We consider the tunneling current through a double point-contact Fabry-Pérot interferometer such as used in recent experimental studies of the fractional quantum Hall plateau at filling fraction $\nu = 5/2$. We compare the predictions of several different models of the state of the electrons at this plateau: the Moore-Read, anti-Pfaffian, $SU(2)_2$ NAF, $K = 8$ strong pairing, and $(3, 3, 1)$ states. All of these predict the existence of charge $e/4$ quasiparticles, but the first three are non-Abelian while the last two are Abelian. We give explicit formulas for the scaling of charge $e/2$ and charge $e/4$ quasiparticle contributions to the current as a function of temperature, gate voltage and distance between the two point contacts for all three models. Based on these, we analyze several possible explanations of two phenomena reported in Refs. 1,2, namely halving of the period of the observed resistance oscillations with rising temperature and alternation between the same two observed periods at low temperatures as the area of the interference loop is varied with a side gate. We conclude that the most likely explanation is that the observed alternation is due to switching between even and odd numbers of charge $e/4$ quasiparticles enclosed within the loop as a function of side gate voltage, which is a clear signature of the presence of non-Abelian anyons. However, there are important features of the data which do not have a simple explanation within this picture. We suggest further experiments which could help rule out some possible scenarios. We make the corresponding predictions for future tunneling and interference experiments at the other observed second Landau level fractional quantum Hall states.

"With luck, we might see a non-abelian interferometer within a year." – attributed to Kirill Shtengel, April 16, 2008 in *Quantum computation: The dreamweaver's abacus*[3].

I. INTRODUCTION

The observation[4,5] of a fractional quantum Hall (FQH) state at $\nu = 5/2$ and suggestion[6] that the Moore-Read Pfaffian (MR) state[7,8,9] might occur at this filling fraction gave the first real indication that non-Abelian topological phases of matter might actually occur in Nature. The striking feature of such new phases is that they possess quasiparticle excitations with exotic non-Abelian braiding statistics[10,11,12,13,14,15,16]. This property makes non-Abelian topological phases appealing for their potential use as intrinsically fault-tolerant media for quantum information processing[17,18,19,20].

Recent experimental studies of transport through a point contact in FQH systems at $\nu = 5/2$ gave evidence that there are charge $e/4$ quasiparticles in this state[21] and found that the dependence of the current on voltage and temperature is most consistent[22] with two particular non-Abelian models: the anti-Pfaffian ($\overline{\text{Pf}}$) state[23,24] and the $SU(2)_2$ NAF (non-Abelian FQH) state[25,26]. However, these results are not conclusive because the $(3, 3, 1)$ state[27], which is Abelian, also supports charge $e/4$ quasiparticles. It is also roughly consistent with the voltage and temperature dependence of tunneling found in Ref. 22 and, in any case, one might expect non-universal physics to have a significant effect on the observed

dependence. Thus, there is a glaring need for experiments which directly probe the braiding statistics of quasiparticles.

In order to probe braiding statistics in FQH systems, one can use a double point-contact interferometer, as proposed in Ref. 28 for Abelian states and later considered for the $\nu = 5/2$ state in Refs. 29,30,31,32. Such interferometers can play a crucial role in properly identifying which phase a FQH state is in by providing information about the topological S-matrix[33]. They are also important for the implementation of topological quantum computation[17,19] because they can be used for the topological charge measurements necessary for readout of qubits[30] and, through adroit manipulation, can even be used to implement computational gates[34,35]. Fortunately, there have been recent advances in realizing quantum Hall interferometers at integer filling[36,37] and fractional filling in the lowest Landau level[38,39]. Even more recently, double point-contact interferometers have been experimentally implemented for the $\nu = 5/2$ FQH state[1,2,40].

In this paper, we study the signatures of non-Abelian statistics which can be seen in a double point-contact interferometer and discuss other effects which can mimic these signatures. We propose further experiments which can help disentangle the effects of non-Abelian statistics from Coulomb blockade and disorder physics.

II. THE EXPERIMENT

In recent experiments, Willett *et al.*[1,2] measured the current through a double point-contact device, depicted schematically in Fig. 1. As a function of magnetic field B, the longitudinal resistance R_L of the device has prominent minima at roughly the B values at which the $\nu = 2, 7/3, 5/3$ and $5/2$ quantum Hall states occur in the bulk (near, but not at, the point contacts). At the minima corresponding to $\nu = 5/2$ and $7/3$, the longitudinal resistance is $R_L \simeq 200 - 300 \, \Omega$, while at $\nu = 2$ and $5/3$ it is $R_L < 50 \, \Omega$. There are small oscillations with B on top of these large features, but these were not the focus of the experiment since changing the magnetic field can change both the flux enclosed and, possibly, the quasiparticle number, thereby making it difficult to isolate the effect of braiding statistics. Instead, a side gate voltage is varied, as shown in Fig. 1. As the side gate voltage V_s is varied, R_L oscillates with an amplitude of roughly $2 \, \Omega$.

The period of the oscillations, ΔV_s, is larger at $\nu = 5/3$ and $7/3$ than at $\nu = 2$. This was interpreted in the following way: it was assumed that the principle effect of varying the side gate voltage is to change the area of the interference loop between the two point contacts and that they are related linearly by $\Delta A = c \Delta V_s$, where c is essentially constant, even between different filling fractions. Thus, the oscillations are hypothesized to be due to the Aharonov-Bohm (AB) effect, which implies a period $\Delta A = (e/e^*)\Phi_0/B$, where e^* is the charge of the tunneling quasiparticle and $-e$ is the electron charge, and $\Phi_0 = hc/e$ is the magnetic flux quantum. Willett *et al.*[2] analyze their data to find that the period at $\nu = 5/3$ and $7/3$, normalized by the corresponding magnetic fields, is three times larger than at $\nu = 2$: $(\Delta A)_{5/3} B_{5/3} \approx (\Delta A)_{7/3} B_{7/3} \approx 3 \cdot (\Delta A)_2 B_2$. Thus, they interpret their findings as evidence that $e^*/e = 1/3$ at $\nu = 5/3, 7/3$, assuming that the oscillation period at $\nu = 2$ reflects interference of ordinary electrons. At $\nu = 5/2$, two types of behavior are seen at 25 mK. In some regions, which we will call type I, $(\Delta A)^I_{5/2} B_{5/2} \approx 4 \cdot (\Delta A)_2 B_2$. In the regions of type II, $(\Delta A)^{II}_{5/2} B_{5/2} \approx 2 \cdot (\Delta A)_2 B_2$. At 150 mK, only one behavior is seen: $(\Delta A)^{II}_{5/2} B_{5/2} \approx 2 \cdot (\Delta A)_2 B_2$. The type of oscillations observed for a region of V_s were found to be reproducible throughout multiple scans over the period of 7 days[2]. The type I oscillations in a given region sometimes exhibited a roughly π phase shift from one scan to another. In the next section, we discuss several possible explanations for the occurrence of these two periods at 25 mK and the disappearance of one of them at higher temperatures at $\nu = 5/2$.

III. INTERPRETATIONS

A. Non-Abelian Interference

At first glance, these experimental results appear to be dramatically consistent with the predicted behavior of the proposed non-Abelian $\nu = 5/2$ FQH states, particularly with that of the MR, $\overline{\text{Pf}}$, and $\text{SU}(2)_2$ NAF states, all of which have

a non-Abelian fundamental quasihole with charge $e/4$. The basic assumption is that as one changes the area of the interferometry region, one also occasionally changes the number n_q of charge $e/4$ quasiholes contained in the bulk within the interference loop. (For the purposes of this counting, charge $ne/4$ excitations, where $n \in \mathbb{Z}$, count as n fundamental quasiholes.) Thus, changing the area will cause the edge current to exhibit interference behavior due to the AB effect, modulated by occasional changes in the number of quasiparticles in the loop and their concomitant braiding statistics. The interference term I_{12} of the backscattered current due to lowest order tunneling of $e/4$ edge quasiparticles is predicted to be[31,32]

$$I_{12}^{(e/4)} \propto \begin{cases} \cos\left(2\pi\frac{\Phi}{4\Phi_0} \mp \frac{n_q\pi}{4} + n_\psi\pi\right) & \text{for } n_q \text{ even} \\ 0 & \text{for } n_q \text{ odd} \end{cases}, \quad (1)$$

where the $-$ corresponds to the MR and $\text{SU}(2)_2$ states and the $+$ to the $\overline{\text{Pf}}$ state; and $n_\psi = 0$ or 1, depending on whether the contained quasiparticles are in a collective state corresponding to the I or ψ fusion channel. This interference exhibits the usual AB oscillations with period $\Delta A = 4\Phi_0/B$ corresponding to $e^*/e = 1/4$, but also a striking complete suppression of this term that results from the non-Abelian braiding statistics of the edge quasiparticle with the bulk quasiparticles when n_q is odd. Thus, as the area of the interferometry region is changed, and bulk quasiparticles enter or exit the interference loop, the non-Abelian states should see $\Delta A = 4\Phi_0/B$ oscillations switch on and off, as they do in going from the type I regions to the type II regions in the experiments of Refs. 1,2.

