Abstract

This paper integrates archaeological, material, microstructural and compositional data of c. 7000 years old metallurgical production evidence with the aim to address the knowledge of the world's earliest metalworkers. The main focus is placed on copper minerals, ores, slags, slagged sherds and metal droplets coming from four Vinča culture settlements in Serbia and Bosnia and Herzegovina: Belovode, Pločnik, Vinča and Gornja Tuzla, all dated between c. 5400 – 4400 BC. Chemical study of copper minerals throughout all sites points at striking uniformity in selecting black and green minerals from the early days of the settlements' occupation, some of which predate the metal smelting events. Microstructural examination of metal production debris showed convincing technological similarity throughout c. six centuries of copper making in the studied sites, as well as a consistent choice of black and green ores for metal extraction. We argue that black and green ores were intentionally selected as ingredients for the metal smelting 'recipe' in the early stages of Balkan metallurgy based on the knowledge related to their characteristic visual aspects. This finding demonstrates how important the adequate combination of colours was for the early copper metalworkers and suggests a unique technological trajectory for the evolution of metallurgy in this part of the world. It also illustrates the capacity that micro-research carries in addressing the how and why of the emergence of metallurgy, and outlines a methodology for future studies of early metallurgies worldwide.

Keywords: *Vinča culture; Balkans; metallurgy; copper slag; technology; colour*

1. Introduction

Studies of prehistoric metallurgy have mostly concentrated on the *impact* metal artefacts had on consumer societies. Extensive scholarship has been devoted to the role of metallurgy in the rise of social complexity, history of warfare, or building broad chronologies for later prehistory worldwide. However, studying ancient metallurgy goes beyond the typological, stylistic and functional analysis of objects or their distribution, as these represent only some of the building blocks for understanding the *knowledge* of

1
2
3
4 metal production. Such knowledge is inherently related to the perception of *immanent* properties of both
5 metal artefacts and components required to make them.
6

7 The unchanging properties of matter, and the physical laws and principles by which they operate are
8 immanent in the material universe. The recognition of these properties, such as a mineral colour, smell or
9 taste, and the physical laws by which they can be manipulated to a particular purpose are usually
10 constrained by social, technological and environmental circumstances within a given time (Simpson
11 1963). Cyril Stanley Smith (1981) was among the first to recognise that the origins of technological
12 breakthroughs (such as metallurgy) was motivated more by appreciation for colour, acoustic properties,
13 scent, or reflectance of materials than by the pursuit for better tools or weapons. As he noted, the ‘desire
14 to beautify the utilitarian has always stretched the ingenuity of the mechanics’ (Smith 1981, p. 330).
15
16
17

18 The sensory experience of materials has therefore been accordingly acknowledged in the literature and
19 emerged as the key area of interest in the studies of material culture. The term *materiality* has been most
20 commonly used in scholarship to encompass these immediately perceptive aspects of an object together
21 with the social connotation of its use (cf. Jones 2004, p. 330). Perhaps the most popular definition of
22 materiality is put forward by Boivin (2008, p. 26), who considers materiality as the *physicality* of the
23 material world, since it has dimensions, it resists and constraints, and it offers possibilities for the
24 (human) organism as outlined by a set of physical properties. Nevertheless, the use of this term has been
25 burdened with its own intellectual luggage, carried over from the times [when it served to show](#) that
26 material culture has had a profound impact on the social world (Gosden 2005, p. 185). Furthermore, for
27 scholars coming from the worlds of both archaeology and materials science, like us, the term materiality,
28 as defined by its use, lacks the depth for the resolution of evidence we are looking at.
29
30
31
32

33 While we acknowledge that physical properties of a finished object, together with its dimensions of use,
34 and material advantages and limitations constitute an object’s materiality, we also believe that the route to
35 its final shape, or the production process, provides crucial complementary information to this concept. It
36 is the properties of raw materials, [their](#) acquisition and preparation, as well as manufacturing techniques
37 that hold information inherent to the appearance and value of the produced object (cf. Smith 1981). We
38 hold that the study of immanent properties of all material components involved in the object making
39 within a given context can contribute to an insightful account of the knowledge applied in its production,
40 and is as important as the final form an object takes. We thus argue that the concept of materiality is short
41 of this ‘organic’ dimension, which makes it unsuitable for the scope of our study presented here. What we
42 aim to demonstrate is that only [an](#) understanding of immanent properties of all production components
43 interacting within specific historical circumstances can shed light on the *how* and *why* of an object’s
44 making in an archaeological inquiry.
45
46
47
48

49 Archaeometric studies have long identified the importance of understanding the interaction of physical
50 properties of materials and social practices involved in their manufacture (e.g. Sillar and Tite 2000; Tite et
51 al. 2001; Jones 2004; Martínón-Torres et al. 2007; Martínón-Torres and Rehren 2009; Killick and Fenn
52 2012). Sillar and Tite (2000) address this interaction with the idea of ‘embedded technologies’, which
53 stands for the wider contextualisation of techniques within cultural and environmental surroundings. A
54 good ethnographic example is provided in the study of Shona iron smelting furnaces, which demonstrated
55 that the surface appearance of their furnaces is not as powerful as the material transformations taking
56 place inside them (Schmidt 2009, p. 279). A powerful set of recorded rituals surrounding the smelting
57
58
59
60

1
2
3
4 activity unveiled the supremacy of the interior material transformation, and pointed at the analytical
5 potency of all evidence coming out of an activity [such as metal making](#).
6

7 Many ethnographers made the connection between distinctive colours, brilliant surfaces and ritual power
8 and potency (Chapman 2007a). Art, technology and aesthetics have already been addressed within a
9 technical system called ‘the technology of enchantment’ (Gell 1992). Enchantment is acknowledged as
10 associated with technology, as its various dimensions have the power to ‘enchant’ during ceremonial or
11 commercial gift exchange, or rituals. The power of artistic objects is particularly distinctive when it
12 comes to their outer appearance, such as colour, or shine. An excellent example of integration of
13 aesthetics and archaeometric techniques is provided by Hosler (1994), who explored the significance of
14 aesthetics [and sound in metal use in historic west Mexico and discussed how those shaped the](#)
15 [Mesoamerican worldview](#).
16
17
18

19 Post-medieval crucible production is another example that pointed out the importance of sensory aspects
20 during the production steps, when choosing a suitable type of clay for crucible making (Martinón-Torres
21 and Rehren 2009). Archaeometric analysis revealed that the reputable endurance of Hessian and Bavarian
22 crucibles was due to particular properties of naturally occurring clays as well as [their](#) manipulation during
23 the firing process. Martinón-Torres and Rehren (2009, p. 69) argue that the potters must have been aware
24 of the qualities of this particular clay, such as its colour, texture, plasticity, taste or smell, and opted for
25 the right combination of these aspects when choosing the raw material for their crucibles. It was therefore
26 the complete sensorial aspect of the raw material, in addition to its colour, that shaped potter’s preference
27 for a particular type of clay.
28
29
30

31 Both studies, and the latter in particular, indicated novel research avenues for the application of material
32 science in addressing the reasoning behind [an object](#) making. Significantly, what emerged to be an
33 important part for understanding the process of object making, besides manufacturing steps, colour and
34 mechanical properties of the produced artefacts is the physics of the production process and the
35 constraints imposed by it (cf. Vincenti 2000; Roux 2010; Charlton et al. 2010). Coming back to the
36 importance of understanding immanent properties of materials, we need to acknowledge the historical
37 manifestations of particular combinations of these immanent processes, or *configurations*. The crucial
38 distinction here is between timeless (immanent) and particular (configurational) properties of an observed
39 phenomenon, which always act together (Simpson 1963; Wolverson and Lyman 2000). This is where we
40 believe the key lies to assessing the knowledge of particular processes, such as early copper smelting. By
41 identifying immanent properties of materials and processes involved in early copper smelting and their
42 particular combination at a given time in (pre)history, we can gain the information on this specific
43 (configurational) development at the time.
44
45
46
47
48

49 The *when* and *where* of (extractive) metallurgy has been attracting scholarly attention for decades. The
50 discovery of [the c. 7000 years old](#) copper smelting debris in the Vinča culture settlement of Belovode in
51 eastern Serbia showed that one of the origins of metallurgy can be sought in the heart of the Balkans,
52 besides the traditionally proposed locations in the Near East, [where copper smelting activities are argued](#)
53 [as roughly contemporaneous, following on from a long practice of malachite bead making](#) (for discussion
54 see Roberts et al. 2009; Thornton 2009; Radivojević et al. 2010). Thus, this discovery revived the theory
55 of multiple origins of metallurgy, indicating that it was invented in at least three places in the world: the
56
57
58
59
60
61
62
63
64
65

1
2
3
4 Balkans, the Near East and the Americas, and possibly elsewhere (e.g. Murillo-Barroso and Montero-
5 Ruíz 2012; Roberts and Thornton 2014).
6

7 While the main focus in the ongoing debates of single vs. multiple inventions of metallurgy still rests on
8 finding ‘the earliest’ evidence for metal production, it overlooks the immense capacity of technological
9 studies to reveal how independent the knowledge of metallurgy was. The case study on the early
10 development of Eurasian metallurgy presented here will therefore address both immanent and
11 configurational aspects of the world’s earliest known metal production and attempts to provide a more
12 comprehensive assessment of the 5th millennium BC metal production technology in the Vinča culture,
13 taking into account four settlements: Belovode, Vinča-Belo Brdo, Pločnik and Gornja Tuzla (Fig 1). In
14 this study, the emphasis is set on *extractive technology* only, as it is a crucial aspect for discussing the
15 evolution of metal production technology and its independence from potentially contemporary
16 developments elsewhere. Microstructural and compositional studies of copper minerals, slags and slagged
17 sherds, and metal droplets, demonstrate common principles of the Vinča culture copper smelting
18 technology as well as sustained metallurgical activities that span c. 600 years.
19
20
21
22

23 The Balkans in the 5th millennium BC are a particularly good case study for this, since the preference for
24 brilliance, colour aesthetics, precision and geometric thinking dominates the material culture at the time
25 (Chapman 2011). Well-executed craftsmanship, bold colours, dramatic shapes and symmetrical design
26 can be encountered together in single objects in the 5th millennium BC Balkan material culture. For
27 instance, a high degree of standardisation is seen in the production of flint blades from the Bükk culture
28 (Vértes 1965), remarkable geometric precision in the pottery of the Cucuteni-Tripolye culture (Washburn
29 and Crowe 2004), spectacular craftsmanship in the gold-decorated vessels in the Varna I cemetery
30 (Ivanov 1988), and outstanding painting techniques in the silver-sheen of graphite-painted pottery of the
31 Karanovo-Gumelnița-Kodžadermen VI cultural complex (Todorova and Vajsov 1993). The preference for
32 black in particular has been argued to be the major factor for the emergence of black-burnished ware,
33 which was mainly favoured by the Vinča culture communities (Chapman 2006, 2007a). This colourful
34 aesthetics of the Late Neolithic/Chalcolithic Balkans has its roots in the Mesolithic (Chapman and Richter
35 2009; cf. Srejović 1972), when such a view first constituted a central role in the culture of living and
36 dwelling (Chapman 2007b). Therefore, the antecedent aesthetics was a crucial prerequisite for the
37 introduction of copper and gold, both of which substantially contributed to the increase in the colour
38 spectra of artefacts discovered predominantly in mortuary contexts (Chapman 2002). Importantly, this
39 preference for colour and brilliance also goes beyond the primary region of interest here, and includes
40 farming communities of Greece and northwest Anatolia.
41
42
43
44
45
46

47 The dazzling objects from the 5th millennium BC Balkans are interpreted as serving one unifying role: to
48 ‘enchant’ the audience with the technological craftsmanship involved in their production (Chapman
49 2011). Our particular interest here, however, is not to elaborate on the brilliance of finished artefacts (e.g.
50 copper implements), but to understand the immanent and configurational properties of its production in
51 the light of the attested preference for aesthetics among the Balkan communities in the 5th millennium
52 BC, and in particular the Vinča culture population.
53
54
55
56

57 **2. Studied sites**

58
59
60
61
62
63
64
65

1
2
3
4 All four sites studied here belong to the Vinča culture, a Late Neolithic / Early Chalcolithic
5 phenomenon which lasted for nearly a millennium in the largest part of the northern and central Balkans
6 (e.g. Garašanin 1973; Chapman 1981) (Fig 1). We follow the periodisation of this culture developed by
7 Milošević (1949) based on distinctive ceramic typology, using alphabetic letters (Vinča A-D, with
8 subdivisions). The estimated duration of the Vinča culture is c. 5400/5300-4650/4600 BC. The start of the
9 Vinča A phase is recognised as c. 5400/5300 BC, while Vinča B starts around 5200 BC. The highest
10 probability end for Vinča B1 is c. 5000/4950 BC; this marks the beginning of the Gradac Phase (Vinča
11 B2), which probably lasted for c. 50-100 years. Vinča C lasts from c. 4900 to c. 4850/4800 BC, while the
12 abandonment of the Vinča culture settlements at the end of Vinča D falls around 4650/4600 BC (Borić
13 2009, p. 234). The Gradac phase within the Vinča culture is particularly interesting, as it marks the
14 occurrence of metal artefacts in the settlements, different settlement patterns and a change in material
15 culture (i.e. decline in stone tool production, or different production trends in pottery making), amongst
16 other observed changes (e.g. Garašanin 1995).

