to cause the final failure occurs much earlier than for tests at low strain rates. For the strain rate of $\dot{\epsilon} = 250 \text{ s}^{-1}$, the macroscopic material behavior is substantially different at the beginning of loading. A significant peak stress (450 MPa) is observed. **This peak is related to the microstructure of the material and more particularly to the dislocation density. Similar behavior has been reported in [15,16] or in [17] where the level of carbon on the macroscopic behavior has been studied. It was observed that a decrease of the carbon level was dissipating the peak stress at the beginning of loading.** There is a relatively

high hardening for quasi-static sollicitation and which decreases when the strain rate increases. The IF steel has a positive sensitivity to strain rate as most materials with bcc crystallographic structure. This sensitivity to the strain rate of the flow stress is defined by:

$$\psi = \left. \frac{\partial \sigma}{\partial \log \dot{\epsilon}} \right|_{\epsilon, T} \tag{1}$$

Fig. 3. Comparison of true stress versus true strain curves of IF steel at different strain rates.

It can be observed that the strain rate sensitivity at room temperature is not constant, Fig. 4. Three characteristic regions with different sensitivity to the strain rate were reported by Campbell and Ferguson [18].

In the next section, the constitutive relation use to describe the material behavior, the comparison between the experimental data and analytical modeling are reported and discussed.

Fig. 4. Flow stress evolution as a function of the strain rate at room temperature for a strain level imposed of $\varepsilon = 0.1$.

3. Thermoviscoplastic modeling of material behavior

Several constitutive relations are available in the literature and used in finite element code to predict the distribution of plastic deformation and the failure in structures impact. Some of them are limited to perfectly plastic approximations with some visco-plasticity. More sophisticated versions, such as those that take into account the effect of the strain rate, temperature and hardening on the flow stress are also available nowadays. In this work, the RK constitutive relation is used. The model is partially based on the theory of dislocations and its phenomenological description is based on the additive decomposition of the total stress [19]:

$$\sigma(\varepsilon, \dot{\varepsilon}, T) = \frac{E(T)}{E_0} \left[\sigma_\mu(\varepsilon, \dot{\varepsilon}, T) + \sigma^*(\dot{\varepsilon}, T) \right] \quad (2)$$

where each term of the previous expression, Eq. (2), is defined below. The multiplicative factor $E(T)/E_0$ defines Young's modulus evolution with temperature [20]:

$$E(T) = E_0 \left(1 - \frac{T}{T_m} \exp \left[\theta^* \left(1 - \frac{T}{T_m} \right) \right] \right) \quad T > 0 \quad (3)$$

where E_0 , T_m and θ^* are respectively the Young's modulus at $T = 0K$, the melting temperature and the characteristic homologous temperature. This expression allows to

define the material thermal softening depending on its crystal lattice [21]. In the case of bcc metals like steel $\theta^* \approx 0.6$.

The internal component of the total stress called the athermal stress is defined by the following equation:

$$\sigma_{\mu}(\varepsilon, \dot{\varepsilon}, T) = B(\dot{\varepsilon}, T)(\varepsilon_0 + \varepsilon)^{n(\dot{\varepsilon}, T)} \quad (4)$$

where, $B(\dot{\varepsilon}, T)$ is the modulus of plasticity, $n(\dot{\varepsilon}, T)$ the hardening coefficient ($B(\dot{\varepsilon}, T)$ and $n(\dot{\varepsilon}, T)$ depend on the strain rate and temperature) and ε_0 is the value of strain corresponding to the yield stress at a given strain rate and temperature.

The authors propose the following formulations to describe the modulus of plasticity and strain hardening exponent:

$$B(\dot{\varepsilon}, T) = B_0 \left(\left(\frac{T}{T_m} \right) \log \left(\frac{\dot{\varepsilon}_{\max}}{\dot{\varepsilon}} \right) \right)^{-\nu} \quad T > 0 \quad (5)$$

$$n(\dot{\varepsilon}, T) = n_0 \left\langle 1 - D_2 \left(\frac{T}{T_m} \right) \log \left(\frac{\dot{\varepsilon}}{\dot{\varepsilon}_{\min}} \right) \right\rangle \quad (6)$$

where B_0 is the material constant, ν proportional to temperature sensitivity, n_0 the strain hardening exponent at $T = 0K$, D_2 the material constant, $\dot{\varepsilon}_{\min}$ the lower strain rate limit of the model and $\dot{\varepsilon}_{\max}$ the maximum strain rate level accepted for a particular material. **The Macaulay operator is defined as follows: $\langle \bullet \rangle = \bullet$ if $\bullet > 0$, otherwise $\langle \bullet \rangle = 0$.**

The effective stress $\sigma^*(\dot{\varepsilon}, T)$ is the flow stress component which defines the rate dependent interactions with short range obstacles. It denotes the rate controlling deformation mechanism from thermal activation. At temperatures $T > 0$ K, thermal activation assists the applied stress.

The theory of thermodynamics and kinetics of slip [22] is founded on a set of equations which relate activation energy ΔG , mechanical threshold stress $\hat{\sigma}$ (MTS), applied stress σ , strain rate $\dot{\varepsilon}$, temperature T and determined physical material parameters. Based on such understanding of the material behavior, Rusinek and Klepaczko [1] derived the following expression, Eq. (7). This formulation gathers the reciprocity between strain rate and temperature by means of an Arrhenius type equation :

$$\sigma^*(\dot{\varepsilon}, T) = \sigma_0^* \left\langle 1 - D_1 \left(\frac{T}{T_m} \right) \log \left(\frac{\dot{\varepsilon}_{\max}}{\dot{\varepsilon}} \right) \right\rangle^{m^*} \quad (7)$$

where σ_0^* is the effective stress at $T = 0K$, D_1 the material constant and m^* the constant defining the reciprocity strain rate-temperature [19].