The observed reproducibility of oscillation type regions in multiple scans[2] suggests that the bulk $e/4$ quasiparticles are pinned and do not move on the time scale of the experiment. The observation of the oscillations in a given type I region being shifted by π from one scan to the next also agrees with the expected behavior of non-Abelian states. Specifically, the collective state of several quasiparticles, some of which are inside and some outside the interferometry loop, is decohered by

FIG. 1: A double point-contact interferometer. Edge quasiparticles tunnel at two point-contacts with amplitudes t_1 and t_2, respectively. The interferometry area is changed by applying a voltage V_s to a plunger gate P that depletes the 2DEG beneath it. Quantum interference between the two paths manifests an observable signature of the Aharonov-Bohm effect and the braiding statistics (of the edge quasiparticle with the bulk quasiparticles in the central interferometry region) in the oscillation patterns of the tunneling current when the area is changed.

the current of edge quasiparticles around the loop[42]. Hence, depending on the bulk quasiparticles entering or exiting the interferometry loop, the collective state of quasiparticles inside the interferometer may be randomized between $n_\psi = 0$ and 1 when n_q is changed to an even value. (This is the same randomization that gives rise to a non-Abelian signature in the switching noise[43].)

There are two sources that could potentially contribute to $\Delta A = 2\Phi_0/B$ oscillations in the non-Abelian $\nu = 5/2$ states. The first is tunneling of the Abelian $e/2$ edge quasiparticles[44,45], which to lowest order gives the interference current[28]

$$I_{12}^{(e/2)} \propto \cos\left(2\pi \frac{\Phi}{2\Phi_0} - \frac{n_q \pi}{2}\right). \tag{2}$$

The second possibility comes from higher-order tunneling processes where the interference path encircles the interferometry area twice. The resulting double pass interference term in the current coming from 2nd order tunneling of $e/4$ edge quasiparticles is[44,45]

$$I_{1212}^{(e/4)} \propto \begin{cases} \cos\left(2\pi \frac{\Phi}{2\Phi_0} - \frac{n_q \pi}{2}\right) & \text{for } n_q \text{ even} \\ \cos\left(2\pi \frac{\Phi}{2\Phi_0} - \frac{n_q \pi}{2} \pm \frac{\pi}{2}\right) & \text{for } n_q \text{ odd} \end{cases}, \tag{3}$$

where the $+$ corresponds to the MR state and the $-$ to the $\overline{\text{Pf}}$ and $\text{SU}(2)_2$ states. Of course, this 2nd order contribution to the tunneling current will typically have much smaller amplitude, since it both incurs an additional tunneling probability factor and doubles the distance over which coherence must be maintained. For the interferometer of Refs. 1,2, the quasiparticle tunneling probability at each point contact is approximately 5%. This estimate is based on the relation[46]

$$R_{xx} = \frac{h}{e^2} \frac{2}{5} \frac{P}{5 - P} \tag{4}$$

for point-contact tunneling of the half-filling edge modes at $\nu = 5/2$, where $P \simeq P_1 + P_2$ here is roughly the sum of individual tunneling probabilities of the two point-contacts, and $R_{xx} \simeq 200\,\Omega$ in Refs. 1,2. Furthermore, there will generally be a suppression of the interference oscillation amplitudes that results from the loss of coherence. Roughly speaking, this gives a suppression factor $Q \simeq \max(I_{12})/(I_1 + I_2)$. The observed oscillations in R_{xx} have amplitude of approximately $2\,\Omega$, indicating a coherence suppression factor $Q \simeq .01$. Combining these, the amplitude of double pass interference oscillations is expected to be roughly .0005 times that of the lowest order oscillation amplitude. (Under the best coherence conditions, $Q \approx 1$, the double pass oscillation amplitude would still only be roughly .05 times that of the lowest order oscillation amplitude.) Hence, the $\Delta A = 2\Phi_0/B$ oscillations, for which the amplitudes are of the same order of magnitude as that of the $\Delta A = 4\Phi_0/B$ oscillations, should be attributed almost entirely to the tunneling of $e/2$ edge quasiparticles. We emphasize that the $\Delta A = 2\Phi_0/B$ oscillations (from both sources) have an amplitude that is independent of n_q (unlike the $\Delta A = 4\Phi_0/B$ oscillations), but pick up phase shifts when n_q changes.

These two sources of $\Delta A = 2\Phi_0/B$ oscillations were not discussed in Refs. 31,32 because it was assumed neither would have significant contributions to the tunneling current. For the double pass interference of $e/4$ quasiparticles, this appears to be a valid assumption, since higher-order tunneling processes are suppressed in the weak-backscattering regime. On the other hand, for interference of $e/2$ quasiparticles this assumption was based on such quasiparticles having less relevant tunneling operators than the $e/4$ quasiparticles. We will see in the following that there are several ways in which this line of reasoning can break down and permit the $e/2$ quasiparticles to have a contribution to the tunneling current oscillations that is comparable to that of the $e/4$ quasiparticles.

Combining these results, we see that tunneling of both non-Abelian $e/4$ quasiparticles and Abelian $e/2$ quasiparticles at the point contacts of the interferometer would produce a combined backscattered current with regions of type I, exhibiting a sum of both $\Delta A = 4\Phi_0/B$ and $\Delta A = 2\Phi_0/B$ oscillations, when n_q is even, and regions of type II, exhibiting only $\Delta A = 2\Phi_0/B$ oscillations, when n_q is odd. We also note that the bulk-edge coupling that occurs as a bulk $e/4$ quasiparticle approaches the edge gives the regions near transitions between type I and II oscillations the most potential for exhibiting non-linear and/or noisy behavior.

In order for interference to be observed, it is necessary that the current-carrying excitations remain phase coherent. Even if we neglect (irrelevant) interactions between the edge modes, coupling to localized excitations in the bulk, and phonons, there will still be thermal smearing of the interference pattern. Consequently, as shown in Ref. 47 (see also Ref. 48), the amplitude of interference oscillation for double point-contact interferometers will be exponentially suppressed in temperature and in the average length L between point contacts along each edge, $I_{12}^{(qp)} \propto e^{-T/T^*(L)} = e^{-L/L_\phi(T)}$), where the coherence length $L_\phi(T)$ and temperature $T^*(L)$ of edge excitations are given by

$$L_\phi(T) = \frac{1}{2\pi T} \left(\frac{g_c}{v_c} + \frac{g_n}{v_n}\right)^{-1} \tag{5}$$

$$T^*(L) = \frac{1}{2\pi L} \left(\frac{g_c}{v_c} + \frac{g_n}{v_n}\right)^{-1}. \tag{6}$$

We can use these expressions, together with estimates of the charge and neutral edge mode velocities from numerical studies of $\nu = 5/2$ on a disk[49] (the charged and neutral scaling exponents g_c and g_n are given in Table II), to estimate coherence lengths and temperatures for the charge $e/4$ and $e/2$ excitations in the various candidate states (the states are all the same, as far as the charge $e/2$ quasiparticle is concerned). In Table I, we give estimates of coherence lengths at $T = 25$ mK and coherence temperatures for $L = 1\,\mu$m, the approximate interference path length in the experiments of Refs. 1,2. We note that the observation of only type II oscillations at higher temperatures in Refs. 1,2 also excludes double pass interference of $e/4$ quasiparticles as the explanation for $\Delta A = 2\Phi_0/B$ oscillations, whereas it fits very nicely with the $e/2$ quasiparticle tunneling explanation.

$e/4$	MR	$\overline{\text{Pf}}/\text{SU}(2)_2$	K=8	(3,3,1)	$e/2$
L_ϕ in μm	1.4	0.5	19	0.7	4.8
T^* in mK	36	13	484	19	121

TABLE I: Estimated coherence lengths L_ϕ at $T = 25$ mK and coherence temperatures T^* for $L = 1$ μm for the (relevant) $e/4$ quasiparticles of the candidate $\nu = 5/2$ states, and the $e/2$ Laughlin-type quasiparticle for all these states. We use the velocity estimates $v_c \approx 5 \times 10^4$ m/s and $v_n \approx 4 \times 10^3$ m/s from numerical studies[49].

B. Coulomb blockade

In the limit that the region between the two point contacts is a nearly isolated puddle, the Coulomb charging energy of the puddle dominates the behavior of the device. Due to its isolation, the puddle must contain an integer number of electrons. The electron number can change when the gate voltage is increased by enough to allow one additional electron into the puddle. At this point, there is a peak in the longitudinal conductance (which are also peaks in the longitudinal resistance, since $R_L \ll R_H$) since it is only at this point (or within $k_B T$ of it) that the charge on the puddle can fluctuate. If the density in the puddle is fixed, then the spacing between peaks as a function of area is naively just the additional area required to allow one more electron into the puddle:

$$\Delta A = \frac{e}{\rho_0} \qquad (7)$$

where ρ_0 is the charge density inside the dot. However, in the case of a paired state, one would expect that it is easier to add an electron when the electron number is odd than when it is even since, in the latter case, it an unpaired fermionic excitation is necessarily created. So one would expect that, instead of evenly-spaced peaks, the interval between an odd peak and the next even peak would be smaller than the interval between an even peak and the next odd peak because V_s must also supply the energy needed to create an unpaired fermionic excitation. Consequently, the peak spacing would alternate between[50]

$$\Delta A_\pm = \frac{e}{\rho_0}\left(1 \pm \frac{v_n}{2v_c}\right), \qquad (8)$$

As a result of this 'bunching' effect, the periodicity would be the interval between two successive even peaks, i.e. twice what one might ordinarily expect. But when there is an odd number of charge $e/4$ quasiparticles in the MR or $\overline{\text{Pf}}$ states, the minimum energy to create a fermionic excitation is zero. Thus, there is no 'bunching' effect in this case, and the period is not doubled[31].