17
18
19
20
21 The Vinča culture material shows strong links to the contemporaneous Karanovo culture (phase III
22 through to Kodžadermen-Gumelnița-Karanovo VI) in Bulgaria, Precucuteni-Tripolye A in Moldavia and
23 Ukraine, and Dimini in Greece. The most distinctive links, amongst others, are noticed in settling
24 patterns, pottery production and the earliest industrial-scale production of metal objects in this part of the
25 world. Almost five tonnes of extant copper implements from the 5th millennium BC Balkans are known
26 today, comprising an estimated 4300 objects in numerous museum collections (Chernykh 1978; Pernicka
27 et al. 1997; Ryndina 2009). These artefacts occur in typologically distinctive shapes and are made from
28 copper from several Balkan deposits (Schubert 1965; Kuna 1981; Pernicka et al. 1993; 1997).

29
30
31
32 The Balkans have also yielded the earliest evidence for copper exploitation in the world, at the mining site
33 of Rudna Glava, spanning the entire duration of the Vinča culture from c. 5400 BC until c. 4650 BC
34 (Borić 2009, p. 205-206). More recently, in the hinterlands of the Rudna Glava mine, at the site of
35 Belovode in eastern Serbia, copper production evidence dated to c. 5000 BC was uncovered. The
36 provenance studies pointed at the potential exploitation of local sources, however not Rudna Glava
37 (Pernicka et al. 1993; Radivojević et al. 2010, p. 2781 ff.). A longer gestation period of copper mineral
38 use prior to copper smelting in the Vinča culture has been acknowledged in previous research (e.g.
39 Chapman and Tylecote 1983; Antonović 2006), which is also demonstrated in case studies presented
40 below (Radivojević and Kuzmanović-Cvetković 2014). Thus, the distinctive typology and quantity of
41 metal artefacts, locally sourced ores and well-documented copper smelting evidence reinforced the idea of
42 the independent origins of metallurgy in the Balkans (Renfrew 1969; Jovanović and Ottaway 1976;
43 Radivojević et al. 2010).

44
45
46
47
48 Nevertheless, the sparse quantity of evidence for copper smelting in Belovode (c. 5 g copper slag were
49 known prior to this research) (Radivojević et al. 2010, p. 2779) does not correspond to the vast amount of
50 heavy copper implements, nor does it explain why the currently earliest metallurgy in the world happened
51 in a location remote from the Near East, traditionally considered as *the* metallurgical heartland (see most
52 recent review in Roberts et al. 2009). In order to address this question, the archives of several excavated
53 Vinča culture sites were carefully searched for materials related to ancient metallurgy, and further metal
54 production evidence was discovered from the settlement excavations of Belovode, Vinča-Belo Brdo,
55 Pločnik and Gornja Tuzla.

1
2
3
4 The site of *Belovode* lies on a windy plateau near the village of Veliko Laole, c. 140 km southeast of
5 Belgrade. It covers an estimated c. 80 ha and the entire duration of the Vinča culture (Radivojević et al.
6 2010, p. 2778-9; Borić 2009, p. 209). Of particular importance here is the dating of the earliest
7 stratigraphic evidence for extractive metallurgy, which starts at around 5000 BC, corresponding with the
8 beginning of the Gradac Phase (Vinča B2). Copper mineral use occurs from the earliest horizons in this
9 site (at c. 5350 BC), and continues throughout the entire occupation. Several kilograms of small-sized,
10 possibly beneficiated copper minerals were uncovered thus far in excavations covering less than one
11 percent of the settlement size; the greatest majority of these minerals are black-and-green and are the
12 focus of research presented below. All materials related to metal production come from domestic contexts
13 (Šljivar et al. 2006), and mostly from a single trench (No. 3). It includes copper slags, slagged ceramic
14 sherds (see Table 1) and a copper metal droplet (M6). These were recovered from a wide and deep
15 depression, mixed with several thousand fragments of ceramic sherds, bones and charcoal, and sealed by
16 a layer of building waste. A single copper mineral (M10) from this trench studied here was found in the
17 earlier building horizon and therefore precedes the copper smelting evidence. The other three minerals
18 studied here also come from domestic contexts from trenches near Trench No. 3 (Radivojević and
19 Kuzmanović-Cvetković 2014)(also Table 1).
20
21
22
23
24

25 *Vinča-Belo Brdo* lies on a plateau located on the right bank of the Danube, in the modern village of
26 Vinča, c. 16 km southeast from Belgrade and covers 10 hectares on the loess terrace. The Vinča culture
27 occupation started at c. 5300 BC (phase A) and ended around 4650-4550 BC (Borić 2009, p. 232). The
28 Gradac Phase starts c. 4950 BC, similarly to the site of Belovode. All metallurgy-related materials
29 originate from domestic contexts from the latest phase of occupation, Vinča D, dated between c. 4770 BC
30 and c. 4600 BC. The four samples studied here come from three artificially defined ‘horizons’ within
31 Vinča D, and only a few meters apart from each other (Tasić 2003-2009). A copper mineral (Vinča 99)
32 and a copper slag (Vinča 79) are the only two contextually directly related samples, discovered outside a
33 dwelling feature and in the vicinity of two features with evidence of intense heating (Table 1). The two
34 slag samples from Vinča (79 and 91) very likely represent debris from contextually different events.
35
36
37
38

39 The site of *Pločnik* is on the left bank of the Toplica river, 19 km west from Prokuplje in south Serbia and
40 spreads across an estimated 100 ha (Šljivar et al. 2006). This settlement is best known for the discovery of
41 34 massive copper metal implements; a distinctive type of the earliest European hammer axes is called
42 after this site. The highest probability for the start of the Pločnik occupation is around 5200 BC, and its
43 end at c. 4650 BC. The *terminus ante quem* for the appearance of metal artefacts in Pločnik is set between
44 c. 5040-4840 BC based on the dating of a structure that preceded the finding of a fragmented copper
45 metal implement from recent excavations (Borić 2009, p. 214).
46
47

48 The use of copper minerals is evident from the early formation of this site: green lumps and pieces of
49 copper minerals are found scattered across the settlement in the same manner as in Belovode, usually
50 outside potential dwelling features in so-called *workshop* areas. Six copper minerals in total have been
51 selected for this study (Table 1) two of which (71, 72m) come from the copper metal workshop in Trench
52 No. 20, which belongs to the Gradac Phase (Šljivar and Kuzmanović-Cvetković 2009, p. 61). Other
53 copper minerals (51, 54m, 57, 209) were sampled in order to provide information on their use in the
54 earlier phases of Pločnik occupation. A copper metal droplet (Pločnik 52) originates from Trench No. 14,
55 a few meters away from the metal workshop in Trench No. 20. It was uncovered on the floor of a
56 collapsed burnt structure discovered in spits 10-11 and directly dated between c. 5040-4840 BC (Borić
57
58
59
60
61
62
63
64
65

1
2
3
4 2009, p. 214; Radivojević and Kuzmanović-Cvetković 2014). As such, it precedes the find of a
5 fragmented copper implement in this trench and represents the earliest dated metal artefact in the site of
6 Pločnik.
7

8
9 *Gornja Tuzla* is a prehistoric settlement located on the terrace of the Jala river, which runs through the
10 modern city of Tuzla, in Bosnia and Herzegovina, and spreads over an estimated 12-15 ha (Čović 1961).
11 Two radiocarbon dates for the Vinča culture occupation published in the 1960s (Vogel and Waterbolk
12 1963, p. 183; Quitta and Kol 1969) and combined in OxCal (ver. 4.2b4) produce peaks around 4450 and
13 4410 cal BC (Radivojević 2012). However, the most recent excavations in this site yielded material dated
14 a few centuries earlier (pers.comm. M. Vander Linden); it remains to be seen how these new dates relate
15 to the earlier excavations that bore archaeometallurgical materials. The 1950s excavations of a single
16 trench unearthed a collection of twenty metallurgy-related finds belonging to the later phases of the Vinča
17 culture (Vinča C-D), of which three were selected for this study (Table 1). The collection includes a
18 slagged ceramic sherd (GT 182a/b), a slag (?) sample (GT 194) and a copper metal droplet (GT 190), all
19 discovered in domestic contexts of stratum II (Čović 1958), following on from the stratum III dated at c.
20 4400 BC.
21
22
23

24
25 Overall, the Vinča culture copper production evidence emerges in the beginning of the 5th millennium
26 BC, usually in the building horizon of the Gradac Phase. In Belovode and Pločnik, metal production
27 activities can be dated from c. 5000 BC until the sites' abandonment at around c. 4650 BC. The
28 production evidence from Vinča-Belo Brdo originates from three different domestic contexts dated to the
29 end of the Vinča culture (Vinča D), between c. 4770 BC and 4650/4550 BC, while the Gornja Tuzla
30 samples can only be dated approximately to around c. 4400 BC. The copper mineral use, on the other
31 hand, occurs from the very beginning of the occupation at both Belovode and Pločnik and pre-dates the
32 metallurgical finds by a few centuries.
33
34
35

36 37 38 **3. Material and methods** 39

40
41 The research material presented here consists of 26 samples selected from c. 1000 relevant pieces
42 stored in various collections in the National Museum and the Faculty of Philosophy (both in Belgrade,
43 Serbia) and the Land Museum in Sarajevo (Bosnia and Herzegovina). This selection of samples
44 complements five more copper slag samples from Belovode, previously studied by Radivojević (2007)
45 and published in Radivojević et al. (2010). More than half of the selection presented here consists of
46 copper slags, slagged sherds samples and metal droplets; the rest are copper minerals (Table 1). In
47 comparison with the amount of technological debris (and slags in particular) in later prehistory periods,
48 the sample size in this study is small. However, it targets a crucial period for the evolution of metallurgy
49 in Europe, and as a coherent assemblage is unprecedented in size, quality and chrono-spatial resolution.
50
51

52
53 All copper minerals studied here are recognised as only potentially representing copper ores. *Ore* is
54 understood as a culturally defined term referring to agglomerations of minerals from which the extraction
55 of one or more metals is seen as a profitable action (Rehren 1997; Rapp 2009). The importance of this
56 distinction of copper minerals in the context of metallurgical activities has already been recognised by
57 Muhly (1989, p. 6), who noted that the presence of malachite at an archaeological site has little to do with
58
59

1
2
3
4 copper metallurgy, as much as the presence of haematite in a cave painting context has nothing to do with
5 iron metallurgy. In the Vinča culture, this non-metallurgical use of malachite manifests itself in a large
6 bead industry, pre-dating copper smelting by up to c. 350 years (Radivojević 2012; Radivojević and
7 Kuzmanović-Cvetković 2014).
8

9
10 Therefore, depending on the nature of activities involved in mineral processing, the term ‘cold’ is
11 reserved to describe techniques borrowed from the lithic industry for bead making, while the term ‘hot’
12 denotes finds related to high-temperature processes of primary metal production (examples in Fig 2). The
13 rationale for a distinction between bead mineral and malachite ore has been developed as part of the
14 previous study on material from Belovode, which identified compositional (and provenance) differences
15 between the two (Radivojević et al. 2010, p. 2784). Namely, the malachite beads from the sites of
16 Belovode were made exclusively from pure green malachite, as were the beads from the sites of Pločnik
17 and Vinča, too (Radivojević 2012; Radivojević and Kuzmanović-Cvetković 2014); this stands in contrast
18 to black and green malachite used as ore in the Belovode smelting events. Thus, our working hypothesis
19 for copper minerals coming from the Vinča culture sites with attested metal production assumes that those
20 destined for bead making and copper smelting respectively would potentially differ in composition.
21
22

23
24 *Slag* is ideal for studying past pyrometallurgical activities because it typically contains information of all
25 components contributing to its formation. Slag chemistry preserves information on physic-chemical
26 conditions of the smelt, indicates which metal was extracted, the contribution of ores, associated clay, fuel
27 ash, potential fluxes or even the design of s/melting installations (Bachmann 1982; Rehren et al. 2007).
28 Early slags are typically found as either free pieces or attached to ceramic / installation walls. Often the
29 slags from early periods were crushed in search for metallic prills for further refining (e.g. Ottaway 2001),
30 making them archaeologically less visible.
31
32

33
34 A total of six free slag pieces are studied here in addition to those from Belovode published earlier,
35 bringing the total slag assemblage from this site to just under 10 grams. They are vitrified, strongly
36 magnetic and green-stained droplets, not exceeding 1 cm in length (Fig 3). They appear to have been
37 highly viscous and very rich in copper metal; however, no visible signs of crushing in pursuit of metal
38 prills were detected. These slag pieces outwardly resemble malachite, as a result of the corrosion of the
39 copper metal entrapped in them. It is therefore possible that the green colour facilitated their recognition
40 in the field excavations, leading to a biased recovery in favour of more copper-rich pieces and
41 overlooking those without green staining. Thus, one could assume that more slag samples may have gone
42 unnoticed in the dark brown soil in the field (Radivojević et al. 2010, p. 2779).
43
44
45

