ABSTRACT

Population ecology aims to search for factors that lead to variation in vital rates and consequently, in the number of individuals. This includes testing hypotheses about natural history traits and threats to populations. However, obtaining data to test hypotheses is challenging because following individuals in the field can be difficult, especially for amphibians and reptiles, where detection probabilities are often < 1 . Mark-recapture methods are widely used to estimate detection probabilities and to test ecological hypothesis. Here we used mark-recapture methods to test hypotheses related to ecology and conservation of amphibian and reptile populations. We implemented open- and closed-population models in Program MARK, to account for detection probabilities and to calculate survival estimates and other population parameters. We organized this dissertation into four chapters. In the first chapter we emphasize the importance of considering detection probabilities besides simulating hypothetical scenarios to show the relationship between field effort, sample size and precision. In the second chapter we used a Cormack-Jolly-Seber model to compare the effect of two amphibian marking techniques, toe-clipping and PIT tagging, on survival in the blacksmith tree frog, *Hypsiboas faber*. In the third chapter our goal was to estimate survival and population growth of the golden lancehead, *Bothrops insularis* accounting for temporary emigration using Pollock's Robust Design. Besides the study of vital rates and population dynamics, energy allocation and its consequences for survival are testable with mark-recapture models. Thus, in the last chapter we used two traits from the lizard mating system, namely jaw size and courtship coloration, to compare survival estimates between males and females of the whiptail lizard, *Cnemidophorus cf. ocellifer*. In summary we observed that detection probability on the studied populations were low and similar to other vertebrate populations from the tropics. However, including covariates in estimation models of vital rates and detection is important to obtain more accurate results to explain population dynamics. Specifically we conclude that (i) return rates were biased low in relation to survival estimates that account for detectability, (ii) the estimates of survival were similar between toe-clipped and PIT tagged individuals of *Hypsiboas faber*, (iii) *Bothrops insularis* showed low survival probability and negative annual population growth. And (iv) larger *Cnemidophorus cf. ocellifer* males showed lower monthly survival probability than smaller males but the opposite was found for females.

RESUMO

A ecologia de populações investiga os fatores que levam a variação das taxas vitais e, consequentemente, no número de indivíduos. Isso inclui testar hipóteses sobre aspectos da história de vida das espécies e entender os fatores que podem modular a dinâmica populacional. No entanto, a obtenção de dados para testar hipóteses pode ser difícil para populações que apresentam probabilidades de detecção < 1 , como anfíbios e répteis. A marcação e recaptura é amplamente usada para estimar a detecção e inferir aspectos de dinâmica populacional e testar hipóteses ecológicas. Neste trabalho empregamos a teoria de marcação e recaptura para testar hipóteses relacionadas à ecologia e conservação de populações de anfíbios e répteis. Utilizamos o programa MARK para implementar modelos de populações abertas e fechadas incorporando a probabilidade de detecção dos indivíduos, para obter estimativas de sobrevivência, e outros

parâmetros populacionais usando máxima verossimilhança. Organizamos esta tese em quatro capítulos. Iniciamos enfatizando a importância da probabilidade de detecção, além de simular cenários hipotéticos para demonstrar a relação entre esforço de campo, tamanho ótimo amostral e viés amostral. Em seguida comparamos o efeito de duas técnicas de marcação, o corte de artelhos e o implante de *microchips*, sobre a sobrevivência individual do sapo ferreiro, *Hypsiboas faber*.

No terceiro capítulo estimamos a sobrevivência e o crescimento populacional da jararaca-ilhoa, *Bothrops insularis* incorporando emigração temporária aos modelos. Além do estudo de taxas vitais e de dinâmica nas populações, a alocação de energia e suas consequências na sobrevivência individual podem ser testadas com modelos de marcação e recaptura. Assim, no quarto e último capítulo consideraremos dois caracteres sexuais presentes no sistema de acasalamento dos lagartos, o tamanho da mandíbula e a coloração chamativa, para comparar as estimativas de sobrevivência entre machos e fêmeas do lagarto cauda de chicote, *Cnemidophorus cf. ocellifer*.

. De forma geral, observamos que a probabilidade de detecção individual nos sistemas estudados foi baixa e condizente com a detecção de vertebrados em ambientes tropicais. Além disso, a inclusão de covariáveis na investigação de parâmetros vitais e no processo de detecção é fundamental para o melhor entendimento dos fatores que explicam a dinâmica de uma população. Especificamente observamos que: (i) demonstramos que as taxas que não incorporam a detecção são enviesadas em relação as estimativas que consideram a detecção, (ii) as estimativas de sobrevivência foram similares em indivíduos de *Hypsiboas faber* marcados com ablação de artelhos e microchips , (iii) *Bothrops insularis* apresentou baixa probabilidade de sobrevivência anual e crescimento populacional anual negativo. Por fim, (iv) machos maiores do lagarto *Cnemidophorus cf. ocellifer* apresentaram sobrevivência mensal menor do que machos menores, mas o oposto foi observado para as fêmeas.

AGRADECIMENTOS

Durante o desenvolvimento desta tese recebi ajuda de muitas pessoas, seja com um conselho, um gesto, ou com braços fortes. Tenho certeza que sem isso eu não teria chegado aqui. Assim tentarei expressar aqui a minha gratidão aos que contribuíram para este trabalho de forma direta ou indireta, e peço desculpas se esqueci de alguém especial.

Agradeço ao meu orientador Ricardo Sawaya pela amizade e respeito acima de tudo, também pelos conselhos e por estar sempre pronto a ajudar.

Agradeço ao Roberto Munguía Steyer pela co-orientação, com paciência e atenção. Obrigado por me guiar nos primeiros passos no mundo da marcação e recaptura e estar sempre disposto a ensinar e dividir.

Agradeço ao Glauco Machado pela sua disponibilidade e preocupação. Obrigado por me apresentar ao Roberto, pelas dicas na entrada no doutorado, pela ajuda no delineamento amostral de parte desta tese e leitura crítica. Obrigado por querer me tornar melhor e por mostrar que não se faz ciência de boa qualidade com uma cesta na mão.

Agradeço também ao Otavio Marques, que me incentivou no início e acreditou em mim. Pela sua serenidade de sempre e franqueza que me permitiram buscar novos horizontes.

Sou grato ao IBILCE, onde iniciei o primeiro curso de doutorado e lá permaneci por 2 anos. Agradeço especialmente ao prof. Francisco Langeani, então coordenador da PG, pelo apoio e compreensão. Agradeço também a prof. Denise Rossa-Feres pelo seu empenho e apoio durante o tempo de coleta do projeto Biota. E aos amigos que lá fiz.