In the case of the $(3,3,1)$ state, bunching generically occurs with either an even or odd number of quasiparticles in the puddle. However, when n_q is odd, the bunching depends on the strength of the violation of S_z conservation (where S_z is the z-component of the spin or, if one contemplates a bi-layer version of this experiment, the layer pseudospin) so $v_n/2v_c$ in

Eq. (8) is replaced by a different constant dependent on this violation. If S_z is conserved (or only weakly non-conserved), there will again be edge zero modes for odd n_q and the bunching will disappear. Thus, switching between bunching and non-bunching regions in Coulomb blockade at $\nu = 5/2$ is not necessarily an indication of a non-Abelian state. More generally, the switching between different bunching patterns in Coulomb blockade described in Refs. 31,50 for non-Abelian states may similarly be mimicked by corresponding Abelian states (see Appendix C for more details).

The strongly-paired $K = 8$ state[27] always exhibits bunching, now with $v_n/2v_c$ in Eq. (8) replaced by a constant dependent upon the finite energy cost of having an unpaired electron. If this energy cost is small, it may not appear bunched. On the other hand, if it is large enough, it will be maximally bunched with $\Delta A = 2e/\rho_0$ corresponding to tunneling electron pairs.

C. Non-linear Area vs. V_s

The assumptions that $\Delta A = c\Delta V_s$ with only a single value of c across a range of filling factors and a range of V_s values are important for the interpretation of this experiment. One might question their validity. However, the assumption that c is independent of the filling fraction for nearby filling fractions is, in fact, reasonable. V_s is several volts, and the oscillation periods are ~ 10 mV which are much higher energy scales than the weak energy gaps and correlation effects associated with the $\nu = 5/3, 7/3, 5/2$ quantum Hall states. Thus, the details of these quantum Hall states are probably unimportant and dA/dV_s is probably determined by the electric potential due to the donor impurities and the electron density, which are not varying significantly. However, when there are filled Landau levels beneath the quantum Hall state of interest, their edges can screen the side-gate voltage, presumably weakening the dependence of A on V_s (since A is the area of the droplet of the fractional state in the partially-filled Landau level). In particular, we would expect $\Delta A = c_1 \Delta V_s$ at $\nu = 1/3$ but $\Delta A = c_2 \Delta V_s$ at $\nu = 7/3$, with $c_1 > c_2$. However, by the same reasoning, we expect that the relationship between A and V_s will be the same for $\nu = 5/3, 7/3, 5/2$ (if the $\nu = 5/3$ edge is two filled Landau levels with a backwards propagating $\nu = 1/3$ edge mode).

Furthermore, it is less clear that dA/dV_s should be constant across an appreciable range of V_s values because the density is not constant across the device. In fact, we expect V_s to vary linearly with total charge in the central puddle. So long as the electron density is essentially fixed, apart from a small number of quasiparticles, V_s will vary linearly with A. However, if there are high-density and low-density regions, then we will have $\Delta A = c\Delta V_s$ in some regions and $\Delta A = c'\Delta V_s$ in the others, with $c \neq c'$. (This could lead, for instance, to $\nu = 7/3$ puddles within the $\nu = 5/2$ droplet.) This would, in turn, lead to two different regions with different oscillation periods. However, it is difficult to see why one period would be twice the other or why there would be two periods only at $\nu = 5/2$ and not at $\nu = 5/3, 2, 7/3$.

One other possibility, which also depends on spatial inhomogeneity although still assuming a linear A vs V_s, is that there are regions in the sample in which the $K = 8$ Abelian state occurs. The rest of the state is assumed to be non-Abelian, i.e. either the MR or $\overline{\text{Pf}}$ state. Then, when a $K = 8$ region is at the edge of the system, varying V_s doesn't change the area enclosed by the edge of the non-Abelian part of the system, which would lead to $e/4$ oscillations. It does cause the total area to vary, but this only causes $e/2$ oscillations since these oscillations can move coherently along both $K = 8$ Abelian and non-Abelian edges. Thus, the two regions correspond to when the edge of the system near the side gate is a $K = 8$ region or a non-Abelian region.

IV. CRITICAL ANALYSIS

The data of Refs. 1,2 are broadly consistent with the hypothesis that the device is functioning as a quantum Hall edge state interferometer. As the temperature is raised, the putative $e/4$ oscillations, which are observed at 30 mK, disappear while the $e/2$ oscillations persist even at 150 mK. This was anticipated in Ref. 49, where it was noted that the coherence length will be substantially longer for $e/2$ quasiparticles than for $e/4$ quasiparticles since the former do not involve the slow neutral edge modes. Thus, any of the proposed $\nu = 5/2$ states (apart from the strong-pairing state) would be broadly consistent with the $e/4$ oscillations seen in Refs. 1,2. However, there is no simple explanation of their absence in the type II regions in the $(3,3,1)$ state, while the MR, $\overline{\text{Pf}}$, and $SU(2)_2$ states all provide a simple explanation, as described in the previous section.

Perhaps the most serious challenge to the non-Abelian interferometer hypothesis is that $e/2$ oscillations should always be present while $e/4$ oscillations should only be observed when the quasiparticle number contained within the interferometry region is even. In particular, $e/2$ oscillations should be present in the $e/4$ regions. This appears to be the case in Fig. 2a and, perhaps to some extent, 2c but definitely not in Fig. 2b of Ref. 2. It is possible to generate some accidental destructive interference between the oscillations due to tunneling of $e/2$ quasiparticles given in Eq. (2) and that of double pass interference of $e/4$ quasiparticles given in Eq. (3), since the relative phase of these terms is not fixed. This could result in the appearance and disappearance of type II oscillations, however, as previously mentioned, the amplitude of oscillations in Eq. (2) are so strongly suppressed in the experiments of Refs. 1,2 that it could not explain such behavior there.

As we describe in Appendix B, a simple model of quasiparticle tunneling predicts that the amplitude for $e/4$ quasiparticle backscattering, $\Gamma_{e/4}$, is much larger than the amplitude for $e/2$ quasiparticle backscattering, $\Gamma_{e/2}$. However, the amplitude for $e/2$ oscillations in the type II regions is comparable the amplitude for $e/4$ oscillations in the type I regions. It may be that $|\Gamma_{e/2}|$ is 'accidentally' large, e.g. due to the presence of a resonant $e/2$ quasiparticle in the point contact. Alternatively, as a result of the shorter coherence length for $e/4$ excitations, the corresponding oscillations are more strongly

suppressed. This would require a coincidence – that thermal smearing of $e/4$ excitations compensates for the the smallness of the ratio $\Gamma_{e/2}/\Gamma_{e/4}$. However, this could be tested by decreasing the suppression by going to lower temperatures and by increasing the suppression by increasing the separation between the point contacts. At any rate, given that $e/2$ oscillations are observed in the type II regions, it would be a problem for the non-Abelian interferometer picture if they are not generically seen in the type I regions.

However, it is worth noting in this context that the presence of charge $e/2$ quasiparticle tunneling is not manifest in the point contact experiments of Refs. 21,22. In the former, the shot noise appears to indicate that only charge $e/4$ quasiparticles tunnel at the point contact (although there is sufficient scatter in the data that one might argue that there could be a component due to $e/2$ quasiparticle, the scatter does not seem to be asymmetric in the direction of charges larger than $e/4$ as one might have expected). In the latter experiment, the best fit to the data is actually $e^*/e = 0.17$, so including any $e/2$ tunneling leads to a worse fit to the data[22]. Thus, the appearance and strength of $e/2$ quasiparticle tunneling remains a mystery in several different experiments.

A conventional Coulomb blockade picture seems inappropriate since $I_b \lesssim .1 I_{\text{total}}$ indicates that the system is in the weak back-scattering limit. It is also unlikely that Coulomb blockade could lead to two distinguishable periods since, for $v_n/2v_c$ small (as we expect it to be), the bunching will be difficult to resolve. Numerical calculations of the edge velocities[49] give $v_n \simeq 0.1v_c$, confirming this expectation. On the other hand, we note that Coulomb blockade is capable of producing peaks that alternate between the $e/4$ and $e/2$ periodicities, with no $e/2$ background in the $e/4$ region. Thus, if the two prior points against it were somehow incorrect, Coulomb blockade could provide a consistent explanation of the periodicity issue.

Furthermore, Coulomb blockade could be easily ruled out by measuring its temperature dependence and its dependence on asymmetry between the tunneling amplitudes at the two point contacts. In particular, the Coulomb blockade peak widths are expected to scale linearly with temperature[51]. However, a more general view of Coulomb blockade has emerged[37] (see, also Ref. 41), according to which Coulomb blockade (CB) can be distinguished from Aharonov-Bohm (AB) interference by *inter alia* the dependence of ΔV_s on B (it should be inversely proportional for AB and independent for CB). This more general view of Coulomb blockade is probably better described as 'Coulomb dominated' since it corresponds to a regime in which the charging energy of the puddle between the point contacts is the dominant energy scale. It does *not* rule out a simple interpretation of the backscattered current according to Eq. 1.