46 *Slagged sherds* are pieces of pottery with metallurgical slag spilt over them (Fig 3). In examples from
47 Belovode, the concave surface is visually unaffected by exposure to heat beyond the initial firing
48 temperature, as opposed to the convex surface, which is entirely or partially bloated and stained with a
49 mass of green and grey appearance. Bloating often continues on the broken sections of the sherds,
50 indicating an already fragmented state of the sherds when the heat was applied. The four slagged ceramic
51 sherds from Belovode come from two consecutive spits (Nos. 5 and 6) in Trench No. 3. They are
52 probably from two different vessels (Fig 3) and most likely originate from the same smelting event,
53 judging by their clustering in the field. Our assumption is that these sherds were used to line a hole in the
54 ground in order to insulate the smelting process against moisture from the soil and prevent the bottom of
55 such an installation of running cold during the extraction process. Samples 30a and 30c are two body
56
57
58
59

1
2
3
4 sherds of similar thickness, c. 1.5 cm, and not exceeding 2 cm in the longest section. A flat body sherd
5 (Belovode 31a) and a vessel rim (Belovode 31b) were discovered together and most probably belong to
6 the same ceramic vessel with c. 1 cm thick walls. Both samples are heavily vitrified and topped with a
7 grey mass which contains small green-stained droplets. They have an almost triangular shape, with the
8 longest section bloated from contact with temperatures higher than the initial clay firing (Fig 3).
9

10
11 A similar example comes from Gornja Tuzla. GT 182a is a 5 mm wide piece of light brown ceramic with
12 green and grey stains on its bloated side; it was attached to a larger piece of slagged ceramic (GT 182b),
13 which is c. 1 cm thick, with inner rims and sections partially affected by heat exceeding the initial firing
14 temperature (Fig 3). The heavily vitrified surface of an old break is stained with a green and grey mass,
15 implying that this sample was used when it was already fragmented, and, as in Belovode, is not part of a
16 crucible / container, but of a sherd-lined hole-in-the-ground smelting installation. The striking similarity
17 of the Gornja Tuzla and Belovode slagged sherds suggests similar technological principles for the Vinča
18 culture smelting installations.
19

20
21
22 *Copper metal droplets* selected for this study come from all four sites. In the sites of Belovode and
23 Pločnik these samples were initially mistaken for copper minerals and selected only for their origin from
24 ‘metallurgical’ trenches (M6 in Belovode and 52 in Pločnik). Their metallic structure was only revealed
25 upon sectioning; they are included here due to the fact that they most likely demonstrate primary copper
26 extraction, or smelting. Significantly, both samples stratigraphically precede metallurgical activities in
27 Belovode (smelting slag) and Pločnik (the occurrence of massive metal implements) (Radivojević and
28 Kuzmanović-Cvetković 2014). Copper metal droplets from the sites of Gornja Tuzla (190) and Vinča (83)
29 are distinguished from other materials by their largely (copper) metallic core accompanied with inclusions
30 and newly-formed phases (GT 190 only), the features of which classify both samples as products of
31 smelting, rather than melting or refining. Metal artefacts and casting debris produced in these activities
32 will be addressed in a sequel to this paper.
33
34
35

36
37 All materials were examined at the Wolfson Archaeological Science Laboratories at the UCL Institute of
38 Archaeology, London, UK for their composition and microstructure (see Table 1 and Supplementary
39 Material for the range of analytical techniques applied).
40
41

42 43 **4. Results** 44

45
46 The knowledge of the early metal worker would have centred on two major areas: correct identification
47 and procurement of suitable minerals to smelt, and appropriate control over the smelting conditions to
48 facilitate formation of metallic copper. Below we present the results of our analyses of copper-rich
49 minerals found within the archaeological layers (‘archaeological minerals’, as opposed to newly-collected
50 ‘geological minerals’ from ore outcrops), and of the smelting debris, followed by our interpretation of this
51 data with regard to the level of knowledge evident from it. We use the compositional characteristics of the
52 debris to explore the possible composition of the smelting charge, focussing on the difference of the slag
53 composition from the composition of the ceramic sherds associated with the smelting. In particular we use
54 the amount of typical fuel-ash oxides (potash, lime, magnesia, and phosphate) and of oxides associated
55 with specific ore minerals, such as arsenate, phosphate, alumina, manganese and iron oxide, to identify
56
57
58
59

1
2
3
4 any contribution to the slag formation other than the fused ceramic and predominant copper oxide (mainly
5 originating from what we believe was malachite ore). Finally, microstructural examination complements
6 our understanding of the formation of particular phases and aids interpretation of the knowledge involved
7 in the metal smelting.
8
9

10 *4.1 Archaeological minerals*

11
12 The copper minerals form two distinctive groups: oxide and sulfide minerals. The oxide minerals
13 are black-and-green, a colour feature microscopically revealed as two distinctive mineral phases: optically
14 bright green crystals and grey oolitic structures (excluding Pločnik 71) (Fig 4). The bright green crystals
15 are mostly copper oxide (probably present as carbonate) with minor concentrations of manganese, zinc
16 and iron (up to 0.5, 1.5 and 0.5 at%, respectively). Oolitic formations appear optically grey and dark and
17 exhibit a more complex chemical structure, which is markedly similar throughout all but one sample,
18 Pločnik 71. They all (excluding Pločnik 71) have copper and manganese contents in ratios varying from
19 1:1 to 2:1 in favour of copper (Radivojević 2012). The ternary plot of MnO/ZnO/CuO (Fig 5) illustrates
20 the striking compositional similarity of oolitic formations in all studied minerals: they cluster halfway
21 through the Cu-Mn axis, with major fluctuations noted in zinc oxide levels. Belovode M10 and Pločnik
22 71 are presented as outliers, due to high manganese and high copper contents respectively.
23
24
25
26

27 Three copper minerals with relevant sulfur content were found at Belovode (3, 33b) and Pločnik
28 (72m). Besides copper oxide / carbonate, these contain phases compositionally closest to covellite (CuS,
29 samples 3 and 33b), chalcocite (Cu₂S, sample 72m), pyrite (FeS₂, sample 72m) and sphalerite (Zn(Fe)S,
30 sample 72m). Macroscopically, these samples appear less granular than the black-and-green oxide
31 minerals, although they too have distinctively coloured cross-sections in shades of green and grey with
32 metallic lustre (sample 3 in Fig 4).
33
34

35 The examination of oxide copper minerals from different Vinča culture sites spanning circa 800
36 years showed that during this period a pattern of selecting manganese-rich batches can be observed. They
37 differ from the 'pure' malachite used for bead making in their common black-and-green appearance and
38 similar compositional ratios of copper to manganese, which is striking as a particular selection choice
39 throughout the Vinča culture (Radivojević et al. 2010; Radivojević 2012). For technological and cultural
40 reasons to be explored below, these minerals were selected over others available in nature, indicating an
41 awareness of their properties throughout c. 800 years.
42
43

44 On the other hand, the presence of sulfide copper minerals in the 5th millennium BC Chalcolithic
45 settlements is noteworthy, as it is rare and still not well documented in this period. Significantly, both
46 oxide and sulfide copper minerals occur together in the studied sites and were distinctively coloured in
47 green and black / grey, by their manganese or sulfur content. It also implies that at this very early stage of
48 pyrometallurgy copper metalworkers from Belovode and Pločnik were experimenting with different kinds
49 of green and black minerals, and that the outer appearance of these minerals played a significant role in
50 the selection process.

4.2 (S)melting: Production Debris

All analysed Vinča culture copper slags, barring GT 194, are similar in their macro- and micro-structure. A common feature of these slags (free slag samples and slagged masses on pottery sherds) is that they solidified from an almost fully liquefied state, while still being heterogeneous. Due to this heterogeneity, we focused on the composition of slag glass matrices (relatively inclusion-free), in order to identify the smelting charge components throughout the studied evidence.

The glassy slag matrices in all studied samples are predominantly made of silica, alumina, lime, iron, and copper oxides, which together amount to around 86 wt% on average of the slag glass constituents (Tab 2). These are followed by phosphorus, potash and magnesia, which amount to another 6-14 wt% on average, and largely originate from the fuel ash intake during the slag formation. Besides copper, which undoubtedly comes from the ore, the other 'ore elements' are manganese, cobalt, zinc, arsenic, tin, and antimony, with totals ranging from as low as 0.5 wt% in a slagged sherd (31a) to the maximum of 12.3 wt% in a free slag sample (136). In comparison with the typical Vinča culture ceramic from these sites (Tab 2), the slags (including slagged areas on sherds) are characterised by a slightly elevated iron content, and more significantly, higher lime levels. The elevated lime levels are usually taken as fuel ash contamination, however, this oxide can also come from the ore body, as elaborated below (see Fig 10). The clearest indication that these slag glasses are not just fused ceramic bodies is the distinctive ore component: the slag matrices from Belovode and Vinča are rich in manganese and zinc, while the Gornja Tuzla slag bears a unique arsenic-tin-antimony signature.

The ternary plot of components taken to represent common ceramic ($\text{SiO}_2/\text{Al}_2\text{O}_3/\text{TiO}_2$), fuel ash ($\text{CaO}/\text{MgO}/\text{P}_2\text{O}_5/\text{K}_2\text{O}$) and ore ($\text{FeO}/\text{MnO}/\text{ZnO}/\text{NiO}/\text{CoO}/\text{As}_2\text{O}_3/\text{SnO}_2/\text{Sb}_2\text{O}_3$) components in the glassy slag matrices (re-cast as Cu-free oxides) in Fig 6 illustrates the difference in composition of these matrices from the average Vinča culture ceramic composition. The most distinctive ones are the group of free slag samples from Belovode and Vinča, which cluster closer to the ore elements corner, along with a few readings from the Belovode slagged sherds. On the other hand, the strongest intake of ceramic and fuel ash contamination is noticed in the Belovode and Gornja Tuzla slagged sherds (including GT 194), with only a few readings from the free slag samples from Belovode and Vinča close to the typical ceramic composition. The glassy matrices are rich in silica and alumina, which explains why the slags are highly viscous, despite the significant input of oxides such as lime, iron and copper oxides (cf. Davenport et al. 2002, p. 63). One of the most important observations is that copper smelting technology exhibits a high level of similarity throughout Belovode, Vinča and Gornja Tuzla, illustrated by the strong cluster in the $\text{SiO}_2/\text{Al}_2\text{O}_3/\text{TiO}_2$ corner of the diagram.

Another strong similarity in the smelting technology across the sites of Belovode, Vinča and Gornja Tuzla is observed in the microstructure of the slags (Fig 7). Copper oxide-based compounds dominate in all samples. These are commonly associated with delafossite, spinels and leucite, with sporadic occurrence of pyroxene, olivine, wüstite and iscorite (Table 2), which are usually present in areas of slag glass crystallisation. Their presence indicates the variable redox conditions as well as variations in ore composition, both of which will be discussed in detail below. Only few residual, partially decomposed quartz grains were discovered in free slag samples, but are a common feature of slagged sherds. Other than occasional quartz grains, there is little evidence of residual minerals except for the 'drossy' areas, which due to c. 7000 years of post-depositional processes, are difficult to identify as either residual ore or

1
2
3
4 newly-formed phases. An exception to the rule is sample GT 182a, where residual minerals rich in
5 arsenic, antimony and tin were identified in a glassy slag matrix (Fig 7h).
6

7 Sample GT 194 yielded scarce information concerning production in the slag matrix; however, the
8 enrichment with iron (Table 2) suggests that this was possibly copper melting debris (cf. Craddock and
9 Meeks 1987). Another aspect supporting this supposition is that no other phase – apart from a charcoal
10 piece and the copper metal entrapped in it – was detected in GT 194, which stands in stark contrast to the
11 smelting evidence from this (and other) Vinča culture sites presented here. Hence, GT 194 most likely
12 represents melting slag fused with corrosion products and a piece of charcoal.
13
14

15 The working temperatures of the smelting systems across all three sites is estimated to have been just over
16 1083 °C, according to the fully molten state of copper metal prills embedded in them. This was evidently
17 not high enough to make the slags analysed here less viscous and more homogeneous (cf. Davenport et al.
18 2002, p. 59-60). Noteworthy is the virtually ‘slagless’ smelting in Belovode and Pločnik, judging by the
19 evidence in samples M6 and 52 (Fig 8). They both contain copper metal and residual primary copper
20 minerals (chalcocite and covellite); the latter probably accompanied secondary copper minerals selected
21 for smelting. Interestingly, these samples did not contain iron or manganese, which are crucial for the
22 generation of slag.
23
24
25
26
27

28 *4.2.1 Variations in Metal Making Recipes*

29

30 The discussed ‘consistency’ of the 5th millennium BC copper production evidence, however,
31 includes noticeable differences in slag microstructure, choice of fuels and ores. As a result, compositional
32 discrepancies among slag samples stem from constraints imposed by the choice of ingredients and redox
33 conditions of the metal production process, both of which are addressed below.
34

35 The *redox conditions* in the studied slags are indicated by the presence of newly formed crystalline phases
36 (Table 3). Since the co-occurrence of cuprite, delafossite and iron spinels dominates the slag samples, it
37 appears that partially oxidised atmosphere prevailed, which was sufficient to smelt copper (cf. Elliott
38 1976). [Relevant](#) levels of iron in copper metal droplets Gornja Tuzla 190 and Vinča 83 suggests that these
39 also formed during primary metal extraction (cf. Craddock and Meeks 1987). These redox conditions
40 suggest that the overall gas atmosphere was slightly oxidising / moderately reducing, which resulted in
41 producing successfully copper metal and the formation of heterogeneous slag in the sites of Belovode,
42 Vinča-Belo Brdo and Gornja Tuzla.
43
44
45