Muito desta tese é baseada em dados obtidos em campo. Trabalho de campo pode ser desgastante, árduo, e as vezes ingrato. Trabalhar sozinho é impossível em determinadas

situações. Na ilha da Queimada Grande experimentei emoções fortes, e creio que aprendi algumas lições. Sou grato ao Otavio Marques por confiar em mim um trabalho importante e por financiá-lo. Agradeço a ajuda e companhia de diversas pessoas que lá estiveram obtendo dados que foram usados aqui: Antônio Carlos Costa, Cinthia Brasileiro, Denis Andrade, Fausto Barbo, Harry Greene, Karina Kasperoviczus, Kelly Zamudio, Ligia Pizzatto, Lilian Parpinelli, Livia Santos, Marcio Martins, Maria Ermelinda, Marília Gaiarsa, Rafael Bovo, Renata Orofino, Ricardo Lobo, Ricardo Sawaya, Valdir Germano e tantos outros. Agradecimentos especiais aos colegas da última e insana fase dos plots: Amom Mendes, Daniela Genari, Laura Alencar, Rogério Zacariotti, Sérgio Serrano e Thiago Pires.

Pelo trabalho na Estação Ecológica de Jataí agradeço ao querido Pará que é um trator, sempre com muita energia. Agradeço ao Amom Mendes por ajudar na fase inicial, limpando alguns quilômetros de trilha sob um sol de 42 graus. Também agradeço ao André Scatigna, José Ferrarini, Juliana Souza, Karina da Silva, Thais Postali e Thiago Pires pela ajuda essencial. E por último devo um agradecimento mais do que especial ao meus queridos companheiros de Jataí. Por 14 meses eles estiveram firmes, sem esmorecer ou desleixar, acordando cedo para abrir as armadilhas e fecha-las ao entardecer. Muito obrigado queridos irmãos Sérgio Coy, Décio Kaka e Thiaguinho Mamute. Sem vocês o grid não iria pra frente! Destes grandes amigos só tenho uma coisa a reclamar: me obrigavam a ouvir música sertaneja. Não poderia esquecer do Ronco, Pidôncio e Zé Pindola por alegrar os dias no campo.

Agradeço aos herpetólogos que emprestaram seu conhecimento para ajudar no delineamento deste experimento: a querida Paula Valdujo, ao Cristiano Nogueira, ao Guarino Coli, ao Mauro Teixeira e Renato Recoder.

Quero agradecer também ao ICMbio pelas autorizações de trabalho, ao Isaías Reis do

RAN, ao diretor da E. E. Jataí, Edson Montilha e a todos os funcionários pelo apoio: Paulinho, Marquinho, Quirela, Nenê, Jair, Miltinho, dona Helena, Cícera, seu Benê e seu Carlito.

Agradeço a equipe do software I³S pelas sugestões de análise dos bancos de dados fotográficos e ao Roberto Sachii pelas dicas do tratamento das imagens. Obrigado a Hamanda Cavalheri e Marília Gaiarsa por me ajudarem a quantificar a coloração nos lagartos. E a Jeanne Robertson pela paciência e disposição em ajudar com os softwares de tratamento de imagens.

Agradeço aos professores Glauco Machado, Paulo Guimarães e Paulo Inácio e a todos os colegas da LAGE pelo abrigo durante um período deste trabalho.

Aos colegas do Labvert, Hamanda Cavalheri, Laura Alencar, Marília Gaiarsa, Paula Valdujo, e em especial ao Marcio Martins pela amizade e confiança. Agradeço ainda por ceder dados de *Hylodes* e pelo financiamento de parte desta tese.

A todos os amigos do Laboratório de Ecologia e Evolução e da Coleção Herpetológica do Instituto Butantan, em especial: Otavio, Valdir, Selma, Maria José, Kiko, Karina, Letícia, Claudio, Christian, Thaís, Darina, Vera, Maria e muitos outros.

Sou muito grato aos meus colegas da Unicamp, em especial a Janaína Cortinoz, Gabi, Paulinho, Décio e Thaís e tantos outros colegas por me ajudarem em diferentes etapas do doutorado. Agradeço também ao professores André Freitas e Gustavo Romero por todo auxílio e pela sua atenção. Um agradecimento especial a Célia Duarte Pio, sempre muito eficiente e atenciosa.

Durante meu estágio nos Estados Unidos agradeço especialmente as pessoas que me ajudaram com dicas, material e conselhos sobre o estágio no exterior. Em especial a Marcela Nascimento, que me forneceu documentos e me ajudou sempre com enorme paciência. Sou grato também a Paula Valdujo por estar sempre disposta a ajudar com grande boa vontade, a Marília

Duarte pelas dicas e ao Nandão por me enviar documentos.

Sou muito grato ao Paul Doherty Jr., meu orientador na CSU. Sua bondade, bom humor e perseverança faziam a vida parecer mais leve e segura. Com ele aprendi coisas importantes sobre a conduta de um orientador, além de ter persistência e *thick skin*. Thank you so much Paul! Vou sentir falta de você entrando no lab e perguntando porque não estávamos trabalhando mais rápido!

Ainda na CSU, devo o pouco que aprendi a muitas pessoas, entre elas: Gary White, sempre com enorme paciência para ensinar, Larissa Bailey pela paciência e simplicidade, por estar sempre disponível para uma conversa; a querida Vivi Ruiz Gutierrez, por ser uma pessoa tão amável, prestativa, pelos ótimos conselhos, discussões sobre a vida, e ajuda com estatística; a Amy Davis, pelo apoio moral e auxílio desde minha chegada a FoCo, pelos primeiros passos no esqui, passeios e principalmente pelos inúmeros auxílios estatísticos e uso do programa MARK. Ao querido e estimado amigo Phillip Street, meu instrutor de esqui e escalada, pelo auxílio no programa MARK e também por ter sido um irmão mais velho que olhou por mim e me ajudou em todos os momentos. Agradeço também a Emily Hamblen, companheira de sempre. E aos companheiros de lab, Amy Davis, Phillip Street, Eric Bergman, Mark Peterson e Jeremy Dertien...o laboratório era sempre animado com alguma gracinha alheia. Agradeço ao Wagar 113 *Superpopulation* pelas críticas e comentários aos meus capítulos. A Joyce Pratt, secretária do FWCB, sempre muito prestativa. A Kate Huyvert, por me acolher em sua casa, me tratar muito bem e ser sempre muito gentil. Aos professores: Kate Huyvert, Mevin Hooten, Bill Kendal, David Anderson, Chris Funk, Kevin Bestgen, Ken Wilson, Kevin Crooks, Tom Seibert, Barry Noon, Ken Burnham e aos colegas Adam Green, Amanda Hardy, Brian Gerber, Perry Williams, Sara Bombaci, Sara Garza, Shane Siers e tantos outros que tive o prazer de conviver. Obrigado

também aos meus *roommates* Jonathan London e Yuichi Iwasaki por partilharem suas culturas, alegrias e o prazer de viver.