At any rate, by this criterion as well, the data appears to be more consistent with AB interference since $(\Delta V_s)_{5/3} B_{5/3} \approx (\Delta V_s)_{7/3} B_{7/3} \approx 3 \cdot (\Delta V_s)_2 B_2$. However, it is worth keeping in mind that we do not know precisely how the area of the droplet changes with V_s or with B; knowing this would enable us to cement an interpretation of the experiment.

Similarly, the possibility that the existence of two periodic-

ities signals different regions with different electron densities and, therefore, two different possible relations $\Delta A = c\Delta V_s$ and $\Delta A = c'\Delta V_s$ could be ruled in or out through a more detailed knowledge of the electron density in the sample.

V. ADDITIONAL PROPOSALS AND NON-TRIVIAL CHECKS

As beautiful as the non-Abelian anyon explanation of the results of Ref. 1,2 may be, it is clear from the preceding analysis that there are some significant gaps which need to be closed through further measurements.

If it is, indeed, the case that R_L is due to the weak backscattering of $e/4$ quasiparticles at the constrictions, then both the non-oscillatory and oscillatory parts of the current should have non-trivial temperature and voltage dependences. Modeling the edge in the simplest way (i.e. fully equilibrated neutral modes and no edge reconstruction) using the "natural" conformal field theory inherited from the bulk, one can perform a more detailed analysis of the tunneling edge current[23,24,46,52], along the lines of that carried out in Refs. 28,53 for Abelian states.

The non-oscillatory part of the backscattered current – the sum of the contributions from each point contact independently – will behave as the power laws:

$$I_b^{(qp)} \propto \begin{cases} T^{2g-2}\,V & \text{for small } eV \ll k_B T \\ V^{2g-1} & \text{for small } eV \gg k_B T \end{cases}, \qquad (9)$$

where $g = g_c + g_n$ is the tunneling exponent combining charge and neutral (Abelian and non-Abelian) sectors of the quasiparticles' tunneling operator [see Eqs. (C9) and (C11) for the definitions]. The tunneling operator is relevant for $g < 1$, and quasiparticles with smaller g are more relevant, and are thus expected to dominate the tunneling current in the weak backscattering limit.

From Table II, we see that the $e/4$ backscattering operator is a relevant perturbation of the edge effective theory for all of the candidate states. Thus, the effective tunneling amplitude(s) will decrease as the temperature is raised, as $T^{-3/2}$, $T^{-5/4}$, or T^{-1} in the MR, $(3,3,1)$, and $\overline{\text{Pf}}$ states, respectively. Charge-$e/2$ backscattering is also relevant in all of the candidate states. Because $e/2$ excitations have $g = 1/2$ and are entirely in the charge sector, their lowest order, single point-contact tunneling current contribution is the same in all of the candidate states and can be given explicitly as

$$I_b^{(e/2)} = \frac{e}{2}\,|\Gamma_{e/2}|^2\,\frac{2\pi}{v_c}\tanh\left(\frac{eV}{4T}\right) \qquad (10)$$

Thus, in the linear response regime, the effective tunneling amplitude for $e/2$ backscattering decreases as T^{-1}. For the MR and Abelian states, charge-$e/4$ backscattering is more relevant than charge-$e/2$ backscattering, so it is expected to dominate at lower temperatures. For the $\overline{\text{Pf}}$ and $\text{SU}(2)_2$ NAF, $e/4$ and $e/2$ backscattering are equally relevant (with $g = 1/2$).

Turning now to the oscillatory current, we note that for $eV \ll v_n/2L$, where $2L$ is the interference path length, it has

$\nu = \frac{5}{2}$	e^*	n-A?	θ	g_c	g_n	g
MR:	$e/4$	yes	$e^{i\pi/4}$	1/8	1/8	1/4
	$e/2$	no	$e^{i\pi/2}$	1/2	0	1/2
$\overline{\text{Pf}}$:	$e/4$	yes	$e^{-i\pi/4}$	1/8	3/8	1/2
	$e/2$	no	$e^{i\pi/2}$	1/2	0	1/2
$\text{SU}(2)_2$:	$e/4$	yes	$e^{i\pi/2}$	1/8	3/8	1/2
	$e/2$	no	$e^{i\pi/2}$	1/2	0	1/2
K=8:	$e/4$	no	$e^{i\pi/8}$	1/8	0	1/8
	$e/2$	no	$e^{i\pi/2}$	1/2	0	1/2
(3,3,1):	$e/4$	no	$e^{i3\pi/8}$	1/8	1/4	3/8
	$e/2$	no	$e^{i\pi/2}$	1/2	0	1/2

TABLE II: Relevant quasiparticle excitations of model FQH states at $\nu = 5/2$. Here we list their values of charge e^*; whether they are non-Abelian; their topological twist factor θ; and their charge and neutral scaling exponents g_c, g_n, and g. The MR, $\overline{\text{Pf}}$, and $\text{SU}(2)_2$ NAF states are non-Abelian, while the K=8 (strong pairing) and (3,3,1) states are Abelian. All of these have Abelian $e/2$ Laughlin-type quasiparticles.

the same voltage dependence as the non-oscillatory current. For larger voltages, it becomes apparent that there are oscillations with a period $\sim 4\pi v_n/L$, but these are much larger voltages than are probed in the experiments of Refs. 1,2 We note that these oscillations can be turned around and interpreted as oscillations as a function of L, which changes when the interferometry area is changed (i.e. when the side gate voltage is changed). However, these oscillations have periodicity $4\pi v/e^*V$, where v represents several characteristic velocities, which are all dominated by the slowest edge mode velocity (which is expected to be v_n). Since $V \simeq 10^{-8}$ V, these will only give rise to envelopes with periods much longer than that of the oscillations observed in the experiment.

The temperature dependence of the oscillatory current includes a power-law prefactor of the form in Eq. (9) in addition to the exponential suppression $e^{-T/T^*(L)} = e^{-L/L_\phi(T)}$ which we discussed earlier. Thus, the relative suppression of the $e/4$ contribution, compared to the $e/2$ contribution, must be due entirely to the shorter coherence length in the $\overline{\text{Pf}}$ case but could be due to a combination of effects in the MR or $(3,3,1)$ case.

To make the case for interference stronger, it would be helpful to disentangle the effects of the temperature dependence of the coherence length from the temperature dependence of the effective tunneling amplitude. One way to do this would be to carefully study the bias voltage dependence of the current backscattered by the interferometer of Ref. 2 at some fixed V_s in the low-T limit. If the behavior is similar to that observed in Ref. 22 (and, especially, if it is the behavior expected for one of the possible $\nu = 5/2$ states), then this is a strong indication that R_L is due to the weak backscattering of charge $e/4$ quasiparticles. Another useful way to do this would be to turn on the point-contacts one at a time and study their tunneling behavior individually. This would help determine which state occurs in the point-contact region; it is important that it is at the same filling fraction as the rest of the bulk. Further-

more, it would allow one to determine the relative tunneling amplitudes of $e/4$ and $e/2$ quasiparticles and confirm that the experiment is not in the CB regime.

It is important to verify that the oscillation periodicities behave as expected. In addition to confirming the dominance of $\Delta A = 4\Phi_0/B$ and $\Delta A = 2\Phi_0/B$ oscillations in the Fourier spectrum, one should examine the spectrum in the different regions more carefully. Specifically, by using windowing techniques in the Fourier analysis of the data, one should check that the type I regions have both $\Delta A = 4\Phi_0/B$ and $\Delta A = 2\Phi_0/B$ oscillations, that the type II regions have only $\Delta A = 2\Phi_0/B$ oscillations, and that the amplitude of $\Delta A = 2\Phi_0/B$ oscillations are roughly the same in the type I and II regions. It is also useful to know the relative oscillations amplitudes of the two frequencies in the type I regions.

Once this is done, it is still important to establish that the periodicities with V_s thereby obtained correspond directly to periodicities with A. One way to attempt to do this would be to vary both V_s and B at $\nu = 2$ and to use the periodicity in B to determine the area for several different values of V_s. One could, in this way, check that the assumed constant c in $\Delta A = c\Delta V_s$ is really constant. Such a measurement would also determine whether the oscillation pattern corresponds to AB interference or Coulomb blockade, as in Ref. 37. One could also check that the oscillations are due to AB interference by turning down or off one of the point contacts (and then the other) and repeating the experiment, which should cause the oscillations to disappear. This will further exclude resonances at a single point contact as the source of oscillations and will give a better value of the tunneling amplitude for a single point contact.

A more ambitious approach to measuring the area within the interference loop, which could simultaneously tackle the even more fundamental problem of determining directly whether the $e/4$ and $e/2$ regions correspond to even/odd quasiparticle numbers, would be to image the 2DEG in the interferometer using a scanning single electron transistor (SET), as in Ref. 54. In this earlier experiment, a scanning SET was used to image the compressibility of the electron liquid at $\nu = 1, 1/3, 2/3$. By measuring the compressibility, it should be possible to determine where the edge of the Hall fluid is in the droplet and, hence, the area of the interferometry region. It should also be possible to find the localized states near the Fermi energy where $e/4$ quasiparticles could be trapped. By imaging the charge $e/4$ quasiparticles, one might even be able to see these localized quasiparticles enter or leave the interference loop as V_s is varied, and hence allow the most direct verification of the non-Abelian interferometer interpretation.