46 Samples from Belovode, the largest assemblage of production debris in this study, deserve particular
47 attention due to their clustering in a single trench in the field. The cluster of samples Belovode 30a/c,
48 31a/b, 131, 134, 136, including M21, M22a/b, M23 (Radivojević et al. 2010), in spits 4-7 in the
49 ‘metallurgical’ Trench No. 3 (Table 1) indicated that they probably represent evidence of a single
50 smelting episode. This assumption is further strengthened by the compositional analyses, which indicate
51 strong correlations in the ore signature (Mn and Zn, Table 2). It follows that slagged sherds 30a/c and
52 31a/b most likely lined the smelting hearth for what appears to be a single smelting episode that resulted
53 in the formation of mentioned samples. The remaining samples (M20, M6) differ from these
54 compositionally, structurally and contextually, for which reasons they most likely represent two
55 additional smelting events in this trench.
56
57
58
59

1
2
3
4 An important feature of the Belovode and Vinča slags is the distinctive presence of manganese (see Table
5 2). Manganese oxide is known to facilitate the formation of a melt under the lower operating temperatures
6 than those required when, for instance, iron oxide is present in the system (Huebner 1969, p. 463, Fig. 3;
7 Heimann et al. 2001, p. 233). Therefore, the advantageous chemical-physical properties of manganese
8 oxides enabled an easier reduction of copper ores to metal and slags within less-controlled smelting
9 environments. This particular feature of manganese-rich ores was probably known to the ancient smelters
10 based on the observation that a particular type of ores (as in particularly coloured) would be more
11 efficient to smelt. This beneficial property of manganese oxide for copper smelting was later also
12 recognised in the mid-4th millennium BC smelting site of Wadi Fidan 4 in Faynan in Jordan (Hauptmann
13 2007, p. 195, 234). Macroscopically speaking, manganese appears in the Balkans as a black phase in
14 paragenesis with green copper minerals (mostly malachite), which makes it a distinctively coloured black-
15 and-green ore.
16
17
18
19

20 The *ore signatures* in the Vinča culture production evidence can be recognised in all identified slag
21 samples. The most informative phases are iron-rich spinels, copper metal, glassy matrices, and a residual
22 phase in GT 182a. Since each of the ore elements partitions differently during smelting, the combination
23 of data obtained from all identified phases is expected to provide the most comprehensive information
24 about the compositional signature of the ores used to make metal in Belovode, Vinča-Belo Brdo and
25 Gornja Tuzla.
26
27

28 *Iron spinels* were found in all production evidence except in GT 182a and Belovode 30a/c (Table 4).
29 Besides iron and copper oxides, manganese oxide is another major constituent (barring GT 190). The iron
30 spinel compositions suggest that the ores used for smelting in Belovode and Vinča differ from those used
31 at Gornja Tuzla, although the consistent presence of cobalt and zinc in all samples (average
32 concentrations of c. 2 wt% each) suggest that the smelted ores could have been part of the same
33 mineralisation or metallogenic belt in the Balkans. The type of ore smelted in the Gornja Tuzla event is
34 best represented by a *residual phase* encountered in sample GT 182a (Fig 7h). It appears as rich in
35 phosphorus with relevant concentrations of arsenic (reaching 3.4 at%) and antimony, tin and tungsten (0.1
36 at%-0.2 at%). The closest mineral match to this phase would be arsenic-rich apatite (Fig 9), which was
37 possibly included with the malachite to make copper in the site of Gornja Tuzla.
38
39
40

41 *Trace element concentrations* in copper metal prills consistently include nickel and gold throughout all
42 metal phases, with the strongest signature of the former at c. 960 ppm mean in Belovode 131 (Tab 5).
43 Arsenic levels are most significant in GT 182a, at 1250 ppm, which are present in conjunction with Sb
44 and S in both GT 182a and Belovode 131, and with c. 1 wt% of cobalt in the latter. The occurrence of
45 antimony and arsenic might point at the sporadic presence of fahlerz or other complex minerals in the
46 smelting charge in the sites of Belovode and Gornja Tuzla, potentially collected as part of the primary
47 mineralisation together with the green copper-rich minerals.
48
49
50

51 Sulfur concentrations are variable throughout, with the highest values in GT 190 at c. 740 ppm. Its
52 presence demonstrates that some of the primary copper ores were potentially included with the secondary,
53 green copper minerals. This is particularly true for the signature of GT 190, where the sulfur content with
54 significant zinc and iron dominates the trace element signature of the copper metal phase. Manganese, on
55 the other hand, is only rarely encountered in the copper metal phase, and its presence in Belovode 131
56 implies that the smelted ores were extremely rich in this element (cf. Tylecote et al. 1977, p. 313, Table
57
58
59

1
2
3
4 7). The data from the trace element analyses of copper metal supports the previous assumption, based on
5 the iron spinel data, that similar ores were used in the sites of Belovode and Vinča, while Gornja Tuzla
6 craftsmen exploited a compositionally distinctive ore.
7

8
9 The *glassy slag matrix* is another reliable indicator of the ore signature in the production evidence (Table
10 2). The three ternary diagrams below illustrate the close correlation of slag glass composition with the
11 potential ores used for metal making in all three sites (Figs 10-12). The geological ores matched on these
12 diagrams show the closest compositional correspondence with the combination of metal oxides in the slag
13 samples. For Belovode data we used the ternary cluster of K₂O-CaO-MnO in order to distinguish between
14 the ore and fuel ash signature (Fig 10); the lime readings in these matrices were too high to be solely due
15 to the fuel ash intake, and our assumption that they may have come additionally from an ore source seems
16 plausible. The alignment of readings along the K₂O-CaO axis indeed presents a potential fuel ash
17 signature (beech ash data after Jackson and Smedley 2004, p. 39, Table 4), while the strong cluster of a
18 selection of glassy matrix data along the CaO-MnO axis demonstrate the use of manganese-rich black-
19 and-green copper minerals. The slag glass signature from Vinča 79, besides the manganese intake (Table
20 2), shows also increased iron and phosphorus concentrations, which match closely the composition of
21 blue/green phosphate vivianite [Fe₃(PO₄)₂•8H₂O] (Fig 11). It therefore indicates the likely combination of
22 ores smelted at this site for this particular event; for Vinča 91 we assume that only a combination with
23 black-and-green manganese-rich copper ores was used. In Gornja Tuzla, the slag glass matrix plots near
24 the projection of secondary minerals of the phosphates/arsenates family such as scorodite
25 (FeAsO₄•2H₂O), strengite (FePO₄•2H₂O) and arthurite (CuFe₂(AsO₄,PO₄,SO₄)₂•4H₂O) (Fig 12).
26
27

28
29 The striking detail that underlines the chemistry of ores smelted at these sites is their dominant colour:
30 whatever the exact minerals that were present in the ore charge, they most likely had strong colours in the
31 range of green/blue (i.e. vivianite, arthurite, apatite, scorodite), and violet (i.e. strengite), in addition to
32 black and green manganese-rich malachite (Belovode and Vinča only). With regard to the Gornja Tuzla
33 evidence, this may have been the case as well in the selection of copper-based ores for smelting. For
34 instance, scorodite is the most common weathered mineral originating from the primary arsenic ore,
35 arsenopyrite. Interestingly, the weathering of arsenopyrite results in green/blue scorodite and red/black
36 goethite [FeO(OH)] (Murciego et al. 2011, p. 594). Thus, the allure of green and dark/black minerals
37 found together in the landscape could have been a decisive factor for the copper metalworkers not only in
38 the sites of Belovode and Vinča, but also in the site of Gornja Tuzla, too. The Bor district in eastern
39 Serbia is a possible source for all these minerals in paragenesis with copper and iron ores, which is not too
40 distant from the studied sites (Belovode being the closest at c. 50 km distance). It contains massive sulfide
41 deposits of cuprous pyrite, with rich primary and secondary copper minerals (Sillitoe 1983; Janković
42 1990) and polymetallic enrichments that makes the occurrence scorodite and strengite, and other
43 phosphates such as apatite and vivianite very likely (see Supplementary materials).

53 **Discussion**

54 The results presented above demonstrate the presence of sustained metallurgical activities from c.
55 5000 to c. 4400 BC in the Balkans. The studied assemblage, although small in size, is unprecedented in
56 terms of resolution and quality, and as such offers an exclusive insight into the origins of metallurgy in
57 Eurasia.
58
59

Green Minerals, Tainted Ores

The compositional analyses indicate a particular preference of Vinča metal metalworkers for black-and-green copper ores. The presence of these distinctively coloured ores at the site of Pločnik may be suggestive of smelting activities taking place in this settlement as well. Besides mineral Pločnik 209, which is abundant with manganese, sulfur-rich copper mineral Pločnik 72m exhibits a similar colour code, which is black/dark and green. This is important since mineral 72m comes structurally and compositionally closest to the one smelted to produce copper metal droplet Pločnik 52. Thus, although no slag has yet been discovered in this site, analysis of sample Pločnik 52 suggest the existence of a smelting event, which probably included black/dark and green ores. In a similar manner, copper metal droplet M6 from Belovode illustrates a comparable event of smelting ore that was probably structurally similar to the one identified in samples Belovode 3 and 33b; hence, this event most likely also included distinctively coloured black and green ores. Importantly, both events (52 and M6) at the sites of Pločnik and Belovode occur stratigraphically before the metallurgical events at both sites; while Pločnik 52 originates from the context preceding the earliest known copper implement from this site (Borić 2009, p. 214), Belovode M6 comes stratigraphically ahead of the earliest known smelting event at this settlement (Radivojević et al. 2010; Radivojević and Kuzmanović-Cvetković 2014). These events are significant because they document events in which dark/black and green minerals were smelted possibly prior to the ‘slagging’ metallurgy encountered from c. 5000 BC.

The field evidence from both Belovode and Pločnik suggests that black-and-green minerals appear from the earliest layers of occupation (Radivojević and Kuzmanović-Cvetković 2014); however, no copper metal artefacts are known from these sites prior to c. 5000 BC. It remains to be seen in future investigations of Belovode what other uses of these black-and-green minerals existed in pre-5000 BC if not for copper smelting. Noteworthy is that we find only pure green and black-and-green minerals in the studied sites; this is particularly startling for Belovode, located in the heart of the copper-rich eastern Serbia, where other geologically similar choices were available. Significantly, this dual selection of copper minerals also appears to be a pattern during the Early Neolithic occupation at the Danube Gorges sites of Lepenski Vir and Vlasac, dated to the late 7th / early 6th millennium BC, where both pure green and black-and-green (thermally unaltered) minerals were discovered in the domestic contexts (Radivojević 2012).

It has already been mentioned that malachite beads from the sites of Belovode, Pločnik and Vinča were made exclusively from *pure green* malachite, in contrast to the black-and-green ore linked to copper smelting. Hence, the dichotomy of *pure* vs. *tainted* copper minerals in the archaeological record across the studied Vinča culture sites could indicate that the decisions made towards their selection were guided by their colour, implying the existence of an awareness that these coloured minerals of a particular character produced a good result. To illustrate, the majority of c. 7 kg of copper minerals recovered from the excavations of Belovode (until 2009) were of black-and-green appearance, which speaks of this particular technological preference, but also of the scope of experimentation / intended production of copper in this site. In terms of technology, the dual principle applies here as well: ‘cold’ techniques were employed for bead-making, borrowed from the lithic industry, while ‘hot’ high temperature treatment of black-and-green tainted copper minerals turned them into ores that produced shiny droplets of copper metal.

1
2
3
4 Although it is not clear from the analyses whether black and green minerals were selected separately or as
5 a mixed ore, the conclusion that emerges from the analytical discussion is the presence of a common
6 knowledge regarding the suitability for smelting of distinctively coloured mixed minerals. **This stands in
7 contrast to the uniformly green pure malachite selected at the same time for bead production.** We are,
8 however, not arguing that the pure green malachite was not used for smelting as well, but rather that the
9 black and green minerals were intentionally selected for high-temperature treatment in the sites of
10 Belovode, Vinča and Gornja Tuzla, for more than half a millennium, as a sole or a combined charge for
11 the early copper extraction. The importance of the colour factor has also recently been argued for the
12 emergence of the earliest tin bronze artefacts in the Balkans (Radivojević et al. 2013), implying that the
13 correct combination of ore colours drove the experimentation phase during the early metal production in
14 this region (Radivojević forthcoming).

15
16
17
18
19 The dual selection principle in separately processing pure and tainted copper minerals for different
20 purposes is without parallel at the time. It indicates the recognition of immanent properties of these
21 minerals and their use for a particular purpose to meet historically specific demands. During the period of
22 at least c. 600 years, the Vinča culture copper metalworkers practiced smelting of black and green copper
23 ores, solely or in combination with pure green copper ores, which constituted the smelting charge most
24 suitable to yield metal under variable conditions of the smelt. Hence, the success of copper smelting using
25 such ore reinforced the preference for black and green ores among the Vinča culture metalworkers. Such
26 knowledge was crucial for a successful transformation of ore to metal, and was accompanied by another
27 transformation, that from the perception of *black and green copper minerals* into *black and green copper
28 ores*.