In the case of adiabatic conditions of deformation the constitutive relation is combined with the energy balance principle, Eq. (8). Such relation allows for an approximation of the thermal softening of the material by means of the adiabatic heating.

$$T = T_0 + \Delta T = T_0 + \frac{\beta}{\rho C_p} \int_{\varepsilon_e}^{\varepsilon_f} \sigma d\varepsilon \quad (8)$$

where β is the Quinney-Taylor coefficient, ρ the density of the sheet steel, C_p the specific heat and ε_f the failure strain level, *Table 2*.

Subsequently a straightforward method was proposed by Rusinek and Klepaczko [1,23] for the model calibration. It allows defining the model parameters step by step. Contrary to other constitutive descriptions, the procedure does not involve a global fitting. It must be noticed that the constants are defined using physical assumptions [1,23].

The main steps necessary for defining the model parameters are :

- ✓ It is assumed that at low strain rate $\dot{\varepsilon} \leq 0.001 s^{-1}$, the stress contribution due to thermal activation is reduced and in this case the following relation is imposed, Eq. (9). Thus, it is possible to define the constant D_1 depending on the melting temperature T_m .

$$\left\{ \begin{array}{l} \sigma^*(\dot{\varepsilon}, T) \Big|_{300K, 0.001s^{-1}} = 0 \\ D_1 = \left[\left(\frac{300}{T_m} \right) \log \left(\frac{\dot{\varepsilon}_{\max}}{0.001} \right) \right]^{-1} \end{array} \right. \quad (9)$$

- ✓ Therefore, at room temperature and under quasi-static loading the contribution of the thermal stress component to the total stress is zero. The overall stress level is defined by Eq. (10). Fitting this equation to experiment results, a first estimation of B and n can be found.

$$\left\{ \begin{array}{l} \sigma(\varepsilon, 0.001, 300) = \frac{E(300)}{E_0} [B(\varepsilon_0 + \varepsilon)^n + 0] \\ B, n \text{ first approximation} \end{array} \right. \quad (10)$$

- ✓ Next, it is assumed that the increase of the flow stress caused by the strain rate augment is due to the thermal stress $\sigma^*(\dot{\varepsilon}, T)$. Thus, the stress increase is defined as follows, Eq. (11). Fitting of Eq. (11) to experimental results for an imposed strain level, makes it possible to determine the material constants σ^* and m^* . The strain level should be assumed not more than 0.1 in order to guarantee isothermal condition of deformation. For larger strain values, adiabatic conditions may induce a thermal softening on the material and in such a case a decrease of the strain hardening.

$$\left\{ \begin{array}{l} \Delta\sigma \Big|_{0.001s^{-1} \rightarrow \dot{\varepsilon}}^\varepsilon = \sigma \Big|_{\dot{\varepsilon}}^\varepsilon - \sigma \Big|_{0.001s^{-1}}^\varepsilon = \sigma^*(\dot{\varepsilon}, T) \Big|^\varepsilon \\ \sigma_0^*, m^* \end{array} \right. \quad (11)$$

- ✓ Finally, combining the complete equation of the total stress (Eq. 2) with the experimental results and replacing the parameters determined above, it allows to determine the parameters $B(\dot{\varepsilon}, T)$ and $n(\dot{\varepsilon}, T)$ depending on the strain rate and temperature.

The curves from RK modeling are plotted in Fig. 5.a. It is noted that the hardening decreases with the strain rate.

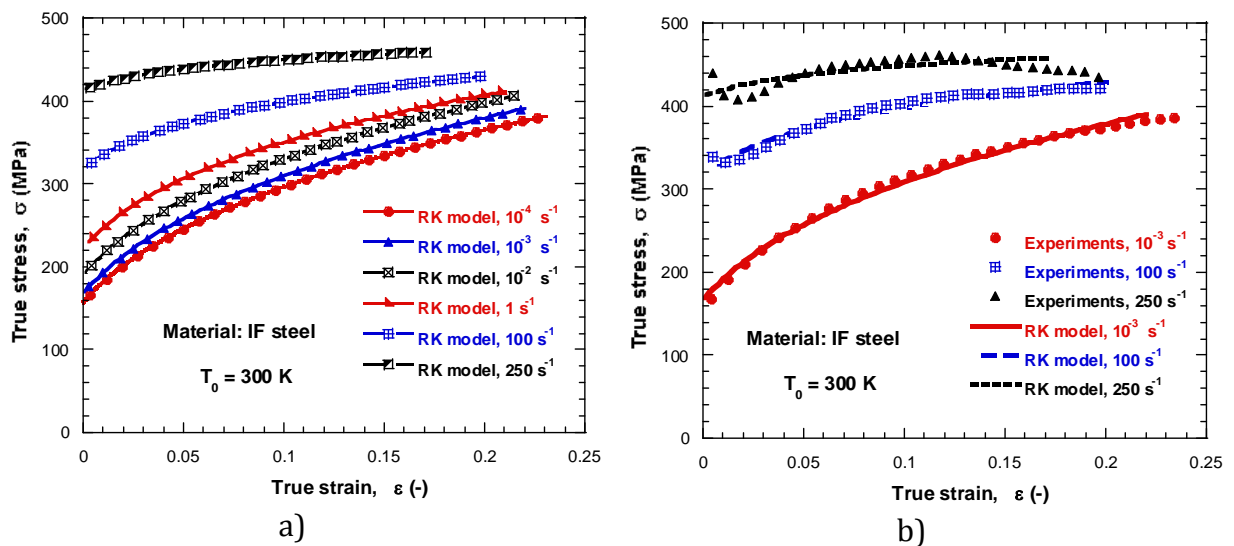

Fig. 5. a- RK model for different strain rates; b- Comparison between RK modeling and experimental data.

Analytical approximations are compared with experiments from quasi-static to dynamic loading with a good agreement, Fig. 5.b. The constants of the model RK determined for the material IF are summarized in Table. 2.