A more crude, but also more easily implementable way to further strengthen the correlation between which oscillation type is observed and the localization of excitations in the bulk is to independently vary two or more plunger gates of the interferometer. By refining the ability to control how the interferometry area is changed beyond a single plunger variable, the changes between oscillation types can be more strongly associated with a particular area. If a region of one plunger's gate voltage exhibits type I oscillations, but then, after changing a separate plunger's position, the same voltage range in the first plunger exhibits type II oscillations, this would demonstrate that a particular oscillation type is not associated with that particular voltage range of the first plunger, but rather that an ability to change between oscillation types is associated with a localized quantity in the area added or removed by the second plunger. This would greatly strengthen the evidence for non-Abelian braiding statistics.

We note, as a consistency check on the data of Ref. 2 that one can use the area periodicity of the AB oscillations to estimate the density of bulk $e/4$ quasiparticles from the observed switching between type I and II regions to be $\rho_{e/4} \approx 50\ \mu\mathrm{m}^{-2}$. This translates to ~ 10 charge $e/4$ quasiparticles in the interference loop. There could also be $e/2$ quasiparticles in the bulk that enter or exit the interference loop when the area is changed (or pairs of $e/4$ quasiparticles that enter or exit nearly simultaneously). Since these would not switch the oscillations between type I and II, but do cause changes in the phase of oscillations, we could attribute (though perhaps less reliably) phase disruptions observed within one type region to an $e/2$ quasiparticle crossing the interferometry region. Using this to similarly estimate the density of bulk $e/2$ quasiparticles gives $\rho_{e/2} \approx 50\ \mu\mathrm{m}^{-2}$, or roughly the same number as charge $e/4$ quasiparticles in the interference loop. Depending on how seriously one takes the $e/2$ contribution, this gives approximately $0.5 - 1.5\%$ depletion of the electron density in the bulk, which is the reported density variation in the device[1,2]. With a scanning SET setup, it may be possible to find the ~ 10 charge $e/4$ quasiparticles that are necessary for the non-Abelian interferometer interpretation and observe them entering or exiting the interference loop. Localized $e/2$ quasiparticles or, equivalently, closely-spaced pairs of $e/4$ quasiparticles should also be observable.

VI. DISCUSSION

A double point-contact interferometer may also be used to test whether the quantum Hall states at $\nu = 7/3, 12/5, 8/3$, and $14/5$ are non-Abelian. These filling fractions all have compelling Abelian alternatives which almost certainly occur at their corresponding lowest Landau level counterparts. While numerical studies strongly support the MR and $\overline{\mathrm{Pf}}$ states at $\nu = 5/2$[49,55,56,57,58,59,60,61,62] and the (particle-hole conjugate) Laughlin state at $\nu = 14/5$[63,64], they are far less conclusive for $\nu = 7/3, 12/5$, and $8/3$[64,65,66,67], where several candidates seem plausible, including ones that are non-Abelian. It is clearly important to also test these FQH states experimentally, so we discuss the signatures of plausible candidates in Appendix A. The signatures of non-Abelian statistics in these states will again be dramatic, though not quite as much as for the MR, $\overline{\mathrm{Pf}}$, or $SU(2)_2$ NAF states.

We close this discussion by assuming, for a moment, that the experiments of Refs. 1,2 are, in fact, performing interferometry on the $\nu = 5/2$ state of the sort envisioned in Refs. 28,29,30,31,32 and are detecting non-Abelian quasiparticles. What forecast would these results give for topological quantum computation[17,18,19,20]? Certainly, it would be encouraging that a non-Abelian topological state, the *sine qua non*

for topological quantum computing, would be found. One potential source of concern is the appearance of some seemingly unpredictable phases slips, which would make it difficult to distinguish the two states of a topological qubit, which differ by a π phase shift in their interference patterns. If, however, further investigation shows that they are π phase slips, then they may be attributable to pairs of $e/4$ quasiparticles entering the loop at nearly the same time. Finally, the apparent stability of the $e/4$ and $e/2$ regions implies that thermally-activated charge $e/4$ quasiparticles do not move in and out of the interferometry region over the time scales of this experiment. Indeed, these regions are stable on a time scale of a week, which would imply a topological qubit error rate $\Gamma/\Delta \leq 10^{-15}$.

"With luck, we might see a topological qubit within a year." – attributed to Kirill Shtengel, January 9, 2009[68].

APPENDIX A: OTHER SECOND LANDAU LEVEL STATES

In this section, we consider the other observed FQH states in the second Landau level[69,70], i.e. $\nu = 7/3,\ 12/5,\ 8/3$, and $14/5$. We provide the data of their prominent candidate descriptions that will be useful for interpreting tunneling and interference experiments, similar to earlier in this paper.

As described earlier, the interference term of the tunneling current combines: (1) the AB effect, (2) the braiding statistics with encircled quasiparticles, and (3) the edge physics. The AB effect simply contributes a phase $e^{ie^*\Phi/\hbar c} = e^{i2\pi e^*\Phi/e\Phi_0}$ when the quasiparticle of charge e^* encircles flux Φ. The physics describing propagation of excitations on the edge gives rise to a temperature, bias voltage, and interference path length dependence of the tunneling edge current[28,47,53] that we denote as $F(T, V, L)$. The details of this edge physics can generally be complicated, but the most significant aspect is the coherence length and temperature, which is given as before in Eqs. (5,6), with the appropriate scaling exponents for excitations of a given state (which are given in the tables).

For the lowest order tunneling interference process, the braiding statistics contributes the factor[33]

$$M_{ab} = \frac{S_{ab}S_{00}}{S_{0a}S_{0b}}, \qquad (A1)$$

where S_{ab} is the topological S-matrix, and a and b are the topological charges of the tunneling edge excitation and the encircled bulk quasiparticle excitations, respectively. These combine to give the lowest order interference contribution to the tunneling current (in the asymptotic limit where the state of the bulk quasiparticles is projected onto a definite value of b)

$$I_{12}^{(qp)} \propto \mathrm{Re}\left\{e^{i2\pi\frac{e^*\Phi}{e\Phi_0}}\, M_{ab}^*\, F(T, V, L)\right\}. \qquad (A2)$$

If either a or b is an Abelian charge, M_{ab} is simply a phase. More generally, when a and b are both non-Abelian charges, M_{ab} is a complex number with $|M_{ab}| \leq 1$. This leads to the potential for a suppression of the interference term [Eq. (A2)] resulting from non-Abelian braiding statistics, similar to the non-Abelian $\nu = 5/2$ states.

For the non-Abelian FQH states considered here, the braiding statistics are essentially given by the $SU(2)_k$ theories[71], up to Abelian phase factors. These theories have topological charges $j = 0, 1/2, 1, \ldots, k/2$ and

$$M_{j_1 j_2} = \frac{\sin\left(\frac{(2j_1+1)(2j_2+1)\pi}{k+2}\right)\sin\left(\frac{\pi}{k+2}\right)}{\sin\left(\frac{(2j_1+1)\pi}{k+2}\right)\sin\left(\frac{(2j_2+1)\pi}{k+2}\right)}. \qquad (A3)$$

The $k = 2, 3$, and 4 cases are the most pertinent to our discussion, so we write them out explicitly:

$$M^{(2)} = \begin{bmatrix} 1 & 1 & 1 \\ 1 & 0 & -1 \\ 1 & -1 & 1 \end{bmatrix}, \qquad (A4)$$

$$M^{(3)} = \begin{bmatrix} 1 & 1 & 1 & 1 \\ 1 & \phi^{-2} & -\phi^{-2} & -1 \\ 1 & -\phi^{-2} & -\phi^{-2} & 1 \\ 1 & -1 & 1 & -1 \end{bmatrix}, \qquad (A5)$$

where $\phi = \frac{1+\sqrt{5}}{2}$ is the Golden ratio, and

$$M^{(4)} = \begin{bmatrix} 1 & 1 & 1 & 1 & 1 \\ 1 & \frac{1}{\sqrt{3}} & 0 & \frac{-1}{\sqrt{3}} & -1 \\ 1 & 0 & \frac{1}{2} & 0 & 1 \\ 1 & \frac{-1}{\sqrt{3}} & 0 & \frac{1}{\sqrt{3}} & -1 \\ 1 & -1 & 1 & -1 & 1 \end{bmatrix}. \qquad (A6)$$

The braiding statistics of the MR, $\overline{\mathrm{Pf}}$, and $SU(2)_2$ NAF $\nu = 5/2$ states are all derived from $SU(2)_2$. The non-Abelian quasiparticles in these states carry $SU(2)_2$ charge $1/2$. It follows that an odd number cluster of such quasiparticles will also carry a collective $SU(2)_2$ charge of $1/2$, while an even number cluster will carry either 0 or 1. Thus, looking at the $(j = 1/2)$ middle column of Eq. (A4), we see exactly the source of the behavior described in Eq. (1).

