How the techniques of molecular biology are developed from natural systems

Isobel Ronai

isobel.ronai@sydney.edu.au School of Life and Environmental Sciences, The University of Sydney, Sydney, NSW, Australia.

Abstract

A striking characteristic of the highly successful techniques in molecular biology is that they are derived from natural systems. RNA interference (RNAi), for example, utilises a mechanism that evolved in eukaryotes to destroy foreign nucleic acid. Other examples include restriction enzymes, the polymerase chain reaction, green fluorescent protein and CRISPR-Cas. I propose that biologists exploit natural molecular mechanisms for their effectors' (protein or nucleic acid) activity and biological specificity (protein or nucleic acid can cause precise reactions). I also show that the developmental trajectory of novel techniques in molecular biology, such as RNAi, is four characteristic phases. The first phase is discovery of a biological phenomenon, typically as curiosity driven research. The second is identification of the mechanism's trigger(s), the effector and biological specificity. The third is the application of the technique. The final phase is the maturation and refinement of the molecular biology technique. The development of new molecular biology techniques from nature is crucial for biological research. These techniques transform scientific knowledge and generate new knowledge.

Keywords: mechanism; experiment; specificity; scientific practice; PCR; GFP.

Introduction

Molecular biology is principally concerned with explaining the complex molecular phenomena underlying living processes by identifying the mechanisms that produce such processes (Tabery et al. 2015). In order to access the causal structure of molecular mechanisms it is generally necessary to manipulate the components of the mechanism and to observe the resulting effects with sophisticated molecular techniques. These techniques generate knowledge that cannot be obtained by any other means. Therefore, scientific knowledge in molecular biology advances in a distinctive way: progress is driven by the introduction and use of novel techniques. However, what drives the development of molecular biology techniques?

In this paper, I firstly provide evidence that highly successful molecular biology techniques are derived from natural systems. In Section 2, I explain how the natural systems' strategy for technique development means that the techniques utilise the activity of a mechanism's effector (protein or RNA) and exploit biological specificity (protein or nucleic acid can cause precise reactions). In Section 3, I present RNA interference (RNAi) as an exemplar case study to describe how molecular biology techniques are typically developed from nature. In Section 4, I show that molecular biology technique development can be divided into four phases. I conclude by discussing the implications of deriving techniques from nature for molecular biology.

1) From natural systems to techniques

A striking feature of the development of molecular biology techniques, which biologists themselves often highlight (for example, Lander 2016; Mello and Conte 2004), is that they are derived from natural systems. These techniques are not developed through rational design. In this paper I identify eight highly successful techniques of molecular biology that are derived from natural systems. In chronological order these are: restriction enzymes; DNA sequencing, polymerase chain reaction (PCR); gene targeting; green fluorescent protein (GFP); RNAi; induced pluripotent stem cells (iPS); and clustered regularly interspaced short palindromic repeats-CRISPR associated (CRISPR-Cas) (see Table 1). Throughout this paper I draw on RNAi as my detailed case study due to my firsthand experience with this technique (Ronai et al. 2016). RNAi is a technique that introduces molecules of RNA into an organism in order to reduce the expression of a gene of interest (reviewed in, Mello and Conte 2004) (Figure 1). The eight molecular biology techniques are so ubiquitous that they are regarded as common knowledge by biologists. So when these techniques are mentioned in the Methods section of a scientific article, a citation to the technique is often not necessary (for example, Ronai et al. 2016).

The eight molecular biology techniques discussed are derived from mechanisms that each evolved for a particular biological function in a natural system (see Table 1). The biological function of the RNAi mechanism, for example, is an organismal defence system for the destruction of foreign nucleic acid and mobile elements (van Rij and Andino 2006; Waterhouse et al. 1998; Waterhouse et al. 2001). Interestingly, the RNAi mechanism is thought to have been co-opted (Cerutti and Casas-Mollano 2006) for the precise regulation of endogenous gene expression, in particular for the regulation of developmental genes (Carrington and Ambros 2003). Therefore, the RNAi mechanism is a deeply entrenched process in eukaryotic organisms. The same biological function, to destroy foreign nucleic acid in the organism, underlies the techniques of RNAi (derived from eukaryotes) and CRISPR-Cas (derived from prokaryotes) (Bhaya et al. 2011; Wright et al. 2016), but the two techniques involve different molecular mechanisms (Table 1). Therefore, the 'arms race' that occurs between viruses and their organismal hosts has provided biologists with the basis of two techniques. In contrast the