Table 2. Constants used to describe the mechanical behavior based on the RK model, Eq. (2), and to describe temperature increase, Eq. (8)

	$D_1(-)$	$D_2(-)$	$n_0(-)$	B_0 (MPa)	$\dot{\epsilon}_{\min}$ (s^{-1})	$\dot{\epsilon}_{\max}$ (s^{-1})	$\nu(-)$	$\epsilon_0(-)$	$m^*(-)$	σ_0^* (MPa)

4. Experimental perforation tests

4.1 Experimental set-up description

Ballistic perforation tests have been carried out on 1 mm thick IF steel targets plates using rigid projectiles with different nose shapes and a pneumatic gas gun. The experimental apparatus used for the realization of ballistic impact tests consist mainly of a gas launcher, Fig. 6, and auxiliary equipments required for the recording and the processing of data provided by the tests: especially the two sensors used to measure the projectile velocity. The first sensor located at the end of the launcher tube allows to measure the initial impact velocity of the projectile and the second sensor just positioned behind the target allows to measure the residual velocity. The complete description of the perforation process is available in [9,24].

Fig. 6. Experimental device used for impact tests.

The projectiles used in this study were designated according to their respective nose shape such as conical, hemispherical, hemispherical + conical (projectile A) and hemispherical-conical (projectile B), *Fig. 7*. They are all machined from Maraging steel with a heat treatment to reach a yield stress of 2 GPa. Therefore, the projectile may be assumed as rigid (without mushroom effect) during the process of perforation. For each configuration the projectile mass was kept constant, $m_p \approx 30 \text{ g}$, to have the same kinetic energy so that the shape effect can be analyzed. The diameter of all projectile is $\phi_p = 13 \text{ mm}$.

The dimensions of the square plates used during experiments are given, *Fig. 8*. The active part is $100 \times 100 \text{ mm}^2$, the thickness is 1mm and it is embedded on a rigid support allowing the reduction of effect during the test. The plate has been impacted by the projectile in the central zone as shown in *Fig. 8*. A wide range of initial impact velocities was considered for a complete definition of the ballistic curve of the steel sheet.

Fig. 7. Projectile shapes used during perforation tests. a- Hemispherical projectile; b- Conical projectile; c- Hemispherical + conical (projectile A); d- Hemispherical-conical (projectile B).

Fig. 8. Geometry of the steel plates used during perforation tests, thickness 1 mm.

4.2 Experimental results under ballistic impact

In this part, the influence of the projectile shape on the perforation tests is studied. The ballistic curves $V_R - V_0$ for projectile are reported on Fig. 9.

The conical and hemispherical shapes are generally used to analyze the process of failure. The first one induces a failure mode by petaling and the second one a plug ejection due to circumferential necking. A previous analysis has been published by Kpenyigba et al. [9]. In addition to these two shapes, projectiles coupling hemispherical and conical design (projectile A and B) have been used. The conical end allows to perforate the plate more easily by a process of piercing. The projectile damages the target plate by radial necking and petal forming. The failure is dominated by the process of high-speed piercing as in the case of a conical projectile. For projectile B, a mix of failure modes is observed: petaling and radial cracks.

It is observed, based on the experimental results that the conical projectile shape allows to decrease the ballistic limit V_b of the material considered, Fig. 9, in comparison with the hemispherical projectile. Moreover, keeping the same conical nose angle $\varphi_p = 72^\circ$ coupled to a hemispherical projectile, Fig. 7-c-d, the ballistic limit is lower than $\Delta V_b^{\text{Conical}} \approx 6 \text{ m/s}$ compared to the conical projectile, Fig. 7-b. The difference is close to $\Delta V_b^{\text{Hemispherical}} \approx 10 \text{ m/s}$ between shape A and B and the hemispherical projectile. Using a reduced conical shape projectile nose allows to induce a failure mode by piercing. After

that, when a hole is initiated the process of hole enlargement is easier and the velocity of the projectile is less reduced. This mechanism is discussed in details using numerical observations in terms of failure time.

Fig. 9. Experimental results in terms of residual velocities for different projectiles shapes.

The ballistic curves in general were approximated using the proposed analytical equation of Recht et al. [25] whose formulation for thin plates is as follows :

$$V_R = (V_0^\kappa - V_B^\kappa)^{1/\kappa} \quad (12)$$

where V_B is the ballistic limit and κ is a fitting parameter.

Table 3. Constants used to fit experiments based on Eq. (12).

Conical	Hemispherical	A	B
$\kappa = 2.21$	$\kappa = 2.39$	$\kappa = 2.25$	$\kappa = 2.28$
$V_B = 86.5 \text{ m/s}$	$V_B = 90 \text{ m/s}$	$V_B = 78 \text{ m/s}$	$V_B = 79 \text{ m/s}$

The difference between the ballistic curves is greater at the ballistic limit than at high impact velocities ($V_0 \geq 150 \text{ m/s}$). When the residual velocity V_R is higher, the energy absorbed by the plate to perforate is lower, as seen in *Fig. 10*. During the perforation of the plate, a part of the kinetic energy of the projectile is absorbed by the global deformation of the steel sheet, the localized plastic deformation in the impact zone and the elastic work. The residual kinetic energy is quite simply the residual energy of the projectile after impact. If the impact velocity is lower than the ballistic limit, the energy absorbed by the plate is directly the kinetic energy of the projectile ($1/2 m_p V_0^2$). The balance of the energy absorbed by the plate during perforation is as follows [26] :

$$W_{Plate}^{Total} = W_{Plate}^K + W^E + W^P + W^F + W_{Débris}^K = \frac{1}{2} m_p (V_0^2 - V_B^2) \quad (13)$$

where W_{Plate}^K , W^E , W^P , W^F and $W_{Débris}^K$ are respectively the energy related to the global deflection of the plate, the elastic deformation energy, the plastic deformation energy, the energy related to the phenomenon of friction and the kinetic energy transferred to the fragments ejected during impact (ejection of plug for example when the hemispherical projectile is used). As shown in [9], the loss of energy due to the friction effect can be disregarded and the energy transferred to the fragments is minor ($W^F \approx 0$, $W_{Débris}^K \approx 0$). The energy balance is then reduced as follows:

$$W_{Plate}^{Total} = W_{Plate}^K + W^E + W^P = \frac{1}{2} m_p (V_0^2 - V_B^2) \quad (14)$$

The evolution of W_{Plate}^{Total} as a function of V_0 obtained experimentally for each kind of projectile shape is presented in *Fig. 10*.