1. $\nu = 7/3$

For the $\nu = 7/3$ FQH plateau, the leading candidates are the Laughlin (L) state[72], two types of Bonderson-Slingerland

$\nu = \frac{7}{3}$	e^*	n-A?	θ	g_c	g_n	g
$L_{1/3}$:	$e/3$	no	$e^{i\pi/3}$	$1/3$	0	$1/3$
$\overline{BS}_{2/3}$:	$e/3$	yes	$e^{-i7\pi/24}$	$1/3$	$5/8$	$23/24$
	$e/3$	no	$e^{i\pi/3}$	$1/3$	0	$1/3$
$BS^{\psi}_{1/3}$:	$e/3$	yes	$e^{i5\pi/24}$	$1/3$	$3/8$	$17/24$
	$e/3$	no	$e^{i\pi/3}$	$1/3$	0	$1/3$
$\overline{RR}_{k=4}$:	$e/6$	yes	$e^{-i\pi/6}$	$1/12$	$1/4$	$1/3$
	$e/3$	no	$e^{i\pi/3}$	$1/3$	0	$1/3$
	$e/2$	yes	$e^{i\pi/2}$	$3/4$	$1/4$	1

TABLE III: Relevant quasiparticle excitations of model FQH states at $\nu = 7/3$. Here we list their values of charge e^*; whether they are non-Abelian; their topological twist factor θ; and their charge and neutral scaling exponents g_c, g_n, and g. The $\overline{BS}$, BS^{ψ}, and $\overline{RR}_{k=4}$ states are non-Abelian, while the L state is Abelian. All of these have Abelian $e/3$ Laughlin-type quasiparticles. (Note: The $e/2$ excitation for $\overline{RR}$ is marginal, but we include it for the sake of representing the possibility of $e/2$ charge.)

$\nu = \frac{12}{5}$	e^*	n-A?	θ	g_c	g_n	g
$HH_{2/5}$:	$e/5$	no	$e^{i3\pi/5}$	$1/5$	$2/5$	$3/5$
	$2e/5$	no	$e^{i2\pi/5}$	$2/5$	0	$2/5$
$BS_{2/5}$:	$e/5$	yes	$e^{i9\pi/40}$	$1/10$	$1/8$	$9/40$
	$e/5$	no	$e^{-i2\pi/5}$	$1/10$	$1/2$	$3/5$
	$2e/5$	no	$e^{i2\pi/5}$	$2/5$	0	$2/5$

	$e/5$	no	$e^{-i2\pi/5}$	$1/10$	$1/2$	$3/5$
	$2e/5$	no	$e^{i2\pi/5}$	$2/5$	0	$2/5$
$\overline{RR}_{k=3}$:	$e/5$	yes	$e^{-i\pi/5}$	$1/10$	$3/10$	$2/5$
	$2e/5$	no	$e^{i2\pi/5}$	$2/5$	0	$2/5$

TABLE IV: Relevant quasiparticle excitations of model FQH states at $\nu = 12/5$. Here we list their values of charge e^*; whether they are non-Abelian; their topological twist factor θ; and their charge and neutral scaling exponents g_c, g_n, and g. The BS, $\overline{BS}^{\psi}$, and $\overline{RR}_{k=3}$ states are non-Abelian, while the HH state is Abelian. All of these have Abelian $2e/5$ Laughlin-type quasiparticles; all of these except RR have a relevant Abelian $e/5$ quasiparticle.

(BS) states[73], and a 4-clustered Read-Rezayi (RR) state[65]. (The bar indicates particle-hole conjugation.) The BS states considered here are hierarchically constructed over the MR and $\overline{Pf}$ states, so have similar non-Abelian statistics derived from Eq. (A4) using the fact that the non-Abelian quasiparticles carry $SU(2)_2$ charge $1/2$. The $RR_{k=4}$ state is related to $SU(2)_4$, and so has more complicated non-Abelian statistics, derived from Eq. (A6). Its fundamental $e/6$ quasiparticles carry $SU(2)_4$ charge $1/2$.

We see in Table III that all of these states have an $e/3$ excitation with smallest scaling exponent $g = 1/3$, and so one expects these to dominate the tunneling. The $\overline{RR}_{k=4}$ state also has $e/6$ excitations with $g = 1/3$, which should give a comparable contribution to the tunneling current. The experiments of Ref. 21, which observes only $e/3$ tunneling, appear to exclude the $\overline{RR}_{k=4}$ state, and agree with the $L_{1/3}$, $\overline{BS}_{2/3}$, and $BS^{\psi}_{1/3}$ states. In fact, since the relevant excitations of these three states all have $e/3$, and furthermore, the most relevant tunnelers are all Abelian, it will likely be difficult to distinguish between $L_{1/3}$, $\overline{BS}_{2/3}$, and $BS^{\psi}_{1/3}$ using tunneling and interferometry experiments. Thermal transport experiments are probably the best hope of distinguishing between these.

2. $\nu = 12/5$

For the $\nu = 12/5$ FQH plateau, the leading candidates are the Haldane-Halperin (HH) state[74,75], two types of BS states[73], and a 3-clustered RR state[65]. These BS states again have non-Abelian statistics derived from Eq. (A4) using the fact that the non-Abelian quasiparticles carry $SU(2)_2$ charge $1/2$. The $RR_{k=3}$ state is related to $SU(2)_3$, and so has non-Abelian statistics derived from Eq. (A5). Its fundamental $e/5$ quasiparticles carry $SU(2)_3$ charge $1/2$.

We see in Table IV that all of these states have an Abelian $2e/5$ excitation with scaling exponent $g = 2/5$, so there should always be a background of such excitations in tunneling. The $HH_{2/5}$, $BS_{2/5}$, and $\overline{BS}^{\psi}_{3/5}$ states all have an Abelian $e/5$ excitation with $g = 3/5$, so there should be a weaker background of these excitation in the tunneling. The smallest scaling exponent for the $BS_{2/5}$ state belongs to non-Abelian $e/5$ excitation, which is therefore expected to dominate the tunneling in this state. The $\overline{BS}^{\psi}_{3/5}$ state has a non-Abelian $e/5$ excitation which has slightly less relevant tunneling operator than the $2e/5$ excitation. The $\overline{RR}_{k=3}$ state has a non-Abelian $e/5$ excitation with the same scaling exponent $g = 2/5$ as the $2e/5$ excitation, so they should have roughly equal contribution to tunneling.

In interferometry experiments, the $BS_{2/5}$, $\overline{BS}^{\psi}_{3/5}$, and $\overline{RR}_{k=3}$ states will all exhibit $e/5$ oscillations that will sometimes be suppressed. However, there are important distinctions within this behavior that can distinguish between them. In particular, the BS states will exhibit an even-odd effect similar to Eq. (1), always returning to suppression for n_{q_0} odd, where n_{q_0} is the number of non-Abelian $e/5$ fundamental quasiparticles. On the other hand, the RR state can exhibit both suppression and full amplitude oscillations for all values of n_q, and it has a probability of switching between them when a given quasiparticle is taken in and out of the interferometry region. Furthermore, when the oscillations are suppressed for the BS state, the smaller amplitude $e/5$ oscillations will be due to tunneling of the Abelian $e/5$ excitations (which will always be present), because the non-Abelian excitation will have fully suppressed interference. The relative contribution to the tunneling of these excitations is not a fixed amount, and will change dependent on temperature and voltage (i.e. they have different scaling). In contrast to this, the suppression that would be observed in the RR state is due entirely to the braiding statistics of the non-Abelian $e/5$ excita-

$\nu = \frac{8}{3}$	e^*	n-A?	θ	g_c	g_n	g

TABLE VI: Relevant quasiparticle excitations of model FQH states at $\nu = 14/5$. Here we list their values of charge e^*; whether they are non-Abelian; their topological twist factor θ; and their charge and neutral scaling exponents g_c, g_n, and g. The BS state is non-Abelian, while the $\overline{\mathrm{L}}$ state is Abelian. Both of these have Abelian $4e/5$ Laughlin-type quasiparticles.

tion, and the suppressed oscillation amplitude should always be a constant factor of $\phi^{-2} \approx 0.38$ smaller than the full oscillation amplitude.

3. $\nu = 8/3$

The candidates for $\nu = 8/3$ FQH plateau are, of course, similar to the $\nu = 7/3$ candidates, since the filling fractions are particle-hole dual. We stress, however, that the physically observed states at these filling fractions need not be particle-hole dual to each other, since physical effects, such as Landau level mixing, will tend to break particle-hole symmetry at these fillings. The leading candidates are the Laughlin state[72], two types of BS states[73], and a 4-clustered RR state[65]. These BS states again have non-Abelian statistics derived from Eq. (A4) using the fact that the non-Abelian quasiparticles carry $\mathrm{SU}(2)_2$ charge $1/2$. The $\mathrm{RR}_{k=4}$ state again is related to $\mathrm{SU}(2)_4$, with non-Abelian statistics derived from Eq. (A6) and fundamental $e/6$ quasiparticles carrying $\mathrm{SU}(2)_4$ charge $1/2$.