Fig. 1: A model of the molecular biology technique of RNA interference (RNAi). (1) Doublestranded RNA (dsRNA) is introduced into the experimental system. (2) The endogenous endonuclease Dicer cleaves the dsRNA into small fragments known as small interfering RNA (siRNA). (3) Or the siRNA is added directly into the experimental system. (4) The siRNA antisense strand attaches to the endogenous RNA-induced silencing complex (RISC), (5) which binds sequence specifically to the target mRNA. (6) RISC cuts the target mRNA which causes it to be degraded, therefore no gene function is executed.

Table 1: Summary and characterisation of eight pivotal molecular biology techniques. These techniques are all derived from natural systems and are now utilised as methodologies. For key references see Table 2.

technique of GFP is derived from a relatively unique biological phenomenon in jellyfish and is therefore taxonomically restricted.

As is usual in biological research practice, when a molecular biology technique is developed for an organismal experimental context (Table 1) it is first tested in a 'model organism' system. Model organisms provide standardised experimental systems that are relatively well characterised at the molecular level act as a prototype for technique development (Ankeny 2000). This is particularly important given the complexity and cost of molecular biology experiments. The expectation is that, due to the fundamental unity of living systems, if a technique is validated in a model organism, then it will be possible to apply it to other organisms. For example, RNAi was first developed using the model organism *Caenorhabditis elegans* (Fire et al. 1998).

The explanatory focus of biology is what occurs in nature so experiments must be compatible with living processes (Weber forthcoming) rather than create artificial phenomena. Therefore, the use of pre-existing, natural mechanisms for technique development in molecular biology is advantageous. These techniques are compatible with other biological processes and able to operate within a cellular context. Furthermore, the use of a natural mechanism may allow the continuing function of the biological process (for example, GFP) and cellular based techniques can be stably inherited in designed constructs with transgenerational effects. These techniques can be used to observe or intervene in active, complex biological processes even when no comprehensive understanding of these processes exists.

2) The importance of natural systems for the development of techniques in molecular biology

In this section I analyse why natural systems are used for the development of techniques in molecular biology. Natural mechanisms have been selected and optimised by evolution. These mechanisms therefore have a high level of validation. Molecular biology techniques exploit two characteristics of natural mechanisms: an effector's activity and the use of biological specificity.

2.1) Effector activity

Living systems use effectors (such as, proteins or RNAs) to generate a particular activity within a mechanism. I have identified the protein effector, all from a natural system, for each of my eight molecular biology techniques (Table 1). The majority of the techniques utilise proteins that are catalytic enzymes (note, enzyme names normally end with '-ase') and the techniques leverage the efficiency of the enzymatic activity (Table 1). The two exceptions are the techniques of GFP and iPS which utilise a protein's stereochemistry, a flurophore or structural motif, respectively (Table 1).

The technique's effector is either endogenous or exogenous to the experimental system (Table 1). Endogenous based techniques use the effector for its original purpose but they co-opt the overall mechanism. Whereas, exogenous based techniques use the effector for its original purpose but in another biological context, so the effector needs to be introduced into the experimental system. For example, the effector of RNAi is the RNA-induced silencing complex (RISC), which is an endogenous component of a molecular mechanism present in all eukaryotes and involves an enzyme (Cerutti and Casas-Mollano 2006). RISC cuts the target mRNA and cause it to be degraded (Hammond et al. 2000; Martinez et al. 2002).

2.2) Biological specificity

Living systems need biological specificity to achieve fine-grained control over their molecular mechanisms (Griffiths et al. 2015; Waters 2007; Woodward 2010). Biologists artificially introduce biological specificity into their experimental systems. The eight molecular biology techniques studied here utilise this biological specificity to precisely access the target mechanism with minimal off-target events. Drawing on this specificity means that the technique can be multiplexed (multiple nucleic acid sites targeted at the same time). I have identified that the majority of the eight molecular biology techniques use nucleic acid sequence informational specificity (Griffiths and Stotz 2013), nucleic acid is the substrate of the mechanism (Table 1). For example, RNAi uses nucleic acid specificity when double-stranded RNA (dsRNA) or small interfering RNA (siRNA) is introduced into the experimental system and binds sequence specifically to the target mRNA. One molecular biology technique (GFP) uses what I have termed 'engineered informational specificity', where the biologist creates the specificity by placing the effector in a highly specific location. Two other molecular biology techniques, iPS and restriction enzymes, use protein stereochemical specificity (Griffiths and Stotz 2013) (Table 1).