Pela participação em minha pré-banca, sou muito grato ao professores Eduardo Martins, Gonçalo Ferraz e Larissa Bailey pela disponibilidade e valiosos comentários muito pertinentes que aumentaram a clareza e o rigor científico, elevando a qualidade dos capítulos desta tese. Agradeço também aos membros da banca: Leonardo Wedekin, Márcio Araújo, Paulo Inácio Prado e Sérgio dos Reis pelos excelentes comentários que enriqueceram a tese.

A família Palumbo Gaiarsa pelo apoio reconfortante e alegria de sempre. Sou muito grato a esta família que me acolheu, me deu conselhos, me amparou e sempre me animou. As vezes encontramos em outras famílias a nossa. Encontramos aqueles que nos ajudam, seja com uma palavra, um sorriso ou qualquer outro nobre gesto sem esperar nada em troca. Muito obrigado Dacio, Zizi, Ma e Pe por serem pessoas tão amáveis, tão queridas, sempre de bom humor, e com sorriso no rosto.

Meu mais sincero agradecimento a minha querida Marília Gaiarsa, minha melhor amiga. Obrigado pela paciência e por acompanhar de perto todas as etapas deste trabalho nos mínimos detalhes. Viu-me cair no mar da decepção e combateu com todas as armas (incluindo o legendário mousse da kopenhagen) a falta de estímulo e os problemas que enfrentei nessa vida de pós-graduando. Sempre de bom humor, nunca me deixava esmorecer, dando apoio incondicional. Sua contribuição nessa tese é imensa! Obrigado pela leitura desta tese, por me ouvir, me aconselhar, por partilhar sua alegria de viver e por me fazer mais feliz!

Agradeço muito a meus familiares pelo incentivo e por me tornarem parte do que sou. A minha mãe Sônia pelo exemplo de vida e de coragem e ao meu pai Jorge. Aos meus queridos

irmãos Marcel e Malcom pela convivência sempre saudosa e agradável. Aos meus avós pelo exemplo de vida e demais familiares.

Agradeço ao Cnpq (processo 140684/2009-3) pela bolsa de doutorado concedida e a Capes pela bolsa de estágio no exterior (processo 2296/11-0). Esta tese recebeu ainda apoio financeiro da Fapesp (processos 2008/54472-2; 2008/57898-0) e do Programa de Pós Graduação em Ecologia da Unicamp.

INTRODUÇÃO GERAL

A ecologia de populações se preocupa em investigar os fatores que controlam a dinâmica temporal e espacial de uma população, decorrentes de variações das taxas vitais, interações bióticas e abióticas (Godfray, 2009). A trajetória demográfica de uma população pode ser definida a partir da combinação de um conjunto de probabilidades de parâmetros, que ocorrem em diferentes escalas, culminando com alterações na abundância. Dentre os parâmetros vitais de uma população se destaca a probabilidade de sobrevivência, um fator chave na dinâmica populacional (Lebreton et al., 1992; Williams et al., 2002).

Caracterizar a sobrevivência é importante para que se possa identificar, por exemplo, a fragilidade de uma população frente ao declínio (Pollock, 1982). Entretanto, mensurar a sobrevivência de populações naturais é uma tarefa árdua, devido à dificuldade de acompanhar os indivíduos no campo (Lebreton et al., 1992), além da dificuldade de se amostrar determinadas populações em função da raridade de algumas espécies ou grupos (Thompson, 2004). Assim, frequentemente, dados de uma parcela da população são utilizados para realizar inferências sobre as estimativas de interesse para a população como um todo, e diferentes métodos são baseados neste tipo de rotina, incluindo a marcação e recaptura.

Com o avanço do ferramental analítico, os modelos de marcação e recaptura constituem-se em ferramentas eficientes e flexíveis que auxiliam a obtenção de estimativas de parâmetros populacionais (Williams et al., 2002; Nichols, 2005) e permitem o teste de hipóteses envolvendo aspectos da história de vida das espécies (Lebreton et al., 1992). Na marcação e recaptura, a partir de múltiplas amostragens, os indivíduos capturados não marcados recebem uma marca individual e os indivíduos capturados já marcados em amostragens anteriores tem sua recaptura registrada (Manly et al., 2005). A partir de uma variável categórica (capturado "1"/não capturado "0") são

construídos históricos de captura individual e a estimativa dos parâmetros é calculada com base na multiplicação das probabilidades (Doherty et al., 2010; Manly et al., 2005).

Para que sejam alcançados resultados acurados, as estimativas devem incorporar a probabilidade de detecção (Yoccoz et al., 2001), que é a probabilidade de encontrar um indivíduo ou espécie quando presente na área de estudo. No entanto, ainda hoje muitos artigos assumem detecção perfeita ou constante nos sistemas, o que gera estimativas subestimadas. O conhecimento do quão enviesada é a estimativa em questão permite obter melhores indicadores de resposta da população, facilitando os esforços de conservação (Ferraz et al., 2007). A probabilidade de detecção se faz importante principalmente em sistemas imprevisíveis, onde a chance de encontrar os indivíduos é variável e geralmente baixa, e pode estar relacionada, por exemplo, a habilidade dos investigadores em encontrar os indivíduos e ao clima. Tratando-se de estudos de vertebrados, existem indícios de que anfíbios e répteis apresentam baixa detectabilidade no campo (Dorcas & Willson, 2009).

De forma geral, anfíbios e répteis apresentam características comuns de história de vida, incluindo tamanho corporal geralmente pequeno, ocorrência em ambientes similares e hábitos elusivos. Devido a tais características, podem ser populações de difícil monitoramento em ambientes complexos e heterogêneos (McDonald, 2004). Além disso, esses grupos veem apresentando declínios significativos nas últimas décadas, sofrendo com a perda e a alteração de habitat, introdução de espécies exóticas, além de doenças e alterações climáticas (Gibbons et al., 2000, Stuart et al., 2004).

Neste trabalho, aplicamos a teoria de marcação e recaptura em populações da herpetofauna para estimar parâmetros populacionais de interesse, considerando a detecção imperfeita dos indivíduos. Implementamos modelos de populações abertas e fechadas para

responder questões inerentes a cada sistema, utilizando a seleção de modelos. As análises foram realizadas no programa MARK 5.1 (White & Burnham, 1999).