We see in Table V that all of these states have an Abelian $2e/3$ excitation with scaling exponent $g = 2/3$, so there should always be a background of such excitations in tunneling. The $\overline{\mathrm{L}}_{1/3}$, $\mathrm{BS}_{2/3}$, and $\overline{\mathrm{BS}}^{\psi}_{1/3}$ states all have an $e/3$ excitation also with $g = 2/3$, so these two excitations are expected to have roughly equal contribution to the tunneling in these theories. However, the smallest scaling exponent for the $\mathrm{BS}_{2/3}$ and $\overline{\mathrm{BS}}^{\psi}_{1/3}$ states belong to non-Abelian $e/3$ excitations, which are therefore expected to dominate the tunneling in these states. The smallest scaling exponent for the $\mathrm{RR}_{k=4}$ state belongs to the non-Abelian $e/6$ excitation, which should

thus dominate tunneling. There are additional relevant tunnelers for $\mathrm{RR}_{k=4}$ that are non-Abelian with different statistics than the fundamental quasiparticle, namely the $e/3$ and $e/2$ excitations which carry $\mathrm{SU}(2)_4$ charges 1 and $3/2$, respectively. The experiments of Ref. 21, which observes only $e/3$ tunneling, appear to exclude the $\mathrm{RR}_{k=4}$ state and best agree with the $\mathrm{BS}_{2/3}$ and $\overline{\mathrm{BS}}^{\psi}_{1/3}$ states.

4. $\nu = 14/5$

The $\nu = 14/5$ FQH plateau is most likely the standard (particle-hole conjugate) Laughlin state[72], but we include this filling fraction for completeness, and list a BS state[73] as an (unlikely) alternative candidate. This BS state again has non-Abelian statistics derived from Eq. (A4) using the fact that the non-Abelian quasiparticles carry $\mathrm{SU}(2)_2$ charge $1/2$.

We see in Table VI that both of these states have Abelian $e/5$ and $4e/5$ excitations with relevant scaling exponents, so there should always be a background of such excitations in tunneling. The $e/5$ excitation is the most relevant tunneler for the $\overline{\mathrm{L}}_{1/5}$ state. For the $\mathrm{BS}_{4/5}$ state, the non-Abelian $2e/5$ excitation has the most relevant tunneling.

We also mention that a BS type hierarchy could be built over the $\mathrm{SU}(2)_2$ NAF state to produce candidates for all the filling fractions listed above[73]. The relevant data could be read off the above tables for the non-Abelian quasiparticle excitations in the BS states by simply adding $1/4$ to g_n and g, and multiplying the twist factors by $e^{i\pi/4}$.

APPENDIX B: CHARGE $e/4$ AND $e/2$ BACKSCATTERING MATRIX ELEMENTS

When they are small, the tunneling amplitudes $\Gamma_{e/4}$ and $\Gamma_{e/2}$ are the matrix elements for the transfer of charge from one edge of a Hall device to the other. For simplicity and concreteness, let us suppose that the device is a Hall bar with a single constriction. Then, the transfer of charge q from one edge to the other entails a momentum change $\Delta k_x \sim$

$(q/e)\,\Delta y/\ell_0^2$, where the x-direction is along the Hall bar. (This is seen most easily in Landau gauge, as we discuss below in the context of specific trial wavefunctions.) However, in order to cause a momentum change of Δk_x, the potential due to the gates must have weight at this wavevector, i.e. the matrix element is determined by the variation of the potential on a length scale $\Delta x \sim 1/\Delta k_x \sim (e/q)\,\ell_0^2/\Delta y$. Hence, in order to transfer charge q from one edge to the other, we need the potential to vary on a length scale Δx satisfying

$$\Delta x \cdot \Delta y \sim (e/q)\,\ell_0^2 \tag{B1}$$

If the constriction were much smaller than this, then we would expect that the potential would have comparable weight at the wavevector necessary for charge $e/4$ transfer, $\Delta k_x \sim \Delta y/4\ell_0^2$, and at the larger wavevector necessary for charge $e/2$ transfer, $\Delta k_x \sim \Delta y/2\ell_0^2$. Otherwise, we expect the weight to fall of rapidly with wavevector, and for $\Gamma_{e/4} \gg \Gamma_{e/2}$.

This can be made a little more precise by considering, for the sake of concreteness, the MR Pfaffian state. We work in Landau gauge on a cylinder[76]:

$$\Psi_0 = S(Z_1,\ldots,Z_n)\,\mathrm{Pf}\left(\frac{1}{Z_i - Z_j}\right)\prod_{i>j}(Z_i - Z_j)^2\,e^{\sum_i y_i^2/2\ell_0^2} \tag{B2}$$

where $Z_i = e^{i(x_i + iy_i)/r}$, x_i and y_i are the coordinates around and along the cylinder, respectively, and r is the radius of the cylinder. $S(Z_1,\ldots,Z_n)$ is a symmetric polynomial which deforms the shape of the Hall droplet from a rotationally-symmetric band around the cylinder to one with a constriction. For instance, we could take $S(Z_1,\ldots,Z_n) = \prod_i (Z_i - \zeta_1)^p (Z_i - \zeta_2)^p$ where ζ_1 and ζ_2 are points *outside* the droplet with the same x-coordinate. The precise form of $S(Z_1,\ldots,Z_n)$ is not important at the present level of discussion, but we will assume that it is a polynomial of degree q which is less than $2N_e$. Then, the wavefunction

$$\Psi_{1/4} = S(Z_1,\ldots,Z_n)\,\mathrm{Pf}\left(\frac{Z_i + Z_j}{Z_i - Z_j}\right) \times$$
$$\prod_{i>j}(Z_i - Z_j)^2\,e^{\sum_i y_i^2/2\ell_0^2} \tag{B3}$$

has charge $e/4$ transferred from one edge to the other, while

$$\Psi_{1/2} = S(Z_1,\ldots,Z_n)\prod_i Z_i \times$$
$$\mathrm{Pf}\left(\frac{1}{Z_i - Z_j}\right)\prod_{i>j}(Z_i - Z_j)^2\,e^{\sum_i y_i^2/2\ell_0^2} \tag{B4}$$

has charge $e/2$ transferred from one edge to the other.

The tunneling matrix elements $\Gamma_{e/4}$ and $\Gamma_{e/2}$ for charge-$e/4$ and $e/2$ quasiparticles, respectively, are

$$\Gamma_{e/4} = \langle\Psi_{1/4}|\hat{V}|\Psi_0\rangle\,, \quad \Gamma_{e/2} = \langle\Psi_{1/2}|\hat{V}|\Psi_0\rangle \tag{B5}$$

where

$$\hat{V} = \int dx\,dy\,V(x,y)\sum_i \delta^{(2)}(z - z_i) \tag{B6}$$

and $V(x,y)$ is the potential due to the gates which define the point contact.

While we would need a detailed knowledge of $V(x,y)$ and of the precise shape of the Hall droplet in order to determine $\Gamma_{e/4}$ and $\Gamma_{e/2}$ quantitatively, we can make a few qualitative remarks which echo our earlier observations. First, let us ignore $S(Z_1,\ldots,Z_n)$. Then, $\Psi_0,\Psi_{1/4},\Psi_{1/2}$ are eigenstates of angular momentum around the cylinder with eigenvalues $M = M_0, M_0 + N/2, M_0 + N$. Thus, the tunneling matrix elements $\Gamma_{e/4}$ and $\Gamma_{e/2}$ are controlled by $\tilde{V}(k_x, y)$ for $k_x = N/2r$ and $k_x = N/r$, respectively. These will be comparable if the scale Δx over which the potential varies in the x-direction is smaller than $1/k_x \sim r/N$. But the distance between the two edges Δy is $\Delta y \sim \ell_0^2 N/r$. Hence, we need $\Delta x \cdot \Delta y \sim \ell_0^2$ in order for the two tunneling matrix elements to be comparable. Otherwise, both are determined by the tails of the (Fourier transform of the) potential and $\Gamma_{e/4} \gg \Gamma_{e/2}$. The presence of the constrictions, which is reflected in $S(Z_1,\ldots,Z_n)$ means that the wavefunctions are no longer angular momentum eigenstates. Instead, Ψ_0 has non-zero amplitude for a range of angular momenta $M_0 < M < M_0 + m$ while $\Psi_{1/4}$ has non-zero amplitude for a range $M_0 + N/2 < M < M_0 + N/2 + m$, and similarly for $\Psi_{1/2}$. Here, m is determined by $S(Z_1,\ldots,Z_n)$; the minimum distance between the two edges at the constriction is $\Delta y \sim \ell_0^2(N - m)/r$. Thus, the tunneling matrix elements $\Gamma_{e/4}$ and $\Gamma_{e/2}$ are controlled by $k_x = (N - 2m)/2r$ and $k_x = (N - m)/r$. Hence, we obtain the same requirement as above, but with Δy now understood as the distance between the two edges at their point of closest approach.

APPENDIX C: COULOMB BLOCKADE FOR GENERAL FQH STATES

Coulomb blockade occurs when a puddle of the Hall fluid is almost completely pinched-off so that it is isolated from the rest of the Hall fluid, with only the possibility of electrons tunneling between this puddle and the other regions of Hall fluid. Electron tunneling is resonant when the energies are degenerate for two different values of N_e, the number of electrons in the pinched-off puddle.

As we mentioned earlier, several authors[37,41,77] have emphasized that a device can be 'Coulomb-dominated' even when it is not strictly-speaking in the Coulomb blockade regime, meaning that the Coulomb energy of the puddle can be the dominant energy even when the puddle is far from being pinched off from the rest of the Hall fluid. In the Coulomb-dominated regime, the number of electrons in the puddle is determined by the condition that they exactly neutralize the positively charged background. As the side-gate voltage is varied (or a back-gate voltage), the charge of the neutralizing background varies. The relationship between the two (the 'lever arm'[37,77]) is not expected to depend on the magnetic field, so the period in side-gate voltage is expected to be independent of the field in this regime (unlike what is observed in the experiments of Refs. 1,2).