Fig. 10. Experimental results in term of absorbed energy for different projectiles shapes.

A decrease of the absorbed energy with the impact velocity is generally observed: an increment of impact velocity leads to a fast localization of the deformation and quick failure of the target.

To estimate the time necessary for the projectile to perforate the plate, called failure time, the experimental perforation tests were recorded using a high speed camera Phantom v710. The failure time is defined as the time elapsing between the beginning of the impact and when the nose of the projectile passes completely through the plate, as shown in Fig. 11 (case of a conical projectile).

Fig. 11. Perforation process steps using a conical projectile, $V_0 = 178\text{ m/s}$.

The experimental results in terms of failure time as a function of initial impact velocity are reported in Fig. 12. For all projectiles studied, the failure time decrease with the impact velocity. The higher is the projectile initial velocity, the faster is the process of perforation.

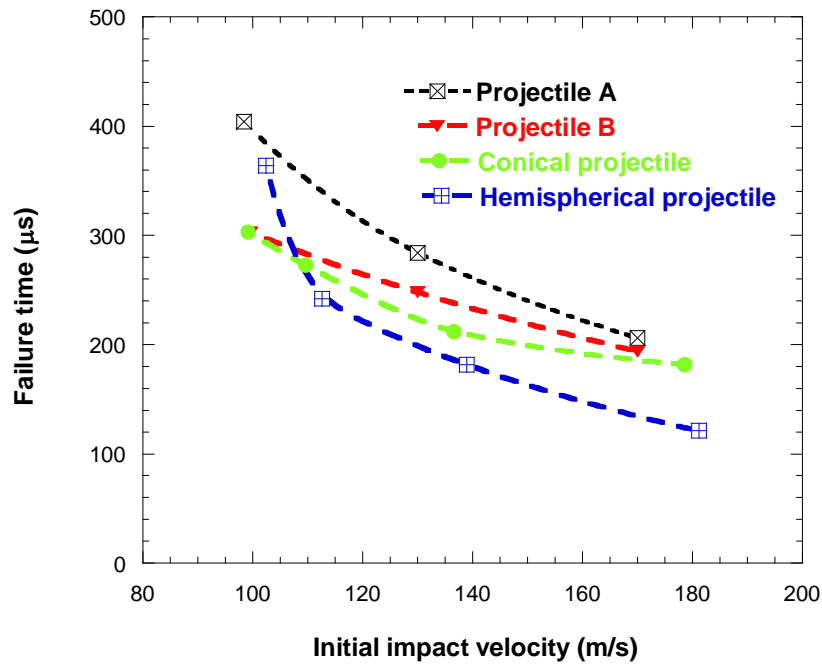

Fig. 12 Failure time depending on the initial impact velocity for different projectiles.

Apart from the lower speed range, in general, the failure time is lower at the same impact velocity for projectile A, followed by projectile B, then the conical and the hemispherical projectiles, respectively.

5. Numerical model for dynamic perforation

The impact and perforation tests using a rigid projectile against thin steel sheet were numerically analyzed for the purpose to predict the experimental observation. The finite element code ABAQUS/Explicit was used to simulate the process.

5.1 Description of the numerical model

In all simulations, the projectile was modeled as a three-dimensional non-deformable rigid body (discrete) with a reference point to affect velocity. The mass and inertia moments were automatically calculated based on the shape, volume and density of the projectile and assigned to its reference point. The target was modeled as a three-dimensional deformable body, Fig. 13. The contact between the projectile and the plate was modeled using the penalty method with finite sliding formulation. A constant coefficient of friction $\mu = 0.2$ was applied based on experimental studies made by Jankowiak et al. [27] and Rusinek et al. [28]. In order to optimize the mesh, after trying several approaches and taking into account the influence of the element type, the mesh density and the computation time, we chosen to divide the geometry of the plate in two parts: a circular central part of 30 mm diameter (more than double of the diameter of the projectile, allowing to begin the process of crack propagation accurately without significant effects on the energy balance) and an exterior part that complements the

structure to have a rectangular target. The central part of the plate was meshed using C3D8R elements (8-node linear brick, reducing integration with hourglass mode control) available in the Abaqus library [29]. This type of hexahedral element are used with success in nonlinear plasticity analysis [9,26,28,30,31]. The effect of hourglass mode is controlled using enhanced method [26] and an optimal mesh. The stability of the results and its mesh size dependence were previously checked [8, 24]. The aspect ratio of elements was maintained close to unity as recommended by Zukas and Scheffler [32]. A convergence study using a linear hexahedral element in the impact zone with the initial size $\Delta x = \Delta y = \Delta z = 0.2\text{ mm}$ ensures the stability of the numerical solution without mesh sensitivity effect and with optimal time computation. The central part of the numerical model has 110390 elements (5 elements through the thickness of the steel plate). The external part was meshed using C3D8I hexahedral elements (8-node linear brick with incompatible mode). These elements have an additional internal degree of freedom which enhances the ability to model an additional displacement gradient through the element, thereby improving the bending behavior of the structure. The size of C3D8I elements used was $\Delta x = \Delta y = \Delta z = 0.5\text{ mm}$ (two elements along the thickness of the steel sheet), leading to a total of 73 640 elements in the external part of the numerical model, *Fig. 13*.