For nucleic acid guided techniques the informational specificity is artificially designed whereas stereochemical specificity uses natural specificity. Therefore, stereochemical specificity is fixed before the start of the experiment and is less programmable than informational specificity.

Before RNAi was developed as a technique only a non-specific, permanent disruption in gene expression via mutagenesis was possible (Bellés 2010). In contrast, RNAi provides more finegrained control because it uses nucleic acid sequence informational specificity. A biologist introduces RNA molecules into the experimental system which initiates the mechanism and its nucleotide sequence specifies the mRNA sequence to degrade. Therefore, RNAi manipulates gene expression at a fine scale to cause a 'knockdown' in gene expression. In addition, RNAi can be 'multiplexed' as different RNA molecules can be introduced in order to target different mRNAs (see for example, Fellmann and Lowe 2014; Kennerdell and Carthew 1998), or the same mRNA in different regions (see for example, Gou et al. 2007). Furthermore, in nature dsRNA acts as a natural multiplexer because it is cut into multiple siRNAs that target different regions of the mRNA (Bernstein et al. 2001).

2.3) The importance of an effector's activity and biological specificity

The effector activity and specificity of a technique are critical to its success. If there are multiple techniques available to achieve the same experimental purpose, then the one with the greatest efficiency or superior type of specificity is preferred by the scientific community. For example, transcription activator-like effector nucleases (TALENs) are a technique derived from the bacteria *Xanthomonas* (Boch et al. 2009; Moscou and Bogdanove 2009). TALENs are similar to the CRISPR-Cas technique, as both are used for DNA editing. However, a TALENs' specificity is stereochemical so it needs to be reengineered for every experiment. Therefore, TALENs are not as easily programmable for a wide range of targets compared to CRISPR-Cas (with the notable limitation of the protospacer adjacent motif (Doudna and Charpentier 2014)). For this reason CRISPR-Cas became commercially viable and has replaced TALENs as the premier gene editing technique (Corbyn 2015; Doudna and Charpentier 2014). Therefore, the effector's

activity and specificity are likely to be critical for the commercialisation of the technique for widespread usage.

Note that biologists implicitly recognise the importance of the effector's activity and the use of biological specificity for their molecular biology techniques. For example, many studies on RNAi discuss the technique's effector's activity (Fellmann and Lowe 2014; Filipowicz et al. 2005; Li et al. 2006; Rana 2007; Siomi and Siomi 2009; Vaucheret et al. 1998) and specificity (Bartel 2004; Elbashir et al. 2001b; Fellmann and Lowe 2014; Fire et al. 1998; Hamilton and Baulcombe 1999; Hammond et al. 2000; Hammond et al. 2001; Kennerdell and Carthew 1998; Parrish et al. 2000; Rana 2007; Siomi and Siomi 2009; Waterhouse et al. 1998; Waterhouse et al. 2001). In this section I have made theoretically explicit these two key characteristics of natural mechanisms: an effector's activity and the use of biological specificity.

3) RNAi: a case study

To answer the question of how a molecular biology technique is derived from nature requires an in-depth examination of how techniques are developed. In this section I describe in detail how the technique of RNAi was developed.

The development of RNAi was preceded by observations of gene-specific transcriptional inhibition when synthetic antisense RNA was introduced into an organism. Experiments in the bacteria *Escherichia coli* indicated that antisense RNA could bind to and inactivate mRNA (Light and Molin 1982). This phenomenon was then observed in many different organisms, including the nematode worm *Caenorhabditis elegans* (Izant and Weintraub 1984) and plants (Ecker and Davis 1986). At the same time, plant virologists showed that when a viral transgene was introduced into a plant the plant became resistant to the virus (Abel et al. 1986). These studies suggested that gene expression could be manipulated with the introduction of RNA.