Esta tese está organizada em quatro capítulos independentes entre si, com objetivos específicos. O **primeiro capítulo** surgiu devido a escassez de trabalhos que incorporam a detectabilidade envolvendo estudos com a herpetofauna no Brasil e na América do Sul. Esse problema enfraquece o poder de previsão sobre os sistemas, com implicações diretas nas ações de conservação das espécies. Inicialmente, comparamos a estimativa de sobrevivência que incorpora a probabilidade de detecção com taxas de retorno, índices sem correção, para a rã-de-correderia, *Hylodes asper*. Em seguida, por meio de simulações, demonstramos a relação entre o esforço amostral e precisão, com o objetivo de fornecer elementos para auxiliar pesquisadores no campo

O **segundo capítulo** aborda a importância de se conhecer os efeitos das técnicas de marcação sobre os indivíduos, e consequentemente sobre a população. Para tanto comparamos os efeitos de duas técnicas amplamente empregadas em estudos com vertebrados, a ablação de artelhos e a aplicação de *microchips*, em uma população do sapo ferreiro, *Hypsiboas faber*.

O **terceiro capítulo** ilustra o primeiro estudo de dinâmica populacional para umas das espécies de serpentes ameaçadas do Brasil. Neste, empregamos o desenho robusto de Pollock para incorporar a migração temporária nas estimativas de sobrevivência e abundância. Além disso, investigamos possíveis respostas comportamentais oriundas do método de captura e provemos uma estimativa de crescimento populacional.

No **quarto capítulo** utilizamos a teoria de seleção sexual para testar o efeito de caracteres sexuais secundários sobre a sobrevivência individual em lagartos. Para tanto utilizamos o tamanho da mandíbula, empregado na luta entre machos, e a coloração de sinalização, para testar

a hipótese de que o maior investimento em caracteres sexuais tem efeito negativo sobre a sobrevivência de machos porém efeitos opostos em fêmeas do calango, *Cnemidophorus* cf. *ocellifer*.

CAPÍTULO 1

**STRENGTHING POPULATION INFERENCE IN HERPETOFAUNAL STUDIES BY
ADDRESSING DETECTION PROBABILITY**

MURILO GUIMARÃES

Programa de Pós-Graduação em Ecologia, Departamento de Biologia Animal, Instituto de Biologia, Universidade Estadual de Campinas. CP 6109, cep 13083-970, Campinas, SP, Brazil. Email: mu.guima@gmail.com

*manuscrito não publicado

ABSTRACT. Accounting for detection probability in population studies has been widely adopted. However, many Brazilian herpetological articles still report estimates without considering how detection can influence estimates of survival and other vital rates, assuming that detection probability is perfect (i.e. 100%). Using data from a population of the torrent frog, *Hylodes asper*, I calculated return rates and compared them with survival probability estimates adjusted for detection probability to show the discrepancies between the two metrics. Using power analysis, I also explored how survival is underestimated, considering different scenarios and sampling efforts, given low detectability. Finally, I provide information on the optimal number of surveys to achieve a 15% coefficient of variation, assuming a fixed number of individuals initially captured for a series of parameter values. Ignoring potential bias of uncorrected estimates may lead to weak inference and erroneous decisions for management and conservation. I suggest researchers consider detection probability in their studies to obtain more accurate estimates of population.

Key words: Mark-Recapture, Detectability, Amphibians, Reptiles, Vital Rates, Abundance, Survival Probability.

INTRODUCTION

Conservation biology often focus on studies investigating population parameters, such as abundance, survival, or other vital rates. Estimating such measures without bias is imperative when dealing with population declines, which have been observed for amphibians and reptiles world-wide (Gibbons et al., 2000; Stuart et al., 2004; Bohm et al., 2013). Until about 10 years ago, most inferences made on herpetological populations were based on raw counts (Schmidt, 2003; Mazerolle et al., 2007), which may erroneously assume perfect or constant detection probability (the probability of seeing an individual or a species when present in the sampling area), through time and space. As such, many studies have overlooked potential biases in vital rate estimates associated with changes in detection probability due to individual and temporal variation (e.g. differences among sexes or size, behavioral responses, seasonal activity), as well as observer bias (Anderson, 2001; Bailey et al., 2004a). Assessments of species occurrence, colonization of fragmented areas, and species richness are also biased when detection probability is not accounted for (Williams et al., 2002; MacKenzie et al., 2006; Ruiz-Gutiérrez and Zipkin, 2011; Yackulic et al., 2012).

Using abundance as an example, consider y the number of animals observed in a survey, p as the detection probability associated with the survey and τ as the true number of individuals. If we assume that (1) we see animals of a specific group with a certain probability p , and (2) one individual does not affect detectability of another (individuals are independent), then y can be model as binomial distribution, with the expected number of individuals observed after repeated counts being:

$$E(y) = \tau p \text{ (Thompson, 2012).}$$

When p is less than 1, the count statistic y must be adjusted by p in order to get an unbiased estimate of τ (Williams et al., 2002; Thompson, 2012). If p varies in time or space, the variation in y could be due to variation in p (Williams et al., 2002; Schmidt and Pellet, 2010). Furthermore, because p can only take on values between 0 and 1 (because it is a probability), the simple count y will only be biased low (Schmidt and Pellet, 2010).

The probability of survival is another important life history parameter, directly related to fitness. Although critical to population dynamics, survival is difficult to obtain because time of death is usually unknown under natural conditions (Lebreton et al., 1992). In this way, inference may be based on marked animals and various robust models that account for detectability are available (Nichols et al., 1994, Schwarz and Arnason, 1996; Williams et al., 2002). However, survival is sometimes estimated through the return rate, a confounded index of survival which includes the probability of the individual surviving from the capture occasion t to $t+1$, and the probability of detecting the individual at $t+1$, given that the individual is alive and in the study area (Lebreton et al., 1992). Because detection probabilities are rarely 1, using return rate to infer patterns of survival may be erroneous (Martin et al., 1995).

Without adjusting for p (detectability), raw counts are referred as population indices when dealing with population sizes, trap rates when considering the number of individuals captured in traps, or as return rates with survival studies- all of which have been argued as being biased because they assume no random or systematic changes in detection (e.g. constant) over time (Anderson, 2001). The animal ecology literature is full of suggestions that detection probability needs to be addressed in conjunction with count statistics (Williams et al., 2002; MacKenzie et al., 2006), since obtaining a $p = 1$ is difficult in most field situations. Besides that, ensuring high

detection probabilities help improving precision of estimates, such as survival or abundance (Otis et al., 1978; Pollock, 1982).