29
30
31
32 This argument takes the debate of the origins of metallurgy in a single place somewhere in the Near East
33 beyond the discussion of the ‘earliest’ dates, as the key evidence appears to be the preference for a
34 particular combination of black and green ores in order to transform them into metal. The current state of
35 research in the Near East has not thus far yielded evidence comparable to the one in the Balkans
36 (Radivojević et al. 2010, p. 2776 ff.), particularly when it comes to investigating types of minerals being
37 selected for metal smelting. The appearance of black and green minerals in the archaeological record of
38 the Balkans around a millennium prior to the earliest recorded smelting events indicates a pre-existing
39 knowledge of these minerals and probably experimentation with their material properties. Thus, the
40 consistent selection of black and green *minerals*, which turned into *ores* around 5000 BC speaks of a
41 unique technological trajectory of Balkan metallurgy, which reinforces assumptions of its independent
42 evolution (cf. Renfrew 1969; Jovanović and Ottaway 1976; Radivojević et al. 2010).

43
44
45
46
47 Although the original reasons for applying heat (as in smelting) to copper minerals are not yet well
48 understood, a clue for such a decision may be found in experimental reconstructions of copper smelting
49 events. The primary author recently took part in a copper smelting experiment and recorded the moment
50 when the flames of this process went green (Fig 13). This happened just after a handful of malachite was
51 thrown onto a bed of charcoal heated up in a small bowl furnace. Thus, it could be assumed that early
52 attempts to smelt copper were potentially driven by curiosity to explore properties of materials that
53 burned with green flames, and that knowledge of copper smelting evolved in the context of appreciation
54 of the aesthetics of coloured flames. Noteworthy is that some of the minerals mentioned in this article
55 from the class of phosphates (vivianite) and arsenates (scorodite) release blue and green flames when set
56 on fire (Dana and Ford 1922, p. 608, 610). This particular feature of ores used for early smelting may

1
2
3
4 have been yet another sensorial aspect included in the early metal production. 7000 years later the
5 property of minerals to colour flames was still being used as a field analytical tool in mineralogy and ore
6 prospection (Henglein 1962).
7

8
9 By and large, and with regards to the knowledge of copper and other, potentially geologically associated,
10 colourful minerals, the metalworkers at the time must have recognised the immanent properties of these
11 raw materials. This recognition most likely evolved over the course of at least several centuries prior to
12 metal extraction, and was based on developing awareness of the most suitable ores due to their colour,
13 smell, taste, behaviour under heat treatment, geological association with other minerals or their place in
14 the landscape. ‘Painting’ the ore charge in black for the process of material transformation was an
15 unprecedented configurational combination of immanent properties of these ores at a particular time with
16 a particular knowledge that defined the historically unique time for the invention of metallurgy in the
17 Balkans.
18
19
20
21
22

23 *A Tale of Three Slag ‘Heaps’*

24
25 The results of our analyses allow for a tentative reconstruction of the metal production technologies used
26 at three different Vinča culture sites: Belovode, Vinča and Gornja Tuzla. Both macro- and micro-
27 analytical approaches demonstrate the practicing of copper smelting throughout c. 600 years altogether,
28 with startling similarities in the level of expertise and technological choices, but with clear differences in
29 the composition of the ores smelted. Particularly interesting is the fact that the technological principle of
30 the Vinča culture production evidence is not chronologically sensitive. The estimated chronological
31 sequence of these finds starts with the Belovode slags at c. 5000 BC (until c. 4600 BC), which for c. 200
32 years overlaps with the Vinča-Belo Brdo evidence (c. 4800-4600 BC). The Gornja Tuzla copper smelting
33 took place up to 200 years after both Belovode and Vinča were abandoned (c. 4400 BC). It seems that
34 over more than half a millennium of evidence for copper production in the Vinča culture, the principle of
35 copper smelting remained consistent.
36
37
38

39
40 Regardless of how insignificant the small amount of slag from these sites may appear, it fits the overall
41 picture of rather ephemeral production evidence in the pre-Bronze Age metallurgy (Craddock 2001, p.
42 152). To illustrate, the early slags of the 5th and early 4th millennium BC mostly look the same: they
43 hardly weigh more than a few grams each and reach nut-size at most (cf. Hauptmann 2007, p. 158); thus,
44 it is not surprising that the earliest documented slags sit on the low end of the size of slag ‘heaps’
45 identified thus far (Bourgarit 2007, p. 4, Table 1). The Vinča culture smelting installations debris thus fit
46 well in this ‘ephemeral model’ of the Chalcolithic metallurgy. Slagged sherds at both Belovode and
47 Gornja Tuzla suggest the presence of a hole-in-the ground installation lined with broken pottery.
48 However, none of them was discovered related to a hearth or a similar detectable feature in the field.
49 Hence, it may be hypothesised that the copper smelting installations at both sites were too ephemeral to
50 survive c. 6000-7000 years of post-depositional processes, and only took the form of shallow indentations
51 in the soil, lined with ceramic sherds. Such installations were possibly run by using blowpipes or bellows,
52 where normally 5-6 blowpipes would suffice for bringing the temperature to around 1100-1200 °C (cf.
53 Rehder 1994, p. 221).
54
55
56
57
58
59
60
61
62
63
64
65

1
2
3
4 The same is true for crucibles, which are also absent from the field record in the Vinča culture sites,
5 although their presence has to be assumed given that they would have been needed for casting the
6 thousands of heavy metal objects known from this period. Interestingly, the casting moulds for the vast
7 number of metal implements from this period are also absent from the archaeological record (Kienlin
8 2010, p. 42 ff). The only two pre-Bronze Age (smelting) crucibles discovered in the Balkans originate
9 from mid to late 5th millennium BC Bulgarian sites of Chatalka and Dolnoslav (Ryndina et al. 1999), and
10 are not culturally related to the Vinča culture phenomenon.
11
12

13
14 Experiments have shown that the slags needed to be crushed in order to extract copper metal globules
15 (Ottaway 2001); however, judging by the evidence presented here, this does not appear to have been the
16 case for the Vinča culture slags. One of the explanations may be that the crushed slags were indeed lost in
17 the field, or that the Vinča smelters were successful in producing more liquefied slags, which facilitated a
18 finer separation of copper metal without the need for crushing.
19

20
21 A particularly intriguing question concerning the early copper smelting operations is how productive they
22 were at this stage. The models based on the Late Bronze Age and later metallurgy assume that large
23 quantities of slag would usually form on top of metal collecting at the lower bottom of the smelting
24 reactor (e.g. Bachmann 1982; Maldonado and Rehren 2009). Nevertheless, experimental copper smelting
25 carried out in smaller containers in Timna (Israel) did not result in the formation of a plano-convex ingot
26 but mainly in copper metal in globular form (Tylecote and Boydell 1978, p. 46). Tylecote and Boydell
27 (1978, p. 49) further argue that smelting in a smaller furnace, which can take up to 5 kg of smelt charge
28 (ores and fluxes), yielded the most satisfactory results in terms of productivity and working conditions, as
29 opposed to the larger smelting reactors which could run cold at the bottom and hence hinder the
30 production process. On this example, we can see how understanding immanent properties of copper ores
31 and limitations of the installation designs can help reconstruction of the early smelting processes. In other
32 words, it is the realisation of, and operation within immanent constraints of metal making ingredients
33 within a given technological context that shaped the way an object was crafted and in effect advanced the
34 knowledge of its production.
35
36
37
38

39 Although these modern experiments were run in furnaces built after Early Iron Age models from Timna,
40 it is tempting to draw parallels between these and the proposed Vinča culture ‘hole-in-the-ground’
41 smelting installations, based on the suggested production potential of small smelting reactors. At the early
42 stage of metallurgy, a much cleaner ore would have been used, resulting in a ‘slagless’ or nearly slagless
43 metallurgy. Depending on the relative proportions of (slag-forming) dark components in the ore and pure
44 green mineral, a large amount of copper may have formed with just the smallest quantity of slag; this is
45 the favoured scenario in our study. Given this scarce evidence one could assume our samples survived as
46 an exception rather than a rule to the early metal extraction process; however, if they were an exception,
47 they would not have consistently occurred in all three studied sites. Furthermore, the studied slags come
48 from the ‘backyards’ of only a few of the excavated dwelling structures and pits in our settlements, and
49 the observed pattern may have been caused by a particular model of organisation of metal production that
50 we cannot reconstruct at the moment.

5. Conclusions

The three slag ‘heaps’, having withstood c. 7000 years of post-depositional processes and retrieved by chance discovery as copper minerals, tell a story that defies several presumptions about early metal production. The compositional and microstructural data presented above demonstrate that the 5th millennium BC copper smelting was a slag-forming process, using various copper-rich ores, chosen mainly for the properties of their (black) impurities, in a moderately reducing / partially oxidising smelt. A combination of immanent properties of colourful ores, the knowledge of which developed over a course of time, with constraints imposed by the design of smelting containers and the very nature of variable smelting conditions yielded a configurational phenomenon in a well-mastered act of material transformation. The sensory aspects of the manufacturing process and the final product are consistent with the particular aesthetic context and preferences of the Vinča culture community, and beyond.

Small-scale smelting reactors emerge as the principal technological choice in the copper metal production of the Vinča culture. This argument is supported by the domestic context of their discovery, but most importantly by the results of the microanalytical approach applied to the study of copper slags. Their minute size and broad compositional similarity at the sites of Belovode, Vinča and Gornja Tuzla point towards a similar technological principle of copper production throughout these settlements. This process can be generally characterised by the use of mixed copper ores selected for their colour pattern, which were smelted in moderately reducing/partially oxidising conditions in an ephemeral ‘hole-in-the-ground’ installation. The process was with startlingly similar technical skill replicated at all three sites, resulting in copper metal being probably produced in globules and together with small quantities of highly viscous slag; some of this slag formed in direct contact with already-broken pottery sherds.

The morphology and quantity of the latter emerges as a crucial argument in characterising the smelting installation as a small, efficient, pottery-lined hole-in-the-ground. In the absence of any other data indicating that the Vinča culture metallurgy was not only household-based, this production evidence stands as the only type of debris for making copper metal during this period, and, as such, may be taken as representative of the ‘true’ nature of the process at this time.

Therefore, regarding the large quantity of extant copper metal artefacts in the Vinča culture, the copper for their making was thus most probably produced in countless individual episodes, within small, household-contained workshops. Although the Vinča culture production evidence studied here represents only a very few of these episodes, the replication of the production pattern across all three sites within different occupational sequences indicates that the level of mastery remained relatively unchanged and potentially stagnant across an estimated period of six centuries. Significantly, the innovative variable in replicating these smelting recipes was the choice of colourful ores in the right proportion with the black component. These black-and-green ores thus remained a smelting ‘recipe’ ingredient prone to the greatest variation and creativity within an otherwise consistent smelting environment. The process slowly evolved into smelting of more complex copper ores only towards the end of this culture, as attested by the Gornja Tuzla example, containing small but significant amounts of arsenic, antimony, and tin. This trajectory towards ‘natural alloys’ is illustrated by the occurrence of complex tin bronzes in the late Vinča culture, which can also be linked to the use of colourful complex copper-tin bearing ores (Radivojević et al. 2013).