Early studies discovered the RNAi mechanism in many different organisms, but the first study was conducted in plants. Napoli et al. (1990); van der Krol et al. (1990) wanted to increase colour intensity in the *Petunia hybrida* flower. They introduced a transgene (sense RNA) into the plant in order to overexpress a gene in the anthocyanin pathway, which controls formation of the flower pigment. Contrary to expectation, transformed flowers had less, rather than more, pigment. The synthetic sense RNA had reduced the mRNA of the endogenous gene. They termed this phenomenon 'co-suppression' (Napoli et al. 1990). In addition, Romano and Macino (1992) identified the RNAi phenomenon in a fungus, *Neurospora crassa*, and termed it 'quelling'. Also, studies in plants demonstrated that silencing occurred post-transcriptionally and therefore the RNAi phenomenon was sometimes referred to as 'post transcriptional gene silencing' (Blokland et al. 1994). At this time multiple studies were conducted on the introduction of RNA into *C*. *elegans* (Fire et al. 1991) (Fire et al. 1991; Guedes and Priess 1997; Guo and Kemphues 1995; Lin et al. 1995; Mello et al. 1996; Powell-Coffman et al. 1996). One of these *C. elegans* studies coined the term 'RNA-mediated interference' (Rocheleau et al. 1997). It is important to note that at this time microRNAs (miRNA), which are transcribed from the endogenous DNA and use the RNAi mechanism to regulate gene expression, were also identified (Lee et al. 1993; Wightman et al. 1993). These successive studies into how an organism actively responds to the introduction of RNA produced knowledge that was critical to the development of RNAi.

The RNAi technique was first applied in the paper 'Potent and specific genetic interference by double-stranded RNA in *Caenorhabditis elegans*' published in the journal *Nature* (Fire et al. 1998). In Fire et al. (1998, p. 807) dsRNA was investigated due to it being a contaminant in earlier experiments as it was found that:

… polymerases, although highly specific, produce some random or ectopic transcripts. DNA transgene arrays also produce a fraction of aberrant RNA products³... we surmised that the interfering RNA populations might include some molecules with double-stranded character.

dsRNA was accidently produced in these earlier experiments and caused the gene silencing.

Fire et al. (1998, p. 806) investigated dsRNA and identified that it is causally specific for the RNAi mechanism, they:

… investigate[d] the requirements for structure and delivery of the interfering RNA. To our surprise, we found that double-stranded RNA was substantially more effective at producing interference than was either strand individually.

Therefore, the study tested the specificity of RNA molecules to control the RNAi mechanism. The study was also a conclusive demonstration of how dsRNA can be used to control the RNAi mechanism and applied as a molecular biology technique to manipulate gene expression. Fire et al. (1998, p. 810) concluded that RNAi:

… adds to the tools available for studying gene function in *C. elegans*. In particular, it should now be possible functionally to analyse many interesting coding regions²¹ for which no specific function has been defined.

Interestingly, Fire et al. (1998, p. 810) did not understand the biological function of the RNAi mechanism:

Whatever their target, the mechanisms underlying RNA interference probably exist for a biological purpose.

Immediately following publication of the Fire et al. (1998) paper, RNAi was shown to work in multiple organisms. Studies rapidly emerged describing RNAi's effectiveness in *C. elegans* (Fitzgerald and Schwarzbauer 1998; Montgomery et al. 1998; Ogg and Ruvkun 1998; Page and Winter 1998; Skop and White 1998; Tabuse et al. 1998; Timmons and Fire 1998); two species of plants, *Nicotiana tabaccum* and *Oryza sativa* (Waterhouse et al. 1998); and *D. melanogaster* (Kennerdell and Carthew 1998). Attempts to conduct RNAi in mammals initially failed due to the immune response elicited, however, when siRNAs were introduced instead of dsRNA gene silencing occurred (Elbashir et al. 2001a). RNAi became a highly selective molecular biology technique for reducing expression of a target gene and today it is widely used for both basic and applied research (Deng et al. 2014; Fellmann and Lowe 2014; Mello and Conte 2004).

In the years following the Fire et al. (1998) paper, many components of the RNAi mechanism were identified and characterised. Biologists wondered how dsRNA could bind to the mRNA to cleave it and why a complete antisense RNA had never been detected in vivo. Biologists set out to look for fragments of the antisense RNA. They found small RNA fragments (antisense and sense) in plants and suggested that these were the molecules necessary for RNAi (Hamilton and Baulcombe 1999). Biologists also found that dsRNA is processed into small RNA fragments in *D. melanogaster* cells (Hammond et al. 2000; Zamore et al. 2000) and in *C. elegans* (Parrish et al. 2000). Small interfering RNAs (siRNA), 21-23 nucleotides in length, were identified as the common intermediary and their specificity guided the cleavage of the mRNA (Elbashir et al. 2001b). Biologists then needed to identify effectors for two distinct mechanistic steps: how dsRNA is cleaved into siRNA; and how the target mRNA is degraded.