The importance of detection probability has been noted in European and North American herpetology journals (Schmidt et al., 2002; Dodd and Dorazio, 2004; Schmidt, 2004; Mazerolle et al., 2007), as well as in general ecology and zoology journals dealing with herpetofauna (Kéry, 2002; Schmidt, 2003; Bailey et al., 2004a; Bailey et al., 2004b; Willson et al., 2011). However, when considering south american and specially, Brazilian herpetological journals, many population and community articles still overlook this issue.

Here, using mark-recapture models, I intend to demonstrate the bias when using estimates uncorrected for detection probability and to make recommendations for study design in order to strength the inference in herpetofaunal studies. Specifically my goals are: (i) to show the discrepancy between estimates that account for detectability, with estimates that do not include detectability; (ii) to show the bias, through simulated scenarios, in estimates of survival probability when using different amounts of effort; and (iii) to provide recommendations of an optimum number of surveys based on given values, with a reasonable level of precision.

METHODS

General approach

In order to achieve my goals I organized this paper in three parts. First, I estimate survival probability, while accounting for detection probability, to contrast it with the return rate and show the bias when p is assumed to be 1. For that purpose, I used empirical data of a population of the torrent frog, *Hylodes asper* (Leptodactylidae). In the second part I use the estimates generated for the torrent frog population to plug into simulations to show the percentage of the simulated

scenarios that underestimate the true value of the apparent survival when different sampling efforts are used. In the third part I combine number of individuals initially released with survival and detection estimates to recommend sampling effort with reasonable precision (see Mackenzie et al., 2006).

*Survival probability and return rates in the torrent frog, *Hylodes asper**

I used a data set of a population of the torrent frog, *Hylodes asper* obtained in the Parque Estadual da Serra do Mar at Núcleo Picinguaba ($23^{\circ} 22' S$; $45^{\circ} 0' W$), coast of São Paulo state, southeastern Brazil. Capture occurred in a 100-meter transect of a rocky stream during 43 consecutive months, from 2007 to 2010. Within each month, two to four trained investigators searched for frogs using visual and auditory cues while walking slowly upstream; this was done for one day on each month. Photographic mark-recapture was used to individually identify frogs and only adult frogs were considered.

I used maximum likelihood estimates to obtain apparent survival probability (Φ), a product of true survival and site fidelity of individuals from the sampling area (thus, emigration and death are confounded), and detection probability (p) in the Comarck-Jolly-Seber open population model (CJS, Cormack, 1964; Jolly, 1965; Seber, 1965) in Program MARK (White and Burnham, 1999).

I fit four models on the data: a constant model, which considers no variation on Φ and p , and three other models considering season (dry versus wet season) as a temporal covariate on one or both parameters. I used the Akaike Information Criterion adjusted for small sample sizes (AICc, Burnham and Anderson, 2002) to select and rank models. The AIC ranks models based on

the fit and on the number of parameters of each model. The model with the lowest AICc is the most parsimonious conditional on the data set (Burnham and Anderson, 2002).

After that, I calculated the return rate, which is defined as:

$$\sum_i^r (m_{i+1}/R_i)/n \text{ (Martin et al., 1995)}$$

where R_i is the number of new individuals marked plus the number of individuals resighted in occasion i , m_{i+1} represents the number of individuals resighted on occasion $i + 1$, and n is the number of field occasions (see Martin et al., 1995 and references therein). I calculated monthly return rates and then averaged within seasons to obtain estimates for both dry and wet seasons. Finally, I compare the estimates that unaccount for detectability (the return rates) with the apparent survival probability, which accounts for detectability.

Sampling effort and bias

Here I set up two hypothetical situations, one called “dry season” and the other called “wet season”. Each situation was composed by an estimate of detection probability, obtained in the torrent frog population and used here, and an estimate of survival probability. Since no variation of survival probability was found between the dry and the wet season in the torrent frog population (see results), I chose two different but close values of apparent survival probability, similar to those obtained for the torrent frog population. Thus, the situation called “dry season”, had detection probability of 0.05 and apparent survival probability of 0.95. In the second situation, “wet season”, detection probability was 0.14 and apparent survival was 0.90. I considered these values the truth for my hypothetical population.

For each situation, I simulated 16 scenarios, representing four different sampling efforts (15, 30, 45 and 60 field occasions) and four different numbers of individual captures in the first

occasion (5, 10, 15 and 20 individuals) in all combinations. I set up the simulations in program MARK, using the CJS model. On each of the 32 scenarios (16 for each situation), I ran 500 simulations. The simulations were based on Bernoulli trials, where the probability of getting k successes (in this case the probability of surviving) is given by the Binomial probability function:

$$\Pr(k|n, p) = f(k| n, p) = \binom{n}{k} p^k (1 - p)^{n-k}$$

where n is the number of surveys and p is the probability of detecting the individuals. To keep a simple design, I based all simulations on the constant model $\{\Phi(.)\, p(.)\}$, which means constant apparent survival and detection probabilities through time and space. To present the results, I calculated the relative number of simulations that presented survival estimates below the true value given by the wet and the dry scenarios.

Optimum number of surveys

In this simulation routine, I fixed the number of initial releases at 10, which means that 10 individuals were captured, marked and released in the population in the first occasion. In the following occasions, based on specific survival probability estimates, I caught/marketed/released new individuals so that a similar number of marks was always present in the population. Then I made different combinations of the fixed number of initial releases with nine different parameter values of apparent survival (from 0.1 to 0.9) and nine different parameter values of detection probability (from 0.1 to 0.9) in all possible combinations, to establish 81 scenarios.

To make the results comparable, I used the coefficient of variation, defined as the standard deviation of a population mean divided by the mean estimate of a population parameter $CV=\sigma/\mu$ (Thompson, 2012). I adopted a CV of 0.15 or 15% as goal. The coefficient of variation is

a useful metric, since it provides a measure of relative precision, which is comparable among studies (Thompson, 2012).

RESULTS

Survival probability and return rates in the torrent frog, Hylodes asper

A total of 220 adult individuals were captured during the study period. The model that included season as a temporal covariate on Φ and p ranked highly and had 0.99 of the AICc weight (Table 1). The constant model, with time constant on survival and detection probabilities had no support (ΔAICc of 29.47, Table 1). Detection probability in the wet season was 0.14 (95% CI 0.10-0.18) and was higher than in the dry season, 0.05 (95% CI 0.03-0.07). Point estimates of apparent monthly survival were about three times higher than return rates in both seasons (Fig. 1).