1
2
3
4 The combination of black-and-green ores in the early Balkan metallurgy emerges as the main argument
5 for building explanatory models for its independence, as well as supporting claims about its unique
6 technological trajectory, which was without parallel at the time. Why was the early copper production
7 'painted black'? The slag-forming behaviour of the black and green manganese-rich copper ores led to
8 slags that were more reliably liquid under variable redox conditions, which serves to facilitate the metal
9 extraction process. Also, the colour preference for black in the context of the Vinča culture contributes
10 significantly to the overall interpretation of this particular aesthetic preference. Glossy surfaces of black-
11 burnished ware and the dark silver sheen of graphite-painted pottery illustrate the aesthetic context at the
12 time of the emergence of metallurgy in this part of the world. While we are reluctant to draw
13 technological parallels between black-burnished pottery and metal production (despite the fact that both
14 resulted in shiny objects), the specific aesthetical desire for black could have encouraged a discovery of
15 another 'colourful medium' (cf. Chapman 2007a, p. 70): tainted ores with a capacity to transform into
16 brilliant artefacts.
17
18
19
20

21 The black in the smelting ore charge could have thus represented a supernatural, a power without which
22 the extraction of metal would not have been successful. 'Painting' the green ore charge in black could
23 have activated the 'enchantment' of material transformation, the one that provides means for tainted,
24 'dirty' materials to transcend into much sought-after radiant objects at the time. The sensory and physical
25 aspects of this transformation process must have been crucial for leading the operation to its successful
26 end. Colours of burning ores or flames were the best indicators of the process flow, the navigation of
27 which demonstrated the configurational knowledge of metalworkers at the time. Thus, the successful
28 transformation of ore to metal was a factor of immanent properties of input and output components,
29 immanent behaviour of the smelting process, and most importantly, a set of configurational skills
30 mastered at the time of inquiry.
31
32
33
34

35 Besides demonstrating that the Balkan metalworkers had their own technological trajectory of mastering
36 metal production, the presented data also shows that the recipe for metal making was culturally shared
37 among these metalworkers and transmitted during c. six centuries of Vinča culture metal production. The
38 continuity and consistency of copper smelting technology suggest that such knowledge was passed as an
39 'all-in-one' package within a strong and conservative tradition. This conservative tradition suggests that
40 the transmission of knowledge was kept within a particular lineage of craftspeople, where skills were
41 most likely passed from a parent to the same gender offspring (Shennan and Steele 1999). The reasons for
42 cooperation between different Vinča culture settlements could thus possibly be sought in their belonging
43 to large webs of kinship (e.g. clans) (cf. Kienlin 2010).
44
45
46

47 The size of a learning network has been shown as very important when it comes to skills transmission in
48 traditional and prehistoric communities (Shennan 2001; Henrich 2004; Roux 2008; Powell et al. 2009).
49 As every innovation, the spread of metallurgical skills in the Vinča culture required a sufficient number of
50 learners, which according to the consistency of selection practices of black-and-green ores and copper
51 smelting technology throughout c. 600 years, appeared stable during this period. The learning network of
52 Vinča culture metalworkers ceased to exist in the sites of Belovode, Vinča, Pločnik and Gornja Tuzla
53 around the mid 5th millennium BC, along with the end of the Vinča culture mysteriously marked by an
54 abandonment of these and other settlements in modern day Serbia. Nonetheless, judging by the continued
55 production of massive copper implements across the Balkans throughout the entire 5th millennium BC,
56 this learning network possibly continued to grow in other parts of this region. A discussion of the
57
58
59
60

1
2
3
4 dynamics of this particular metallurgical learning network is beyond the scope of this paper and remains
5 to be addressed in future publications.
6

7 Extractive metallurgy, as any other *idea*, had multiple origins. In addition to other places, it found fertile
8 ground to progress within the Vinča culture phenomenon. It evolved through *experimentation*,
9 demonstrated by the presence of black-and-green minerals and ‘slagless’ extraction *prior to* the earliest
10 documented smelting, but also by the selection of compositionally different yet similarly coloured ores.
11 The Vinča culture metalworkers also developed an *understanding* of the smelting process and applied it
12 in a consistent manner throughout the centuries of practice. *The Vinča culture communities must have*
13 *had social institutions in place to provide logistics for the distribution of metal implements to markets that*
14 *desired these objects (Radivojević forthcoming)*. Nearly five tonnes of extant copper metal implements
15 discovered *in domestic, ritual and/or funerary contexts across the Balkans testify the high demand at the*
16 *time, the economic gain that metal-producing communities must have had, and possibly different value*
17 *system under which they were acquired and consumed (e.g. Radivojević 2006; Kienlin 2010)* .
18
19
20
21

22 Dazzling metals on the one hand and glittering black-burnished ware on the other represent only some of
23 the spectacularly crafted objects in the wider context of the 5th millennium BC material culture in the
24 Balkans (cf. Chapman 2011). What emerges to arise as a pattern is not only the lustrous colour spectra,
25 which continued to expand over the course of this period with the discovery of gold, but also a specific
26 pursuit for the ultimate expression of a completely homogenised brilliance in artefacts. In this light, the
27 emergence and spread of metals, first copper, and in succession gold and tin bronzes may be the best
28 illustration for such particular quest for the decisive material statement at the time. The vast number of
29 shiny metals, pottery, stones, animal and marine materials that served the purpose of dazzling the audience
30 and / or their owners may in this context rightly be used to define the 5th millennium BC in the Balkans as
31 the *Age of Brilliance*. It may not be only supported by the fascinating material culture discovered thus far,
32 but also by acknowledging the generations of craftsmen that persisted with this pursuit and how important
33 the *production of* brilliant objects was as part of both cultural and technological identity.
34
35
36
37

38 From the green flames and black-and-green ores of the Vinča culture, and despite technological
39 stagnation in the metal making recipe, the knowledge of metallurgy grew in more than half a millennium
40 into what appears to be one of the major subsistence economies in the 5th millennium BC Balkans,
41 covering a wide range of colourful metals and alloys (Radivojević et al. 2013). This study does not
42 exclude the possibility for the existence of a similar contemporary development in other regions of
43 Eurasia; however, the characterisation of early metallurgical knowledge in those regions remains a task
44 for future research. We attempted to demonstrate the potential material science carries in addressing the
45 knowledge of early metallurgy in a nuanced detail, and beyond the world’s earliest dated smelting event
46 discovered in the Balkans. By looking at immanent and configurational aspects of this transformative
47 technology, we suggest a direction for future research on the *how* and *why* of metallurgies *worldwide*.

21 **Figure 11-** Ternary plot of Al₂O₃-P₂O₅-FeO values in glass matrices in Vinča 79 and 91 tested against the
22 compositions of lazulite, turquoise and vivianite (mineral images are copyright of Rob Lavinsky,
23 www.irocks.com). The closest match to the composition of slag matrix in Vinča 79 is vivianite, a
24 colourful hydrated iron phosphate.
25
26

27 **Figure 12-** The As₂O₃-P₂O₅-FeO plot of slag matrices in GT 182a and GT 194 against mineral
28 compositions of arthurite (copyright by Leon Hupperichs), scorodite (copyright of Rob Lavinsky,
29 www.irocks.com) and strengite (copyright www.fabreminerals.com). GT 194 shows that this is a different
30 type of metallurgical event, while yellow ellipse around GT 182a values indicates that the smelting charge
31 possibly included a mixture of these minerals, or potentially phosphoroscorodite, (Fe(As,P)O₄·2H₂O), an
32 intermediate phase between scorodite and strengite.
33
34

Table 1- Sampled materials description, context and relative chronology. All samples were analysed with optical microscope (OM) and scanning electron microscope with energy dispersive spectrometer (SEM-EDS), and only a selected number with Electron Probe Micro Analyser (EPMA). The Vinča culture is dated between c. 5400 and 4600 BC. Vinča A lasted from c. 5400/5300 BC until c. 5200 BC; Vinča B from c. 5200 BC to c. 5000/4950 BC, which us the beginning of the Gradac Phase, which lasted for c. 50-100 years in central parts of the Vinča culture, and longer elsewhere. Vinča C is dated from c. 4900 – 4850/4800 BC, and Vinča D from c. 4800 BC until c. 4650/4600 BC.

Table 5: EPMA compositional data of copper metal prills from production evidence from the sites of Belovode, Vinča and Gornja Tuzla, normalised to 100%. Reliable values established at ≥ 10 ppm. Mn and Fe readings in Belovode 134 (*here italic*) are not taken into consideration since the diameter of the analysed metal prills was smaller than the effective analytical volume excited by the electron beam; thus we suspect that we received readings from the immediate analytical surrounding, including the glass matrix. All data are corrected for values obtained from the reference material (pure copper standard, published in supplementary materials). Analytical totals represent average values of total of all measurements in each sample (bdl=below detection limit).

Supplementary Materials

1 Methodology

1.1 Sampling and Preparation

The sampling strategy initially involved selecting materials on the basis of their visual appearance, and their response to a magnet (slag and slagged materials). The research collection was appropriately catalogued, measured and photographed prior to sample preparation and analysis. This stage was followed by careful designing of analytical strategy for each sample (Table 1).

Samples selected for microstructural and compositional study were cut to size (where necessary) using an abrasive saw, washed with water, dried and mounted in an epoxy resin. These were then ground using abrasive disks (1200 and 2400 grit) and polished using diamond pastes (1 μm and $\frac{1}{4}$ μm). Mounted polished blocks were washed in an ultrasonic bath and rinsed with ethanol between each grinding and polishing stage. As polished blocks they were suitable for the initial analytical stage, reflected light microscopy (OM), with photomicrographs taken on the Leica and Olympus microscopes at 25x, 50x, 100x, 200x, 500x and 1000x. In the following analytical stage, compositional analysis, samples were carbon-coated to be suitable for examination under the Scanning Electron Microscope with Energy Dispersive Spectrometry (SEM-EDS) and Electron Probe Micro Analyser (EPMA) respectively. The EPMA was used only for the samples which contained a distinctive copper metal phase. The EPMA analyses were conducted by Kevin Reeves, technician at the Wolfson Archaeological Science Laboratories, UCL Institute of Archaeology, London.

1.2 Microstructural Analysis

Analyses of microstructures were conducted primarily with optical microscopy (OM), while SEM-EDS played only a minor role in distinguishing phases in the

studied samples. Optical microscopy is an established method in archaeometallurgy for studying optical properties of geologically-formed minerals (e.g. oolitic formations) or artificially generated phases (e.g. crystals in the slag matrix). These properties were used to identify which minerals/phases were present in the sample and inform on their generation. OM analyses were conducted on all polished blocks, using two different microscopes (Table 1).

| Instruments | Aim of Analysis | Analytical Parameters |
|--|--|---|
| Reflected Polarized Light Microscopy (Leica DMLM and Olympus BX60) | Phase identification and visual characterisation of microstructure | Plane polarized light and crossed polarized light were applied to examine phases in samples, their colour, homogeneity, porosity and inclusions (shape, size and uniformity). Cross-polarized light was also applied for internal reflection and identifying the composition of phases present. The microscope was equipped with a Nikon digital camera, with highest magnification of 1000x. |
| SEM-EDS Scanning Electron Microscopy with Energy Dispersive Spectrometry (Philips XL30ESEM, Superprobe JEOL- JXA-8600, Hitachi S-3400N, and Belgrade-based JEOL JSM-6610LV for copper mineral ornaments from Lepenski Vir) | <ol style="list-style-type: none"> 1. Phase identification in samples using electron images and area/point analyses 2. Quantitative compositional analyses of observed phases 3. Observation of the relationships between phases on the basis of their atomic number contrast | Backscattered electron (BSE) imaging used. All materials analysed on Philips and JXA-8600. Environmental Secondary Electron Detector in VP-SEM (vacuum) mode was applied for analyses of malachite beads (Hitachi, JSM-6610LV). The accelerating voltage was 20 kV, with average dead-time of 35-40 % and working distance of 10 mm. The analytical volume of the beam depended on the density of analysed material, for metallic phases its diameter was c. 2 μm , and for lighter materials (slag, ceramic), nearer 5 μm . All data are presented as normalized with stoichiometrically added oxygen, if not otherwise stated. The iron content is presented as FeO, which here stands for total iron (both valencies). |
| EPMA Electron Probe Micro Analysis (Superprobe JEOL-JXA-8100) | Compositional analysis of copper metal phases in all samples (down to trace element level) | All samples analysed at an accelerating voltage of 20 kV, beam current 50 nA, with average dead-time of 35-40 % and working distance of 10 mm. The following elements were checked for: Se, Zn, Cu, Fe, As, Ag, Cl, Te, S, Au, Sn, Bi, Co, Sb, Ni, Mn, Pb. All data presented as wt% and ppm, with the trusted values for the latter established at ≥ 10 ppm. |

Table 1: Analytical instruments used in this study, aim of analysis and relevant analytical parameters.

1.3 Compositional Analysis

1.3.1 SEM-EDS

SEM-EDS was used to chemically characterise the phases present in the samples and assess their relation to the given analytical context (Table 1). It was applied for analysing all types of materials mounted in polished blocks. All polished blocks were carbon-coated, and analysed under the same conditions: accelerating voltage of EDS was 20 kV, with an average dead-time of 35-40% and working distance of 10 mm. The analytical volume of the beam varied depending on the density of the analysed material. For metallic phases, its diameter is in the range of 2 μm , while for lighter phases/materials such as slag or ceramic, it is nearer 5 μm . BSE imaging was used as default for faster recognition of samples' components. The data processing was controlled by INCA X-cite software, which processes, displays and stores the images and spectra acquired by the analyser. A cobalt standard is used to calibrate the EDS analyser, and is scanned every 25-30 minutes to guard against analytical drift. The acquired spectra from all analysed samples were carefully checked for every detected element, and particularly visually searched for the following elements: P, S, Mn, Fe, Co, Ni, Cu, Zn, As, Sn, Sb, and Pb. The detailed examination of spectra led to establishing the minimal reliability threshold for measurements acquired by the INCA software for each of the checked elements. These values were used as guidelines in the following round of data digestion, which scrutinised measurements below the set minimum for each of these compounds (Table 2), expressed as oxides with oxygen determined by stoichiometry.

Table 2: Reliability threshold values for the SEM-EDS data for ceramics, slags, oxidised metal and minerals. Negative values stand for elements that should not be trusted once offered by the INCA software. Copper oxide values are trusted for oxidised metal, while SnO₂ and PbO were not detected in ceramic and slag.

| Name | Description | Selected for | Analytical instrument |
|-----------------|--------------|-------------------------|-----------------------|
| BIR1 | Basalt glass | slag, ceramic, minerals | SEM-EDS |
| BCR-2 | Basalt glass | slag, ceramic, minerals | SEM-EDS |
| BHVO-2 | Basalt glass | slag, ceramic, minerals | SEM-EDS |
| Cu No. 096255LN | Pure copper | copper metal phases | EPMA |

Table 3: CRMs used during SEM-EDS and EPMA analyses of all materials in this study.