Fig. 13. Numerical model used in this work and mesh density distribution.

The material behavior of the IF steel used as a target was incorporated through RK thermoviscoplastic material model described previously (Eq. 2). Using the flow stress definition provided by the RK relation is possible to particularize the heat equation (Eq. 8). Thus, the temperature increase is decomposed in two contributions due to the internal stress $\sigma_{\mu}(\varepsilon, \dot{\varepsilon}, T)$ and the effective stress $\sigma^*(\dot{\varepsilon}, T)$:

$$\begin{cases} \Delta T = \Delta T_{\text{internal stress}} + \Delta T_{\text{effective stress}} \\ \Delta T = \frac{\beta}{\rho C_p} \int_{\varepsilon_e}^{\varepsilon_f} \frac{E(T)}{E_0} [\sigma_{\mu}(\varepsilon, \dot{\varepsilon}, T) + \sigma^*(\dot{\varepsilon}, T)] d\varepsilon \end{cases} \quad (15)$$

In order to reproduce the perforation process it is necessary to consider a failure criterion. In this work, the failure criterion used is based on the work by Wierzbicki et al. [33,34] who showed that the equivalent strain at failure expressed as a function of the stress triaxiality would be more appropriate for problems involving fast loading. The general form of this type of failure strain can be written as follows:

$$\varepsilon_f = f(\eta) = f\left(\frac{\sigma_m}{\bar{\sigma}}\right) \quad (16)$$

where ε_f is the effective plastic strain to failure and η is the stress triaxiality defined by the ratio of the mean stress σ_m to the equivalent stress $\bar{\sigma}$. This kind of fracture model is expressed in the code Abaqus by erosive criterion inducing instantaneous removal of an element when an imposed plastic strain level is reached in the element. This failure criterion model based on the level of failure strain is often used for dynamic applications [35–37]. The average value of the stress triaxiality can be estimated just before the failure of the target for each projectile studied based on the work of Lee and Wierzbicki [38]. Based on a process of optimization for the whole range of impact velocities considered, the failure strain was estimated depending on the projectile shape, given in *Table 4*. The process of numerical optimization was to minimize the error on the residual velocity based on experiments. More details on the optimization process are available in [9,24].

Table 4. Failure strain values used to simulate perforation depending on the projectile shape.

	Projectile A	Projectile B	Conical shape	Hemispherical shape
Failure strain level, ε_f (-)	1.2	1.2	1.2	0.65
Stress triaxiality, $\bar{\eta}$	1/3	1/3	1/3	2/3

Numerical simulation were performed for a wide range of initial impact velocities ($20 \text{ m/s} \leq V_0 \leq 200 \text{ m/s}$) to cover the range of velocities investigated experimentally, and to provide an accurate and global description of the ballistic curves. All numerical

results in terms of ballistic curves, failure modes, the energy absorption balance and failure time are presented and discussed in the next sub-section.

5.2 Numerical results and discussion

The results obtained from the numerical predictions in terms of ballistic curves $V_R - V_0$ are compared to experiments for each projectile and are presented in *Fig. 14*. A small difference is observed for impact velocities close to the ballistic limit. At impact velocities greater than the ballistic limit ($V_0 \geq 100 \text{ m/s}$), a good agreement with the experimental results is generally obtained.