The enzyme that cleaves a dsRNA into siRNAs was identified as a ribonuclease type III named Dicer (Bernstein et al. 2001). The endonuclease that cuts the target mRNA sequence-specifically was identified as Argonaute, which is part of the RNA-induced silencing complex (RISC)

(Hammond et al. 2000; Martinez et al. 2002). Biologists then pursued the mechanistic details such as the functions of different forms of Dicer and Argonaute and how RISC works (Rana 2007). To this day the mechanism of RNAi is still being investigated.

In the following section I use the history of RNAi as the basis for an account of molecular biology technique development. I show that technique development can be demarcated into phases.

4) Molecular biology technique development has four phases

I propose that molecular biology techniques derived from natural systems have a specific pattern of development with four critical phases. These phases are: the discovery of a phenomenon; identification of the mechanism's trigger(s); application of the technique; and maturation of the technique. The eight molecular biology techniques I have explored in this paper show the four phases of technique development (Table 2).

The first phase is discovery - an interesting phenomenon is identified in a natural system. Biologists are curiosity driven and routinely identify and describe unusual phenomena. However, at this stage the underlying mechanism is not well characterised and the biological function of the mechanism is typically unknown.

The second phase is the identification of the trigger(s). The effector component of the mechanism is identified and the specificity is identified (see Table 3A&B), note that for stereochemical techniques the effector is the specificity. If the effector is endogenous to the experimental system, then it does not need to be added to the experiment and its identification is not essential for the development of the technique. For example, the RNAi effector component was identified two years after the RNAi technique was developed (Table 2). I term the effector and specificity 'the trigger(s)' because they are the key causative agents and are 'the causally specific actual difference maker' under typical conditions (Carrier 2004; Waters 2007; Woodward 2010). Once biologists identify the trigger(s) they can use it to precisely access the causal structure of the mechanism.

The third phase is application of the trigger(s). In a conclusive demonstration that the trigger(s) is introduced into the experimental system and achieves some intended effect on the target of the specificity. The trigger(s) is exploited in three types of investigative strategies: to manipulate an effector's activity in a non-cellular experimental system, for example, restriction enzymes; to intervene on a cellular experimental system, for example, RNAi; or as a tracer to follow a natural process (for an in depth discussion see Griesemer 2007), for example, GFP (Table 1). At this stage a deep understanding of the mechanism underlying the technique is not necessary for the technique to work.

The fourth phase is maturation. Once the technique is established its performance can be improved. The scientific community invests considerable research activity into characterising, both spatially and temporally, the mechanism in natural systems. Therefore, the technique generates further research on the mechanism that underlies it. The new knowledge acquired may improve access to the mechanism or allow the technique to be better controlled, enabling the technique to continue to be refined.

Table 2: The four phases of development for the eight highly successful molecular biology techniques. For each technique I identify the first paper that: discovered the phenomenon; identified the mechanism's effector; identified the mechanism's specificity applied the trigger(s); and any highly cited papers that demonstrate the maturation of the technique.

¹ This paper was published in two parts.

 2 ² This study only applied primers with DNA polymerase to synthesise DNA rather than amplify a DNA region.

 3 A single study cannot be identified because the biological mechanism underlying gene targeting has multiple effectors.

Table 3: The key experiments for the RNAi technique conducted by Fire et al. (1998). Experiments that (A) identified the triggers in the RNAi mechanism; and (B) identified the target of the specificity in the RNAi mechanism.

(B)