Sampling effort and bias

Among the 32 different simulated conditions, dry- and wet-season scenarios suggested gradual improvements with increased effort (Fig. 2). Simulations with 15 occasions performed poorly, with about 50% of the simulations resulting in biased apparent survival estimates, independent of the number of individuals initially released. With a 4-fold increase in the effort (60 occasions), the estimator underestimated 8.2% and 14.8% of the simulations in the dry and wet seasons, respectively. The larger the number of initial releases, the better the results achieved.

Optimum number of surveys

If survival probability is high (> 0.8), the investigator will need a few visits in the field, even if detection probability is low (< 0.3 , Table 1). Considering apparent survival and detection probabilities of 0.9, the investigator will need only two occasions of effort in the field (Table 2), the minimum necessary for a mark-recapture study. However, when survival and detection are very low, close to 0.1, it will be necessary to increase the effort by at least 3 orders of magnitude to achieve the goal of 15% coefficient of variation (Table 1).

DISCUSSION

In this paper, I revisited detection probability in an attempt to reinforce the importance of considering the issue. Addressing detectability in wildlife studies is unavoidable if we want to draw more accurate conclusions about the studied systems. Below, I discuss each section of this paper and important topics in each.

*Survival probability and return rates in the torrent frog, *Hylobates asper**

Detection probability differed between the two seasons and was low, which is generally common in complex systems and occurs in different taxa (Ruiz-Gutierrez and Zipkin, 2011; Kajin and Grelle, 2012; Maritz and Alexander, 2012). Point estimates of monthly apparent survival probability for dry and wet seasons were high and very similar here. These estimates, may be plausible since they represent monthly survival, and may reflect the species' life history where individuals can live up to 3 years (Pato and Pie, 2001).

The return rates were lower than the estimates of apparent survival and the discrepancy usually occurs because return rates are uncorrected and confounded counts between survival and

detectability that assume constant or complete detection, disregarding any variation in space and time (Lebreton et al., 1993; Martin et al., 1995; Anderson, 2001). Despite the clear problem in using return rates, several articles, including, for instance, those comparing effects of marking techniques in amphibians (McCarthy and Parris, 2004), have based conclusions on return rates. Such estimates are generally biased low, leading to wrong answers and possible erroneous conservation decisions.

Sampling effort and bias

I showed simulation scenarios that could represent many amphibian and reptile populations, which are characterized by high survival and low detection (Parker and Plummer, 1987). Using different combinations of survey schemes and effort, my results emphasize the importance of improving the detection process (i.e., increasing the detection probability) and obtaining large sample sizes. I kept simulations simple for demonstration purposes here, assuming no variation on each parameter. However, the literature shows that constancy is rarely achieved (Schmidt, 2003; Bailey et al., 2004a; Mazerolle et al., 2007; Schmidt and Pellet, 2010; Willson et al., 2011), and parameters fluctuate over time and space. Thus, one possible challenge is gathering data for amphibians and reptiles given their secretive life histories. The investigator must struggle to get good quality data of the target species whatsoever, always concerned in maximizing detectability.

Optimum number of surveys

My goal here was to provide investigators the optimum number of surveys, which could be site visits or number of transects, necessary in the field, given specific population parameters

in order to achieve 15% of coefficient of variation. Although the results obtained here may be applied for different populations and species, each field survey may have a different cost and the investigator should be warned that achieving the conditions exemplified here might vary among systems.

Sometimes the level of effort necessary to achieve good precision may not be even possible. Thus, when dealing with an organism with low survival probability (<0.4) the investigator will probably need to redesign the study such that the survival probability that will be estimated is higher (>0.5). Besides that, the investigator will also need to ensure that detection probability is also around 0.5. A population with parameter values like those above cited may require multiple consecutive days/visits of effort.

Another key factor for the success of the study lies on the sample size. For simulation purposes here, I fixed the number of individuals captured in the first occasion; however, this is barely true in real studies dealing with amphibians and reptiles, since the number of captures usually does not represent the unit effort. More common measures of effort are time-constrained surveys, number of traps, transects and so on. Less effort will be necessary when detection probability is high, close to 1. However, low estimates of detectability will demand high sampling effort (MacKenzie et al., 2006).

Considerations and recommendations

Planning and designing the sampling scheme is a key step for the success of the study (Yoccoz et al., 2001), but unfortunately this is seldom done. Different approaches are available to incorporate detection probability in the sampling design. The multiple-observer sampling and the double sampling ratio estimator are two methods that encompass detection in design-based

studies. In model-based approaches, methods such as radio telemetry and distance sampling also account for detection (Thompson, 2012). Mark-recapture is another powerful technique used intensively in the wildlife for many decades to obtain robust estimates of detection, and other parameters of interest.

Detectability varies with field methods and populations, which means that even when applying searching standard methods, such as constrained searches by time or area, detection will vary (Mazerolle et al., 2007; Schmidt and Pellet, 2010). Tropical systems, such as rain forests, are generally characterized by high diversity and high complexity which may decrease detection when compared to simpler systems, where detection may be higher for small and elusive taxa such as amphibians and reptiles (Willson et al., 2011) and other groups (Ruiz-Gutierrez and Zipkin, 2011; Kajin and Grelle, 2012). Also, the use of temporal, spatial, and individual covariates may help to improve the estimates, and consequently all other parameters in the study (Williams et al., 2002). Detectability may be improved by increasing the number of site visits, as cited above, and trained observers. Besides that, increasing the number of traps and/or reducing the sampling area may also help.

The use of raw counts might be valuable if proved that detection does not vary over time and samples, as well as observers. In this case indices could be useful in monitoring population relative changes, such as abundance. However, detection is usually influenced by all these factors, and the use of raw counts is generally unadvisable (Anderson, 2001), since the proportion of variance explained by the raw counts can be very low (Pellet et al., 2007; Schmidt and Pellet, 2010). In all cases, estimates incorporating detection probability outperform raw counts (Schmidt and Pellet, 2010).

Imperfect detection is composed of two elements, easily discernible in theory, but not in practice (Schmidt and Pellet, 2010). To be detected, an individual must be available to be detected and must be found by the observer. If the population is closed and all individuals are available for detection, then availability is not a problem. However, sometimes individuals are not available because they have temporarily left the study site or because they are crossing a larger area and are captured just once, when crossing the study site, being characterized as transient individuals. Other times, such unavailability may be caused by inherent biology of the target species (e.g. females that are present in a breeding pond for only a few days). Unavailability may also be caused by weak study design when, for example, the investigator searches for the target species in different time or uses wrong capture method. Both transient individuals and temporary immigrants can be estimated using mark-recapture and other methods (see Schmidt and Pellet, 2010).