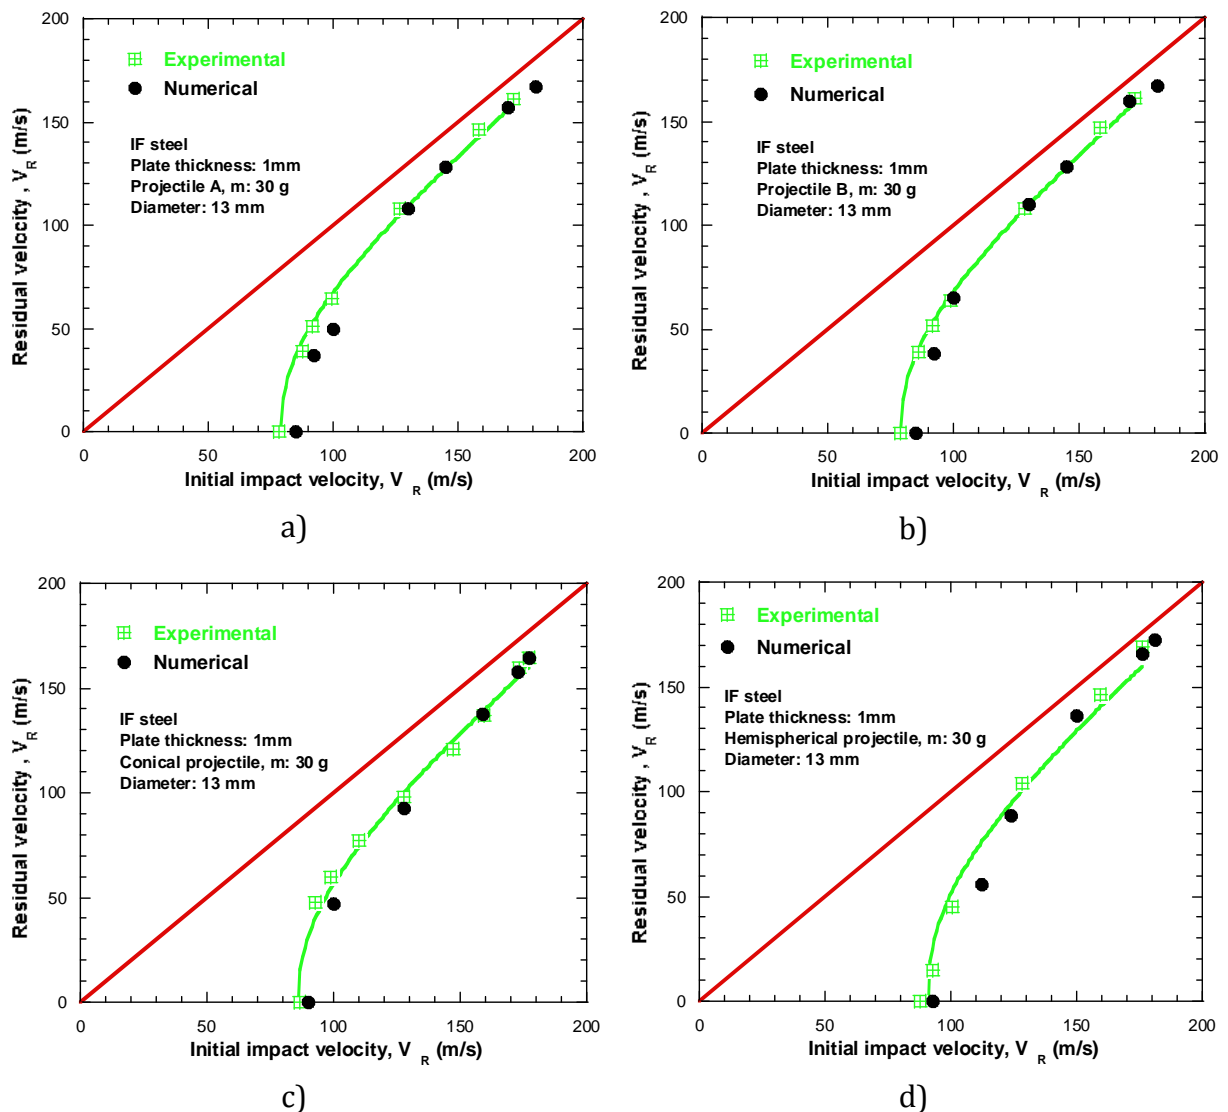

Fig. 14. Definition of the ballistic curve, comparison between experiments and numerical simulations. a-Projectile A; b-Projectile B; c-Conical projectile; d-Hemispherical projectile.

Numerical predictions of the ballistic limit velocities are 85 m/s for projectile A, 86 m/s for projectile B, 90 m/s for the conical projectile and 93 m/s for the hemispherical projectile. The ballistic curves of projectile A and B are almost the same, with their ballistic performance improved by the double nose shape.

The failure time was also estimated numerically using the same definition as in the experiments. The comparison is illustrated in Fig. 15, showing a decreased failure time in increased impact velocity for all shapes of projectiles. This is reasonable because the higher the impact velocity is, the less time the process of perforation takes.