Since two different SEM-EDS instruments were used for analysing these samples (Table 1, Philips and JXA-8600), the acquired data are corrected against certified reference materials (CRM), analysed under the same conditions on both machines (Table 3). A correction factor was applied only in cases where divergence was higher than 10% (Tables 4 and 5).

1.3.2 EPMA

EPMA was used for analysing copper metal phases in all studied samples, with particular benefit for detecting present elements present at the ppm ($1/10^6$) level. Seventeen chemical elements were searched for in all samples (Table 1), with analytical background of these adjusted during analysis of certified reference material (CRM) for pure copper. Since the Zn peak is known to overlap with a Cu peak, additional analytical work was required for setting the background, hence separate analysis for Zn and Cu only (Table 6). Each sample had nine to eleven runs for the best precision data. The analytical conditions were set at accelerating voltage of 20 kV, beam current of 50 nA, deadtime 35- 40% and working distance of 10 mm. In order to assess the true presence of trace elements in copper metal phases in various samples, all gained values were assessed in relation to measurements acquired for pure copper CRM (Table 6). During data analysis and interpretation, the threshold for trusted values for trace elements was established at ≥ 10 ppm.

Table 4: SEM-EDS compositional data of certified reference materials (CRM) for basalt glasses: BIR1, BCR-2, BHVO-2, given in wt% and conducted on Philips. All measured values are presented against certified average values for CRMs, with correction value calculated only for relative errors above 10% divergence. The averages of all correction values and correction factor are given in the bottom two lines; the correction factor was applied for calculating real values for samples analysed with this instrument.

Table 5: SEM-EDS compositional data of certified reference materials (CRM) for basalt glasses: BIR1, BCR-2, BHVO-2, given in wt% and conducted on JXA-8600. All measured values are presented against certified average values for CRMs, with correction value calculated only for relative errors above 10% divergence. The averages of all correction values and correction factor are given in the bottom two lines; the correction factor was applied for calculating real values for samples analysed with this instrument.

1.4 Reporting and Data Processing

Photomicrographs were carefully labelled for sample magnification and polarisation under which they were taken. The SEM data were searched for particular elements within the INCA software, during which process analytical reliability threshold was established for each of them (Table 22). These data were then extracted from the (INCA) analytical software into Excel spreadsheets and subsequently digested in more detail. Statistical analyses were conducted in Excel, and SPSS (ver. 17) and 'R' statistical analysis software environments, while ternary diagrams were produced using OriginPro8. Where necessary, images were processed in Photoshop CS2.

Compositional data are presented here as percent by weight (wt%) unless stated otherwise, typically determining oxygen by stoichiometry rather than by elemental analysis. [We used atomic weight in cases when it was necessary to identify a formula of a particular newly-formed phase in the slag matrix, or a mineral phase in a copper ore.](#)

All data presented in the main texts were corrected against CRMs (Tables 3). While accuracy of the SEM-EDS data was tested against CRM for basalt glass (BHVO-2, BIR1, BCR-2, Tables 4 and 5), the EPMA measurements were corrected against CRM for registered standard No. 096255LN for pure copper (from the Reference standards for X-Ray Microanalysis, Micro-Analysis Consultants, Ltd) (Table 6). The corrected EPMA data is reported to ppm level, while acknowledging an error margin of an estimated 5-10 % relative for absolute values below 1 wt%.

Table 6: EPMA compositional analyses for copper standard #096255LN, expressed in wt%. Average values for trace elements (bottom line) were used to subtract from the trace element values measured for all copper metal artefacts and metal phases in the studied samples, with an aim to present the true presence of trace elements in them.

2 A brief geological overview

2.1 Copper in the Balkans

Copper ores represent one of the main mineral deposits exploited to the present day in Serbia. The largest copper producing mines are located in Bor, a mining district in eastern Serbia, although there are a few more in central, west and south Serbia (Fig. 1). The dominant types are porphyry copper and massive sulfide deposits with significant Pb, Zn, and Au mineralisation (Janković 1967; Jelenković 1999; Neubauer and Heinrich 2003; Monthel et al. 2002). The porphyry deposits at Bor also carry enargite (copper-arsenic-sulfide), a common mineral for this locality (Sillitoe 1983). Gold deposits are particularly interesting since they were discovered in many localities in the Bor area (Fig. 2), largely followed by copper, but also by Sn-W-Mo mineralisation, as in Blagojev kamen (Fig. 3). However, the richest occurrence of tin (cassiterite) is related to the west Serbian deposits in Bukulja and Cer (Jelenković 1999: 145-146).

The Bor district forms part of a larger metallogenic subprovince (Bor-Srednegorie) within the Carpatho-Balkan metallogenic unit, which is characterised by an abundance of base and precious metals (Au, Ag) (Janković 1997: 431; Neubauer and Heinrich 2003). The Bor-Srednegorie subprovince stretches from Transylvania via Bor to Srednegorie in central Bulgaria and ends near the Black Sea coast in the Burgas region in Bulgaria. It is characterised by morphologically variable copper occurrences: in Bor and Panagyurishte there are porphyry (Majdanpek, Assarel, Elacite) and massive sulfide deposits (Radka), while in the Burgas ore district the mineralisation of vein quartz-chalcopyrite association (Zidarovo, Rossen) prevails (Bogdanov 1982). Copper deposits in this subprovince are commonly accompanied by gold, silver, lead-zinc and molybdenum.

Another important metallogenic unit, the Serbo-Macedonian unit, stretches in parallel to the Carpatho-Balkan unit, cutting across central Serbia and Macedonia and ending at the Chalkidiki shores in Greece. It is abundant with lead, zinc, copper and antimony, but also accompanied by gold, silver, arsenic, thallium, bismuth and iron (Janković 1997: 431; Jelenković 1999: 14). This unit is noteworthy as it includes the areas with ancient mining of copper (Rudnik), silver (Avala, Kosmaj, Srebrenica) and modern exploitation of lead and zinc (Trepča) (Jovanović 1983; Dušanić 1995; Hirt 2010).

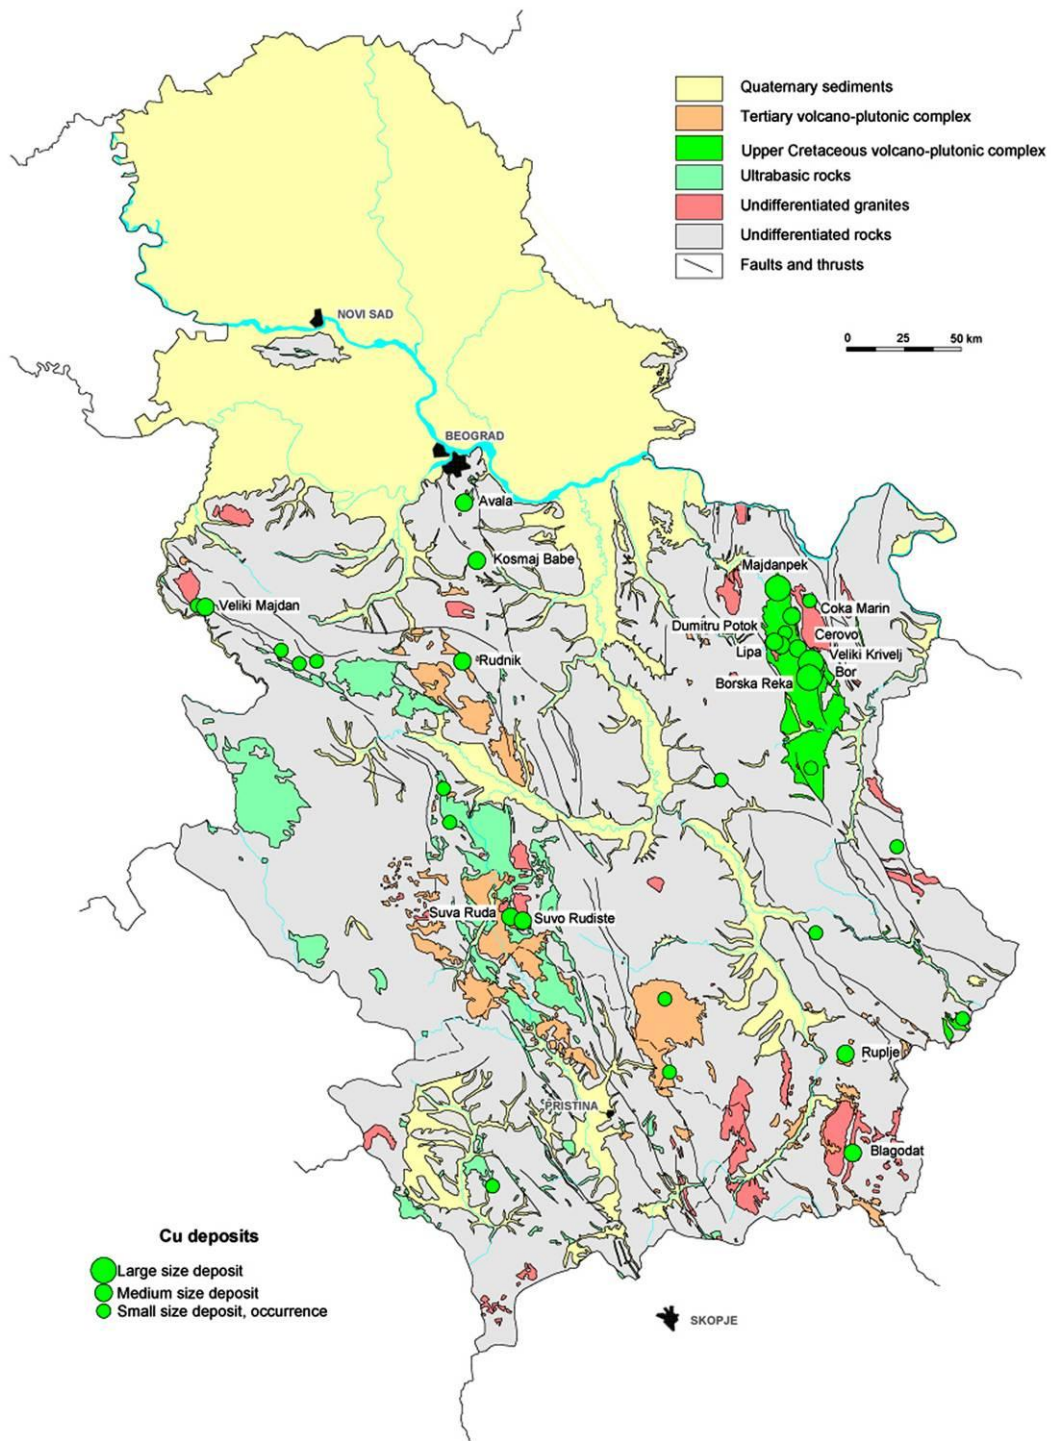

Figure 1- Copper deposits in Serbia (after Monthel et al., 2002, p. 35, Fig. 14).