With a vast literature warning about the problem of unaccounted detection probability, why do researchers still rely upon indices, return rates, and trap rates? Mazerolle et al. (2007) and Schmidt and Pellet (2010) argue that investigators may be reticent to adopt a better approach because of misleading reasons, such as costly (energy, time and money) methodologies, unrealistic assumptions, no need to account for detection (since the investigator assumes his experience, and the fact that detection does not vary make this trait negligible), and that the use of standardized searching methods will make detection constant. Although this problem is not exclusive to herpetology, different solutions are available and imprecise corrected estimates are preferable to biased ones. Less costly methodologies such as distance sampling and occupancy modeling are good alternatives to mark-recapture (xxxx) allowing for robust estimates and reasonable assumptions that account for detectability.

I suggest researchers address detection probability. Also, thinking hard about hypotheses and predictions, pilot studies, power analysis and simulations are great tools that will assist and improve the sampling design in order to get estimates and reduce heterogeneity (Lebreton et al., 1993; Anderson, 2001; Anderson, 2008; Schmidt and Pellet, 2010). If uncorrected estimates are relied upon for population trends and dynamics, biased conclusions may lead to poor management and conservation decisions.

ACKNOWLEDGMENTS

I thank Eduardo Martins, Gonçalo Ferraz and Larissa Bailey for valuable suggestions and critical review. Paul Doherty and the Superpopulation 113 provided insightful comments on earlier drafts. Marcio Martins, Marília Gaiarsa and Laura Alencar gently provided the data of the torrent frog. Marília Gaiarsa also provided fruitful comments on the torrent frog system. The author was supported by CNPq (processo 140684/2009-3) with a fellowship during graduate school and by CAPES (processo 2296/11-0) during a long-term visit to Colorado State University.

Abstract. Amphibians have been declining worldwide and the comprehension of the threats they face could be improved using mark-recapture studies to estimate vital rates of natural populations. Recently the consequences of marking amphibians have been under discussion and the effects of toe clipping, the most common technique for amphibian individualization, on survival are debatable. The passive integrated transponder (PIT tagging) is an alternative technique, but there has been no comparison between toe clipping and PIT tagging for free ranging populations. We compared these two marking methods using mark-recapture models to estimate apparent survival and recapture probability of a neotropical population of the blacksmith tree frog, *Hypsiboas faber*. We tested the effects of marking method and number of toe pads removed, while controlling for sex and rainfall. Survival was similar between toe-clipped and PIT-tagged frogs and did not vary by sex. Sex was the best predictor for recapture probability, with males being nearly five times more likely to be recaptured. In conclusion, we (i) recommend the use of covariates to better understand the effects of marking methods on frogs, and (ii) suggest the use of toe clipping, given the lack of comparisons with other alternative marking methods in the literature and logistical and cost issues associated with PIT tagging.

Key words: *amphibians; detection probability; Hylidae; mark-recapture; multi-model inference, return rate.*

INTRODUCTION

With the current scenario of amphibian declines (Stuart et al., 2004), quantitative links between vital rates and explanatory covariates are fundamental to understand the dynamics of, and threats to populations (Biek et al., 2002). Among different strategies used to infer vital rates, mark-recapture constitutes an important tool, providing accurate information on population trends and demographic estimates (Manly et al., 2005) especially when population dynamics are poorly understood, such as occurs in the neotropics (Hiert et al., 2012).

Although field biologists strive to apply the least harmful marking technique to their study species, most techniques remain invasive and may affect behavior and survival (Lemckert, 1996; Bloch and Irschick, 2004; Schmidt and Schwarzkopf, 2010). Among the different methods used to mark anurans (Donelly et al., 1994), the most common is the toe clipping (Bogert, 1947), which consists of removing different combinations of digits to give individuals a permanent mark.

However, the scientific community has recently been debating the impacts of marking individuals, especially toe clipping, with divergent opinions (May, 2004; Funk et al., 2005; Corrêa et al., 2013). Several recent papers have related the number of toes clipped to individual response of amphibians, including lower return or survival rates (Parris and McCarthy, 2001; McCarthy and Parris, 2004; Waddle et al., 2008). Although more research evaluating such impacts is needed, novel methods have been proposed to replace toe clipping but they remain to be tested (Brown, 1997; Hoffmann et al., 2008; Campbell et al., 2009, Kenyon et al., 2009).

The passive integrated transponder (PIT tag) is one such alternative to toe clipping, which consists of a glass-encapsulated electromagnetic coil with a unique alphanumeric code that is lodged under the skin or in the body cavity of an animal and read by a handheld scanner

(Gibbons and Andrews, 2004). Because of its low cost and the possibility to mark an unlimited number of individuals, PIT tags have been used in anurans as an alternative marking method (Christy, 1996; Jehle and Hödl, 1998). Nevertheless, negative effects on frog survival have already been reported (Scherer et al., 2005) and little is known on the impacts of PIT tags on anurans (e.g. Christy, 1996; Brown, 1997; Phillot et al., 2008). Behavioral and physiological deleterious effects from the injection of the tag may occur and frog response might be different from toe clipping. Overall, direct comparisons between different marking techniques are still lacking.

Another issue for studies that have attempted to quantify the effects of marking methods on frogs is the absence of statistical power, especially by toe clipping (Schmidt, 2003). Furthermore, past studies have been based on the return rate to infer survival (e.g. McCarthy and Parris, 2004), which consists of the proportion of marked individuals recaptured at least in one occasion (Lebreton et al., 1992). The return rate assumes a constant detection probability, which is unrealistic in natural systems, due to heterogeneity in behavior (e.g. between sexes) and climatic conditions, such as rainfall, which influences amphibian activity (Duellman, 1986). Despite the number of studies reporting decreased return rates with increasing number of toes removed, only a few studies have assessed the issue accounting for detection probability, which is likely less than one (e.g. Waddle et al., 2008; Grafe et al., 2011). Waddle et al. (2008) found different recapture probabilities for individuals with two, three and four toes removed in the squirrel treefrog, *Hyla squirella*, but survival was similar among the groups. The use of return rate in this case would lead to the erroneous conclusion that toe clipping reduces survival.

Here we contrasted the effects of toe clipping and PIT tagging on a free ranging neotropical tree frog population using mark-recapture models, which allowed us to disentangle

survival and recapture probabilities (Schmidt, 2003; Waddle et al., 2008). We specifically compared survival and recapture probabilities between marking techniques, while controlling for sex differences and climatic variability in rainfall. We hypothesized that individuals marked with PIT tags will present lower survival than individuals marked with toe clipping, and that the removal of more toes will linearly decrease individual survival.