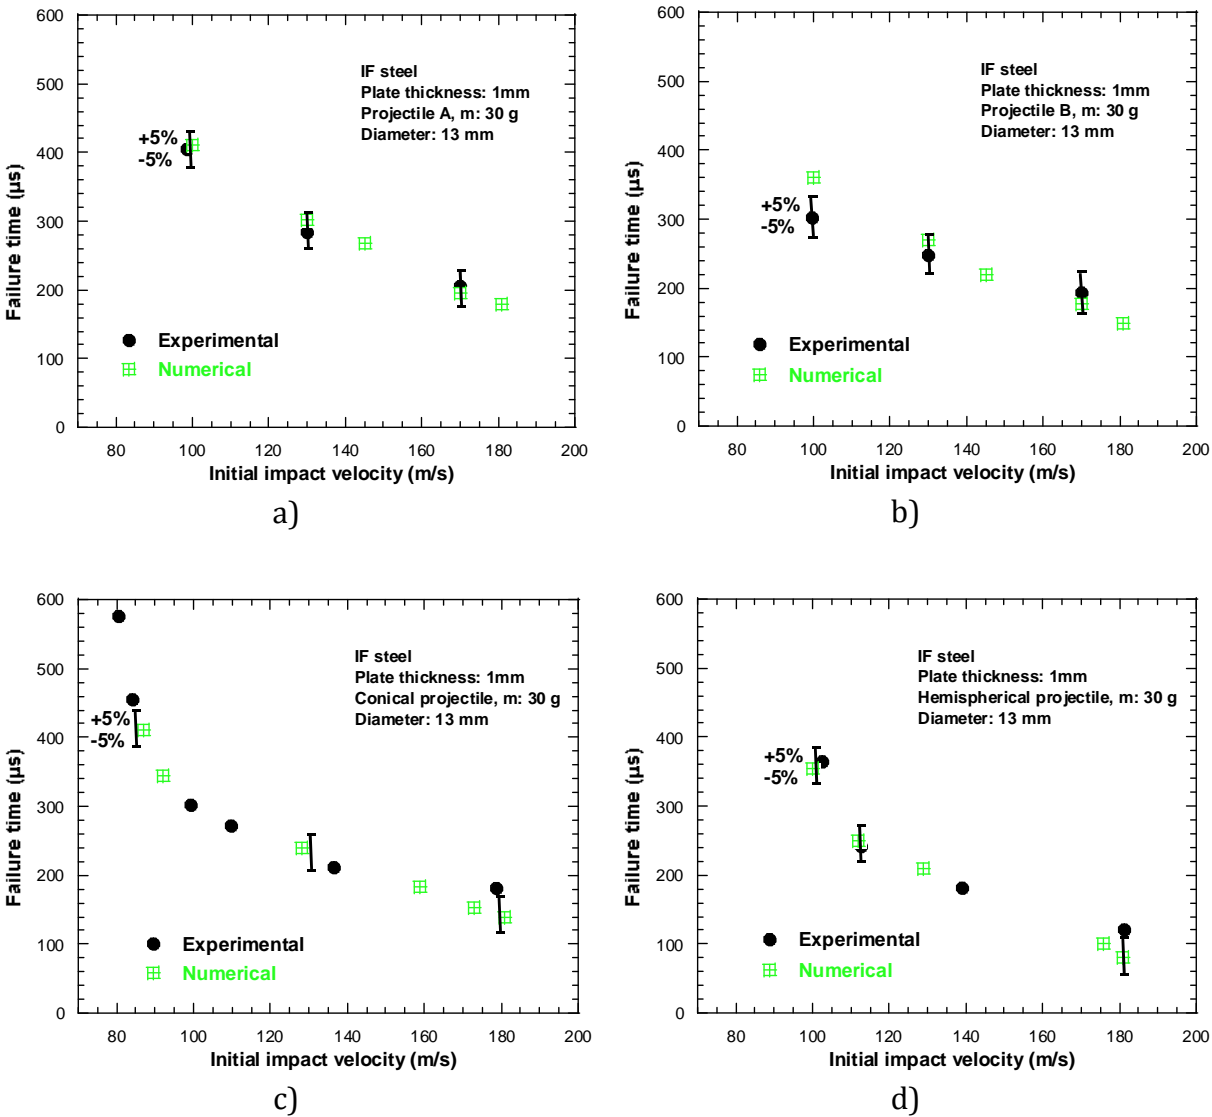

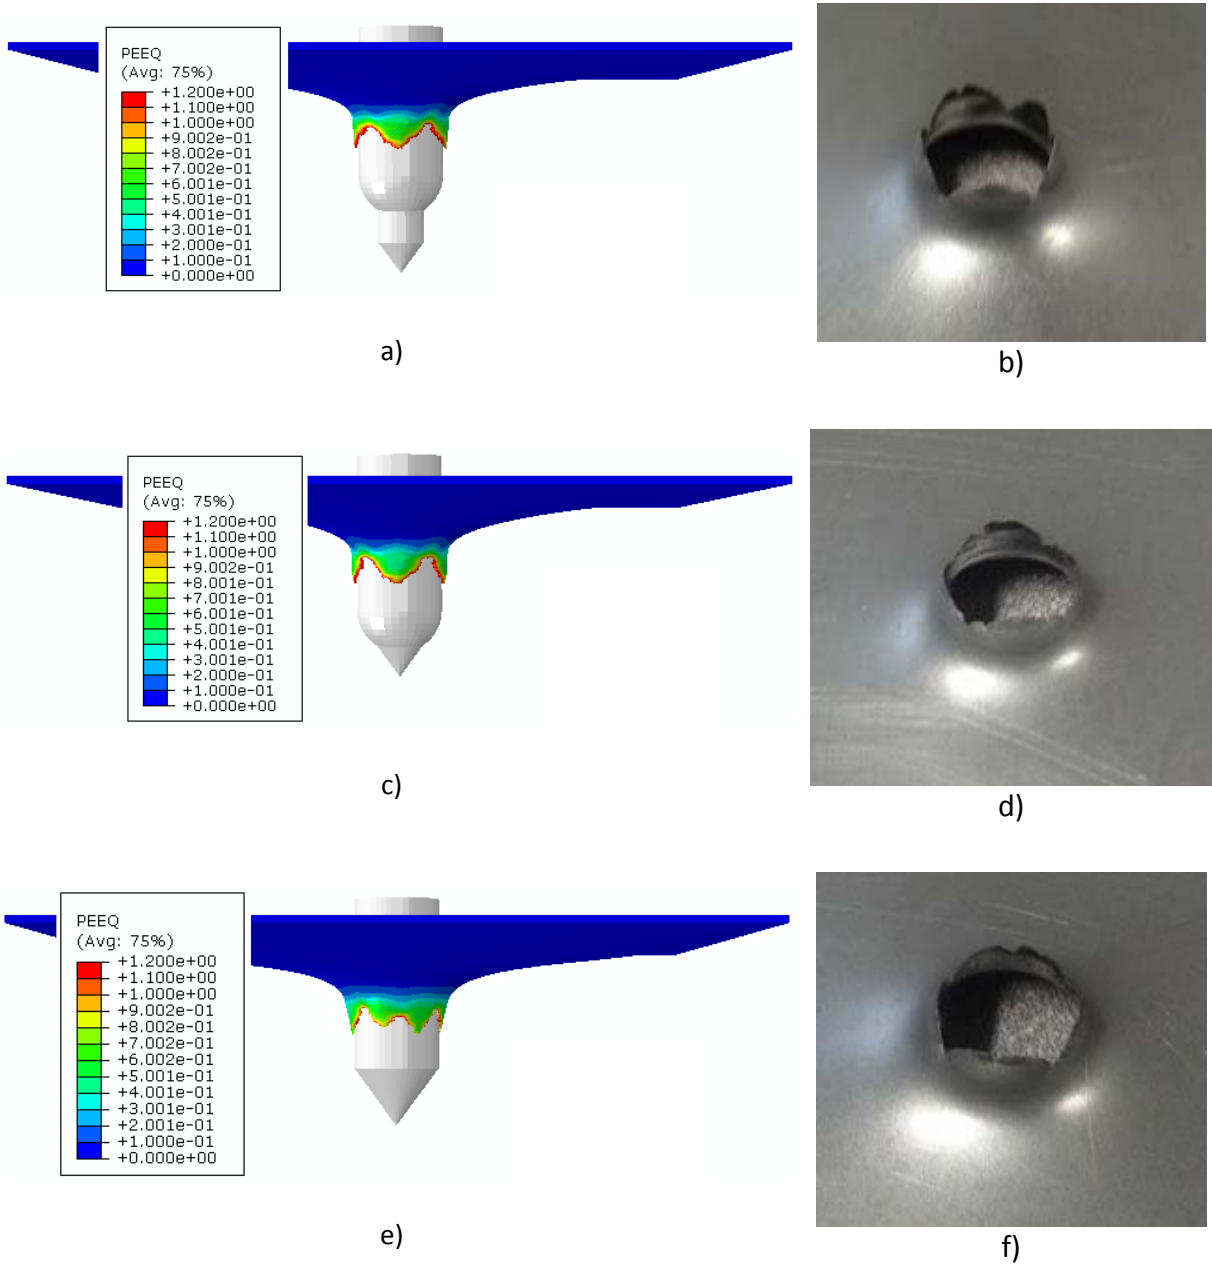

Fig. 15. Failure time as a function of initial impact velocity, numerical results compared to experimental ones. a- Projectile A; b- Projectile B; c- Conical projectile; d- Hemispherical projectile.