4.1) Cognitive values and the success of the techniques

Cognitive values play an important role in the assessment of theory change in the sciences (Darden 1991; Douglas 2013; Kuhn 1977). Here I identify the cognitive values that are important for the widespread adoption of a technique. Three cognitive values are important for the assessment of a technique. First, the technique needs to be fruitful for further research. Techniques need to generate new knowledge and open up areas of research that were previously unimaginable. For example, RNAi has helped biologists manipulate RNA thus leading to a more sophisticated understanding of the function of RNA (Mello and Conte 2004) and this has allowed biologists to manipulate genes that are lethal in development in order to investigate their functions (for example, Fitzgerald and Schwarzbauer 1998). Second, the technique should allow expansion of its scope of application far beyond its original biological context. After the effector protein is identified it must either be endogenous to the experimental system (and also conserved in the taxa that will be the experimental system) or be exogenous and able to operate in a range of experimental systems. A technique that has applications in many contexts means a bigger scientific community can use the technique. In addition, a technique that can be used in mammals is particularly desired due to the value placed on medical and therapeutic research. For example, the RNAi effector, RISC, is present in all eukaryotes (Cerutti and Casas-Mollano 2006) and RNAi can be used in human cell lines (Elbashir et al. 2001a). Third, the technique needs to have extendability. The technique should accommodate modifications so that it can be used for different or expanded capabilities. Therefore, a technique can become the progenitor for a family of related techniques. For example, a form of RNAi was developed that used RNA molecules targeted at promoters to increase rather than decrease gene expression (Li et al. 2006). It is important to note that whether a technique rates highly on these three cognitive values it can only be identified in hindsight as that judgment is based on the employment of the technique (Darden 1991; Douglas 2013). The three cognitive values I have identified do not compete with one another as similar theoretical values do (Darden 1991) - a technique can be fruitful, have broad scope and be extendable at the same time.

5) Conclusions

A deeper understanding of the characteristics of natural systems and the development of scientific practice is gained by examining how molecular biology techniques are developed by biologists. In this paper I have investigated eight highly successful techniques of molecular biology that are derived from natural systems. I have argued that the development of these techniques falls into four phases. What are the implications of the fact that biologists develop molecular biology techniques from natural systems? Biologists' knowledge about natural systems limits what can be developed as a technique. Molecular biology techniques, and therefore molecular biology knowledge, are contingent. If biologists had discovered different phenomena in natural systems in the past then different techniques would have been developed. Molecular biology knowledge would have been altogether different, although we might speculate that deeply entrenched biological processes that are highly conserved across taxa (for example, the RNAi mechanism) will always be discovered.

There are other molecular biology techniques that are derived from natural systems and are likely to use the four phases of development of a molecular technique. These include techniques such as: reverse transcription; molecular cloning; monoclonal antibodies; site directed mutagenesis; and immunotherapy. Further research could identify these techniques' effector's activity and specificity.

It is an open question whether molecular biology will continue to progress through the development of molecular techniques derived from natural systems. Perhaps knowledge construction in molecular biology requires a natural systems strategy. Alternatively, as a relatively immature science that is still discovering its fundamental phenomena, adopting this strategy could be just an immature stage for molecular biology. There is some evidence that biologists working on synthetic biology have started to use rational design in organisms, for example, the high profile 'Human Genome Project–Write' (Boeke et al. 2016). However, biologists often find that rational design is not optimal and that selection methods lead to improved technique development and outcomes (Silverman 2003). Furthermore, a rational design strategy cannot be used to access the causal structure of molecular mechanisms when no comprehensive understanding of these mechanisms exists.

The addition of new molecular biology techniques accelerate research, transform biological knowledge and generates new knowledge that would otherwise not exist. A new technique can help uncover previously undetected phenomena and paradoxically, in turn lead to the development of yet another technique. Therefore, the techniques in molecular biology build upon one another and are cumulative.

Perhaps it is the fact that molecular biology's scientific practice is based on a collection of research tools, that makes it such a unique area of the biological sciences (Burian 1993). Biologists imbue their explanations of molecular mechanisms with the techniques they use to investigate the mechanisms (Trujillo et al. 2015). In molecular biology, even more than in other areas of science, the development of technological capabilities and scientific knowledge are inextricably linked.

Acknowledgements

I thank Paul Griffiths for all of his excellent advice, from when this project was an abstract idea and spanned across the paper's many iterations. I would also like to thank the participants of the 'Reductionism and Integration, Bioethics and Behavior: A Conference Celebrating the Career of Kenneth F. Schaffner' (Centre for Philosophy of Science, University of Pittsburgh) for their feedback when I presented this paper, in particular my commentator William Wimsatt. I am also grateful to Nicolas Rasmussen, Alan Love, members of the Theory and Method in Bioscience group (The University of Sydney) and members of the Behaviour and Genetics of Social Insects Laboratory (The University of Sydney) for their thoughtful comments that improved earlier versions of this paper. Finally, thank you to Lindell Bromham for encouraging me to pursue this project and for telling me to start writing this paper, when I was in the midst of my laboratory experiments.