In this appendix, however, we focus on the Coulomb block-

ade regime of a nearly pinched-off puddle – which, as we have argued, is not likely to govern the experiments of Refs. 1,2. The bulk of the pinched-off puddle will have some definite total collective topological charge a, determined by N_e together with the bulk quasiparticle excitations in the puddle. If the bulk quasiparticles are all Abelian, then this uniquely specifies a, i.e. $a = N_e a_e \times \prod_j a_j$ where j indexes the bulk quasiparticles (where a_e is the topological charge of an electron and a_j the topological charge of the jth bulk quasiparticle). When the bulk quasiparticles are non-Abelian, there can be multiple fusion channels, and so we write $a \in N_e a_e \times \prod_j a_j$ to indicate that a is one of the allowed fusion channels of the electrons plus quasiparticles. The entire puddle must have trivial total topological charge 0, so, to compensate for the bulk topological charge a, the edge of the puddle carries the conjugate topological charge $\bar{a}$. This topological charge determines which sectors of edge excitations are allowed to occur, and hence the energy spectrum of the edge excitations. Thus, the pattern of tunneling resonance peaks is determined entirely by the ground-state energy $E\left(N_e, B, A, a_j, a\right)$ of the puddle[50], which depends on the number of electrons N_e in the puddle, the background magnetic field B, the puddle area A, and the collective topological charge a of the bulk.

The edge of a quantum Hall fluid can be described using CFT. For a pure CFT on a circle of length L, the energy of a mth level descendent of the primary field φ is $\frac{2\pi v}{L}\left(h_\varphi + m\right)$, where v is the velocity and h_φ is the conformal scaling dimension of φ. For a quantum Hall system, there can be multiple edge modes, and the topological charge $\bar{a}$ on the edge determines which primary field $\bar{a}^{(i)}$ of the ith mode is present. For this analysis, we are interested in the ground-state energies, and can ignore descendents (let $m = 0$). Some of the edge modes may couple to other quantities that break their conformal symmetry. We can thus write the energy as the sum over effective energies from the edge modes

$$E\left(N_e, B, A, a_j, a\right) = \sum_i \frac{2\pi v_i}{L} \tilde{h}_{a^{(i)}} \qquad (C1)$$

where L is the length of the puddle's perimeter, v_i is the velocity of the ith mode, and $\tilde{h}_{a^{(i)}}$ is the effective scaling dimension of the ith edge mode. The effective scaling dimensions includes any modification of these modes that arise when the CFT couples to other quantities. When there is no modification of an edge mode, one simply has $\tilde{h}_{a^{(i)}} = h_{a^{(i)}}$, the conformal scaling dimension of $a^{(i)}$. For example, we include the electrostatic area dependence in the energy of the charge mode (denoted c) by writing[50]:

$$\tilde{h}_{a^{(c)}} = \left(\sqrt{h_{a^{(c)}}} - \sqrt{\frac{\nu}{2}\frac{B\left(A - A_0\right)}{\Phi_0}}\right)^2 \qquad (C2)$$

$$= \frac{\nu}{2}\left(a^{(c)} - \frac{B\left(A - A_0\right)}{\Phi_0}\right)^2, \qquad (C3)$$

where A_0 is the area of the puddle with just enough quasiholes fewer than the given configuration in order to have $a^{(c)} = 0$ (see Refs. 50,78 for more clarifying details). This can be written somewhat more transparently as

$$\tilde{h}_{a^{(c)}} = \frac{\nu}{2}\left(N_\phi^q + S - N_\phi\right)^2 \qquad (C4)$$

$$N_\phi^q = \frac{N_e}{\nu} + \sum_j a_j^{(c)} \qquad (C5)$$

$$N_\phi = \frac{BA}{\Phi_0}, \qquad (C6)$$

where N_ϕ^q is the quantized number of fluxes ascribed to the electrons (which have $a_e^{(c)} = 1/\nu$ flux per electron) and bulk quasiparticles (the jth quasiparticle having $a_j^{(c)}$ fluxes), S is a finite shift, and N_ϕ is the actual number of magnetic fluxes through the puddle. In this form, the energy is seen to be due to the discrepancy between the actual number of fluxes through the puddle and the flux quantization condition. From this, we can see that without the inclusion of neutral modes the spacing between resonance peaks would simply be $\Delta A = e/\rho_0$, the area that a single electron occupies.

The charge sector CFT scaling dimension of an excitation with electric charge e^* is given by

$$h_{a^{(c)}} = \frac{\nu}{2}\left[a^{(c)}\right]^2 = \frac{1}{2\nu}\left(\frac{e^*}{e}\right)^2. \qquad (C7)$$

If there is an array of Abelian $U(1)$ sectors with coupling K-matrix, it is useful to separate them into the charge and neutral modes. This can be done by directly diagonalizing the K-matrix, or at the level of the flux vector, where for an excitation with $U(1)_K$ flux vector $\vec{l}$ one can write[53]

$$a^{(c)} = \frac{e^*}{\nu e} = \frac{\hat{t}_c \cdot K^{-1} \cdot \vec{l}}{\hat{t}_c \cdot K^{-1} \cdot \hat{t}_c} \qquad (C8)$$

$$h_{a^{(c)}} = \frac{\left[a^{(c)}\right]^2}{2}\hat{t}_c \cdot K^{-1} \cdot \hat{t}_c \qquad (C9)$$

$$\vec{l}_n = \vec{l} - a^{(c)}\hat{t}_c \qquad (C10)$$

$$h_{a^{(n)}} = \frac{1}{2}\left|\vec{l}_n \cdot K^{-1} \cdot \vec{l}_n\right|, \qquad (C11)$$

where $\hat{t}_c$ is the "charge vector" of the corresponding K-matrix (and $\hat{t}_c \cdot K^{-1} \cdot \vec{l}_n = 0$). (Note: these equations can also be used for electrons by treating them as excitations with $e^* = e$, rather than their actual charge $-e$.) In these terms, the charge sector's scaling exponent is $g_c = 2h_c$ and the $U(1)$ sectors' contribution to the neutral sector scaling exponent is $g_n = 2h_n$.

From this, we get that the spacing between two peaks, say the resonances between $N_e = N$ and $N_e = N \pm 1$, will be

$$\Delta A_N = \frac{e}{\rho_0}\left[1 + \sum_{i \neq c}\frac{\tilde{\nu}v_i}{v_c}\left(\tilde{h}_i^{(a_{N+1})} + \tilde{h}_i^{(a_{N-1})} - 2\tilde{h}_i^{(a_N)}\right)\right] \qquad (C12)$$

(assuming that $\tilde{h}_i$ do not depend on A for $i \neq c$), where the fractional part of the filling is denoted $\tilde{\nu} \equiv \nu - \lfloor\nu\rfloor$. This general, yet simple equation allows one to easily predict the

spacings for a candidate state just by knowing the conformal dimensions of the corresponding CFT's primary fields, and how the edge modes couple to other quantities.

When there are non-trivial electrically neutral excitations in FQH state, there will generally be tunneling of such excitations between the edge and bulk quasiparticles that will not change the bulk energy, but may lower the edge energy. (Note: this can occur for Abelian states.) If the area of the puddle is changed slowly compared to the tunneling rate of such neutral excitations, the spacing between consecutive resonance peaks will be modified because the topological charge on the edge (and in the bulk) will change as a result of the tunneling event. The resulting spacing when such bulk-edge relaxation occurs will be[78]

$$\Delta A'_N = \frac{e}{\rho_0} \left[1 + \sum_{i \neq c} \frac{\tilde{\nu} v_i}{v_c} \left(\tilde{h}_i^{(a_{N-1})} - \tilde{h}_i^{(a_N)} \right. \right.$$
$$\left. \left. + \tilde{h}_i^{(a'_{N+1})} - \tilde{h}_i^{(a'_N)} \right) \right], \quad \text{(C13)}$$

where the primed topological charges are the ones that result from the unprimed ones when relaxation has occurred between the $N_e = N - 1, N$ resonance and the $N_e = N, N + 1$ resonance (or vice-versa if the area is being varied in the other direction). When the area of the puddle is changed quickly compared to the neutral excitation bulk-edge tunneling rate, the spacing will simply look like Eq. (C12). For intermediate time scales, the spacing between consecutive resonance peaks will be given by some smearing between Eqs. (C12) and (C13).

When there are multiple flavors of electrons (e.g. in bilayer or unpolarized FQH systems), one generalizes the above discussion in the obvious way. Specifically, each electron flavor may have a different topological charge assigned to it, and tunneling a particular electron flavor may be energetically favored in a given configuration, so this must be taken into account when determining the spacing of resonance peaks.

From Eqs. (C12) and (C13), it is clear that states with dramatically different braiding statistics can nonetheless give rise to Coulomb blockade patterns that are experimentally indistinguishable, even assuming one has good enough experimental resolution to overcome the challenges introduced by the likely small values of v_i/v_c and the thermal smearing of resonance peaks. The only requirement for indistinguishability is that the conformal scaling dimensions be such that they produce similar relative spacings between resonance peaks. Hence, in contrast to interference experiments, Coulomb blockade lacks the ability to unambiguously identify the presence of non-Abelian statistics in a FQH state.