There is a good agreement between the numerical predictions and experiments. The errors are less than $\pm 5\%$. At a fixed impact velocity, projectile B takes less time than all other projectiles to perforate the plate, followed respectively by the conical projectile, projectile A and the hemispherical projectile.

All failure modes obtained experimentally were reproduced numerically, shown in Fig. 16. Numerical results show a failure mode by petals forming for conical projectile as well as projectiles A and B. For the hemispherical projectile, a plug ejection failure mode was obtained. The petals formed by projectiles A and B are broader, and those by a conical projectile are more pointed. It is also believed that it is the conical nose of the projectiles A and B which governs the failure of the target.

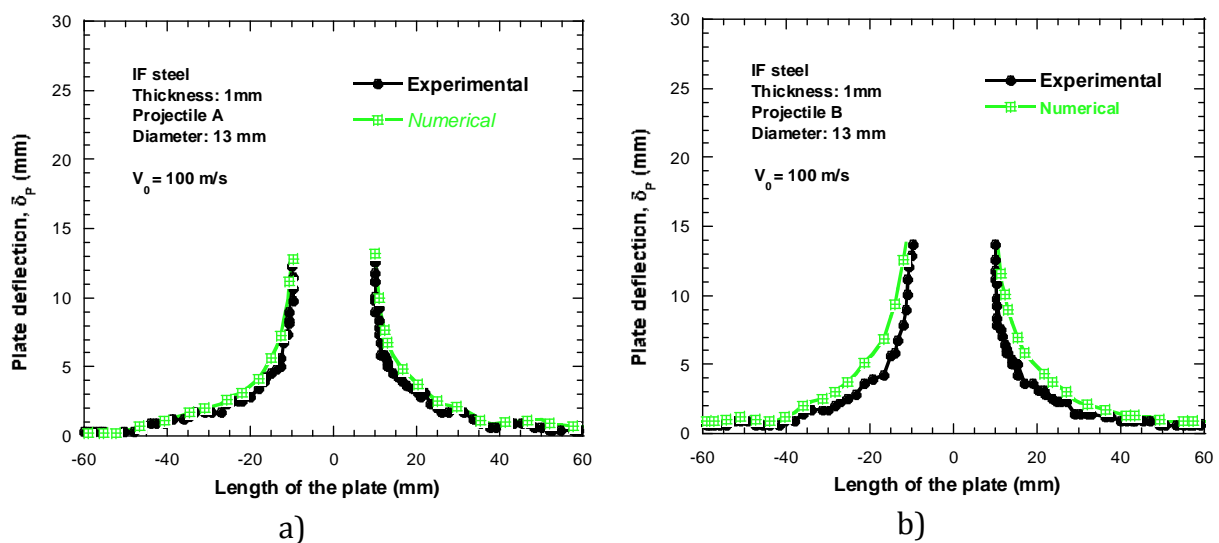

Fig. 16. Comparison between the failure modes obtained numerically and experimentally. a- Projectile A, numerical; b- Projectile A experimental; c- Projectile B, numerical; d- Projectile B, experimental; e- Conical projectile, numerical; f- Conical projectile, experimental; g- Hemispherical projectile, numerical; h- Hemispherical projectile, experimental.

The pictures in Fig. 16 clearly show that the numerical models qualitatively reflect the overall physical behavior of the plate during the impact and perforation. A localization of the plastic strain is noted at the ends of the petals in the case of the conical projectile as well as projectiles A and B, but in the zones of the necking for the hemispherical projectile. The maximum equivalent failure strain corresponds to that set by the failure criterion for each projectiles shape.

We also measured the overall deflection of the plate for each projectile shape. The comparison between experimental and numerical results is presented in Fig. 17. The numerical simulation is in perfect agreement with the experiment. The maximum deflection measured is 14 mm for the case of the conical projectile due to the petals and the minimum is 12 mm for the hemispherical projectile. Because the thickness of the plate is low (1mm) compared to the diameter of the projectile (13mm), the deflection of the plate does not change significantly with the impact velocity when it is greater than the ballistic limit.

6. Conclusions

Experimental and numerical investigations have been made on an IF steel subjected to impact and perforation loading. Material tests were performed to determine the material constants for the constitutive relation proposed by Rusinek and Klepaczko [1] **to take into account hardening, strain rate and temperature sensitivities**. Four different shapes of projectile were considered in this work such as a conical, a hemispherical and two double nose (combination of conical and hemispherical shape) projectile. The ballistic limit for each projectile shape was determined and the ballistic curves plotted. It is found that the ballistic limit, the failure mode and the energy absorption capacity of the target are strongly linked to the projectile nose shape. Energy absorbed by the perforated structure is dissipated by its overall deflection, the elastic deformation and plastic deformation in the localized impact area. The hemispherical projectile is the least efficient to perforate the target followed respectively by the conical projectile, projectile B and A. This observation is confirmed by measuring the failure time of the target using a high speed camera. Indeed, at a giving impact velocity, the projectile A takes less time to perforate the target, followed respectively by projectile B, conical and hemispherical projectile. A numerical analysis of the impact problem has been made using the finite element code ABAQUS/Explicit. The mechanical behavior of the target material has been implemented in the code using the RK constitutive relation. The results obtained from the numerical part were compared to experiments and a good agreement is observe in terms of failure mode, ballistic limit, ballistic curves, energy absorbed by the target and the global deflection of the target.