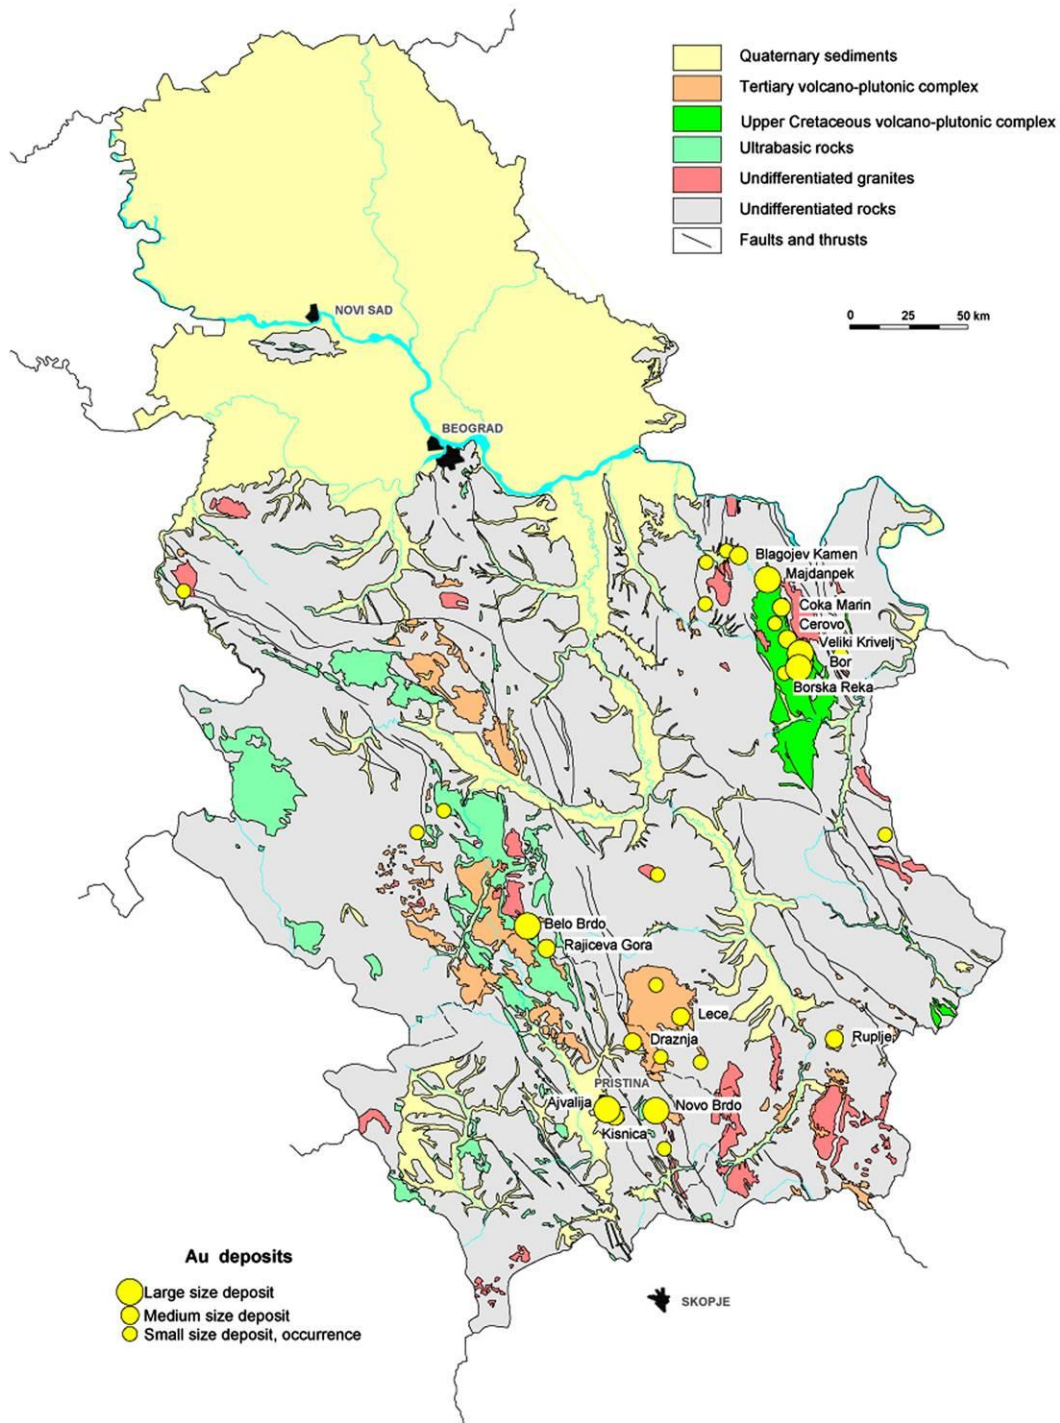

Figure 2- Gold deposits in Serbia (after Monthel et al., 2002, p. 40, Fig. 19).

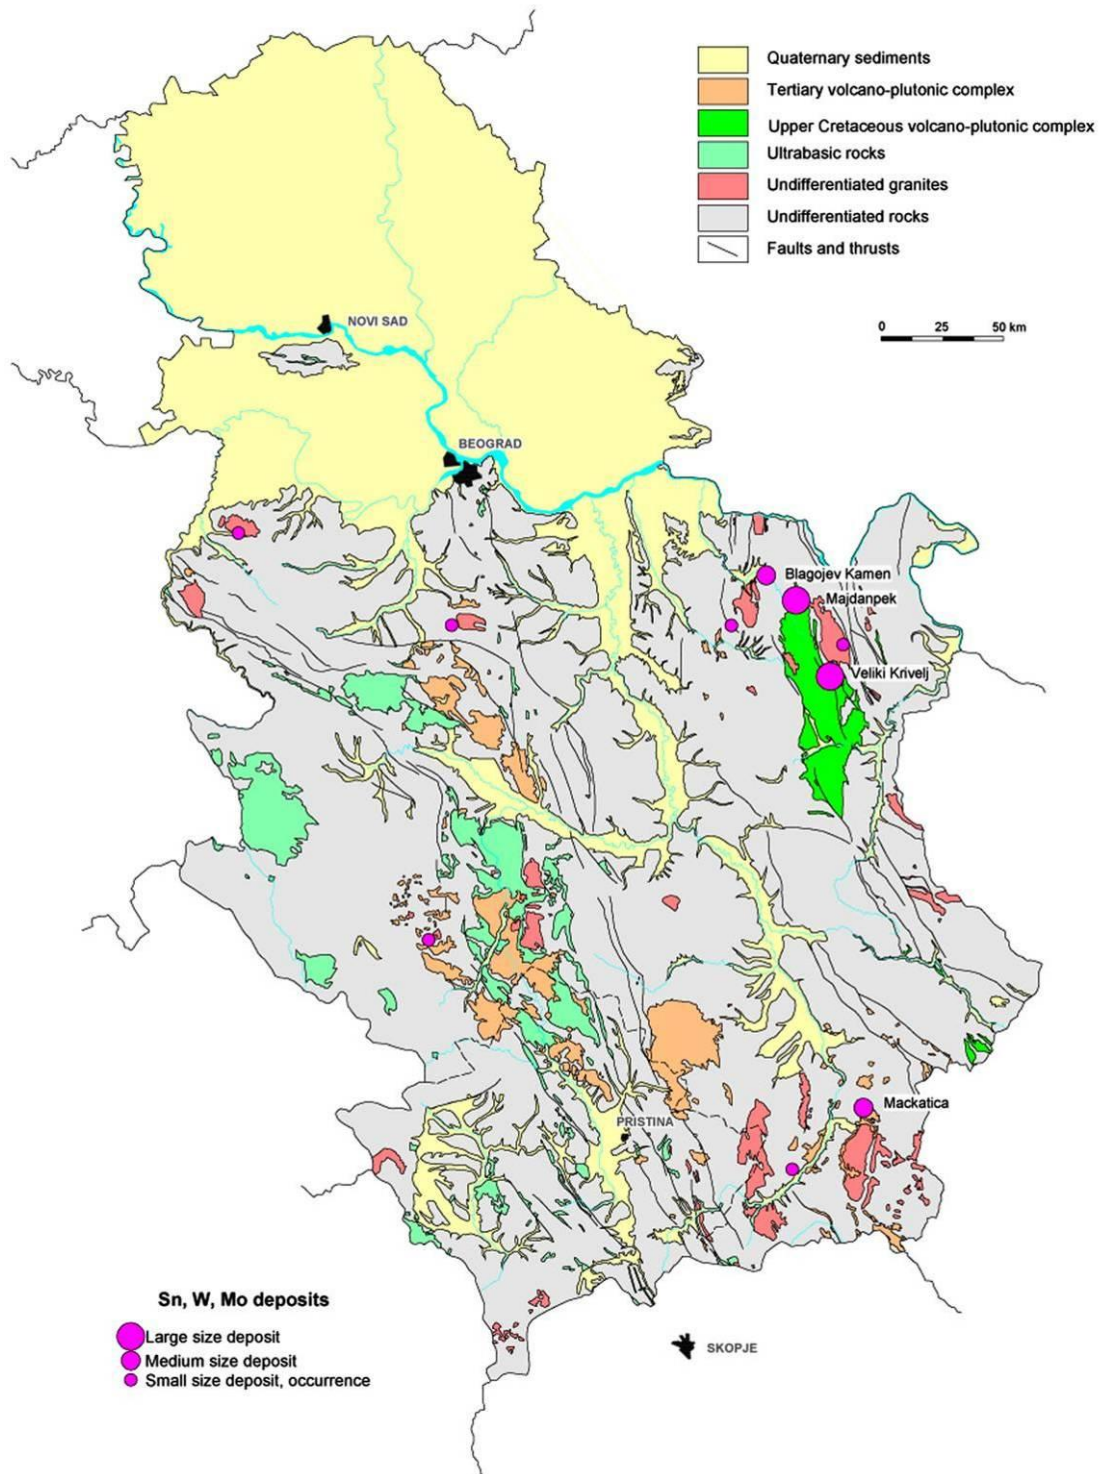

Figure 3- Tin-tungsten-molybdenum deposits in Serbia (after Monthel et al., 2002, p. 39, Fig. 18).

The dominance of lead and zinc occurrence together with massive sulfide and porphyry copper deposits is not only characteristic of the Balkan metallogeny, but also of the massive Tethyan Eurasian metallogenic belt (TEMB) that formed on the southern margin of Eurasia (Janković 1977, 1997). This c. 10,000 km long belt with similar metallogenic features runs from the western Mediterranean via the Alps and southeast Europe, the Pontides and Anatolia, Iran and Afghanistan, passing into the Tibet Plateau, and reaching Burma and Sumatra only to link with the West Pacific metallogenic belt. The TEMB includes confirmed traces of ancient copper mining from the early beginnings in western Eurasia, and importantly so, of complex copper ores including tin-bearing ones (e.g. Deh Hosein in Iran, Mushiston in Tajikistan) (Weisgerber and Cierny 2002; Nezafati et al. 2011; Stöllner et al. 2011). The discussion on the early appearance of copper metallurgy in western Eurasia therefore involves early histories of the use of other metals, particularly in the light of the geological opulence of various metal deposits in this area.

2.2 Phosphates, arsenates and vanadates in the context of Balkan metallogeny

We dedicate further attention to the formation of several specific minerals mentioned in this paper: apatite, vivianite, scorodite, strengite and arthurite, all of which belong to the same class of minerals, termed phosphates, arsenates and vanadates.

Apatite ($\text{Ca}_5(\text{PO}_4)_3(\text{OH},\text{F},\text{Cl})$) is the most common phosphate mineral, which includes Fluorapatite, Chlorapatite and Hydroxyl-apatite, of which fluorapatite is the most ordinary form of apatite in nature. Apatite occurs in rocks of various kinds and ages, but most commonly in metamorphic crystalline rocks and in many metalliferous veins (tin mostly), also in gneiss, syenite, hornblende gneiss, mica schist, beds of iron ore. Colour varies from white, sea-green to black (Dana and Ford 1922, p. 595-597).

Vivianite [$\text{Fe}_3(\text{PO}_4)_2 \cdot 8\text{H}_2\text{O}$] is a mineral that belongs to the eponymous group of phosphates. It can be colourless and pale green, and with oxidation it becomes dark blue, dark greenish blue, indigo-blue, and then black. Interestingly for the context of early metallurgy, it colours the flame to bluish green when set on fire. It occurs in association with pyrrhotite and pyrite

in copper and tin veins, less frequently in narrow veins with gold, or limonite, or bog iron ore (Dana and Ford 1922, p. 608; Anthony et al. 2000, p. 632).

Both *scorodite* ($\text{FeAsO}_4 \cdot 2\text{H}_2\text{O}$) and *strengite* ($\text{FePO}_4 \cdot 2\text{H}_2\text{O}$) belong to the variscite mineral group; while scorodite commonly occurs as secondary mineral resulting from the oxidation of arsenopyrite other arsenic-bearing species, strengite is formed by the alteration of iron-bearing phosphates, but also can be found in limonite ore deposits and gossans. The colour of scorodite is green-blue, while strengite varies from colourless to violet. Interestingly, scorodite colours the flame in blue (Dana and Ford 1922, p. 610). Both scorodite and strengite occur in association with vivianite and iron ores, while apatite is more commonly found with strengite (Anthony et al. 2000, p. 531, 567)

Arthurite ($\text{CuFe}_2(\text{AsO}_4, \text{PO}_4, \text{SO}_4)_2 \cdot 4\text{H}_2\text{O}$) occurs in association with scorodite (among others) and forms in oxidised zone of some copper deposits, or by alteration of arsenopyrite or enargite. It is mainly coloured as apple-green (Anthony et al. 2000).

According to mineralogical data, there is a great likelihood that these minerals would paragne in the same, or similar, locality, which in our case could be characterised as the deposit of primary copper ore, with occurrences of iron ores, arsenopyrites and arsenic-bearing species (like enargite).

Significant massive sulfide deposits of cupriferous pyrite are found in the Bor district in eastern Serbia, together with volcanogenic massive polymetallic deposits that contain a pyritic Zn-Cu-Pb association (Janković 1990). These are situated in the zone 80 x 20 km as a part of the Carpathian-Balkan metallogenic province, which belongs to the Tethyan Eurasian metallogenic belt (Janković 1977). This massive sulfide ore body is particularly interesting as it contains high concentrations of pyrite and copper minerals (chalcopyrite and bornite) with significant contents of chalcocite, covellite and enargite (Janković 1990, p. 471). The economic importance of enargite in addition to copper in the Bor district has also been documented by Sillitoe (1983).

The trace element enrichment of Ag, Sb, As, Ti, Se, and to some extent of Pb, Zn and Sn has been established in the massive deposition of chalcopyrite-bornite-pyrite in the Bor district (Janković 1990, p. 473). Also, the polymetallic deposition in the Čoka Marin region (within the Bor district) revealed significant content of gold, occurring as native gold and/or

associated with sulfides. Chalcopyrite, enargite, cassiterite and stannite are only some of the minerals associated with this particular locality (Janković 1990, p. 475).

Thus, given the geological characterisation of the nearest mining region to the three sites with early metal production evidence, there is a great likelihood that all colourful minerals mentioned in our research could have been associated in the same locality in eastern Serbia. We are not arguing here for the exploitation of a particular deposit but rather that the possibility is high in the Bor district in eastern Serbia to come across all minerals like apatite, vivianite, scorodite, strengite or arthurite while prospecting for copper ores. Belovode is the site closest to these deposits, and we do not exclude the possibility of the existence of an ore exchange network at the time maintained by the Belovode miners, for instance.