METHODS

Study site and study species

We conducted this study in a 970-square meter permanent pond in Estação Ecológica de Jataí ($21^{\circ}30' S$, $21^{\circ}40' W$), a conservation unit in the state of São Paulo, southeastern Brazil. The unit is located in a transitional area between the Atlantic Forest and the Cerrado biomes, composed of open grassy areas and semi-deciduous forests. Average temperature in the coldest months (June to August) is about $11^{\circ} C$, and about $30^{\circ} C$ in the hottest months (December to February). Annual rainfall is about 1500 mm. Precipitation during the rainy season (October to March) typically exceeds 270 mm per month, but does not exceed 27 mm per month during the dry season (April to September) (CEPAGRI, 2011).

We sampled an adult population of the blacksmith tree frog *Hypsiboas faber* (Anura, Hylidae) (Fig. 1), a large tree frog (snout-vent length = 92.3 ± 4.8 mm, N = 305; this population) distributed from northern Argentina to eastern Brazil (Martins, 1993). Males of this species occupy a pond and build nests at the beginning of the breeding season (generally from October to March; pers. obs), then begin to vocalize until a female approaches to inspect the nest. Males usually do not spend the whole reproductive season at the breeding site (Martins, 1993); females visit ponds only long enough to oviposit in the breeding site before leaving (Martins, 1993).

Data collection

We collected data during two reproductive seasons, from November to March, in 2010-2011 and 2011-2012. We captured individuals during three nights per month and pooled nights within the same month together, resulting in 10 sampling occasions, five on each breeding season. On each capture occasion, three researchers systematically walked inside and in the margins of the pond capturing adult individuals by hand based on visual and acoustic cues in all accessible microhabitats.

We determined sex and randomly assigned one type of marking method to each individual, toe clipping or PIT tagging. We placed individuals in four different groups: group one (one toe clipped), group two (two toes clipped), group three (three toes clipped) and group four (PIT tag). We marked individuals in the toe clipping groups starting with the removal of one toe. When all combinations for removing one toe were used, we started removing two toes in unique combinations, and finally, three toe removal combinations, clipping up to two toes per limb. This sampling design generates uneven toe pad removal groups over the study period (see Grafe et al., 2010), which we accounted for by including a linear trend model in the parameter estimates (see Statistical analysis).

We adapted the marking method of Waichman (1992), removing only the toe pad ("toe tipping", *sensu* Phillot et al., 2007), which is enough for individual recognition as tissue regeneration is rarely observed (Luddecke and Amézquita, 1999; Phillot et al., 2007, Grafe et al., 2011). The PIT-tagging group received a 2.2 mm x 12.2 mm, 0.5 g internal transponder (Animall Tag company) implanted in a posterior laterally-dorsum position, using sterilized needles and followed by the use of surgical glue to help healing. The mass ratio PIT tag/tree frog never

reached 0.5%. To control for possible effects of the glue, all individuals from the toe clipping groups also received the same amount of glue on the same local.

The effects of marking technique and number of toes removed were assessed in three different ways: (i) by comparing the survival on individuals with one, two, three toe pads clipped and PIT tagged (hereafter ‘group effects’); (ii) by comparing the effects of toe pad clipping against PIT tagging, where we combined groups one, two and three and compared to group four (hereafter ‘marking method effects’); and finally (iii) by forcing a linear trend effect only on toe clipped groups (hereafter ‘linear trend effect’), to test the hypothesis that removal of more toes decreased survival. In addition, the inclusion of a linear trend in the recapture probability was used to account for the uneven toe pad removal groups over the study. Although the linear trend was applied only on the toe clipped groups, the PIT tag group was also included in the analysis. Sex was included in each analysis as an individual covariate. Total monthly rainfall during sampling periods was also included as a temporal covariate in both parameters in order to accommodate weather variability in the models (Table 1).

Statistical analysis

We obtained maximum likelihood parameter estimates using a Cormack-Jolly-Seber (CJS) model (Cormack, 1964; Jolly, 1965; Seber, 1965) in Program MARK (White and Burnham, 1999). The CJS model estimates the parameters apparent survival probability (Φ), which is a combination of true survival and site fidelity, and recapture probability (p). We constructed 577 different models representing hypotheses about the effects of marking methods, time, sex and rainfall, using the strategy proposed by Doherty et al. (2010) to run all possible

additive combinations of factors, except for combinations that did not make logical sense (e.g., different representations of marking effects, or temporal covariates and time effects in the same model).

Goodness-of-fit and a variance inflation factor (i.e., median \hat{c}) were assessed using the general model ($\Phi_{\text{group+time}} p_{\text{group+time}}$). We selected and ranked models using Akaike Information Criterion (Akaike, 1973) adjusted for small sample sizes (AICc, Burnham and Anderson, 2002). Survival and recapture probabilities were model averaged using all models, in order to include uncertainty in model selection (Burnham and Anderson, 2002). We then calculated the relative importance of each covariate through the cumulative AICc weights (Doherty et al., 2010) in order to determine the important covariates for each parameter. Following Barbieri and Berger (2004) we considered covariates with cumulative AICc weight above 0.5 to be important.

RESULTS

In group one (one toe clipped) we marked 14 males and four females, in group two (two toes clipped) 110 males and 40 females, in group three (three toes clipped) 120 males and 30 females, and in group four (PIT tag) 177 males and 50 females. We recaptured 117 out of 545 individuals at least once. The goodness-of-fit test showed no problem with transient individuals or trap dependence effects and no extra binomial variation was detected ($\hat{c} = 0.96$).

The top model (AICc weight = 0.05) included constant apparent survival among groups and detection probability varying as an additive effect of linear trend on toe clipped groups, time variation and sex. However, many models had similar AICc weights, with considerable model selection uncertainty (Table 2). Considering all models averaged, apparent monthly survival

probability was very similar among the four marking techniques and sexes (Fig. 2), with none of the covariates having an important effect on apparent survival probability (Table 3), highlighting the importance of the constant survival among groups.

The best covariates predicting the recapture probability were sex and time (Table 3). Males presented higher averaged recapture probability than did females (Fig. 3), but no difference was detected among groups one, two, and three (toe clipped groups) when compared to group four (PIT tag). Groups presented monthly recapture estimates from 0.12 to 0.39.

DISCUSSION

Our first hypothesis relating lower survival for PIT tagged individuals was not corroborated, since the apparent survival probability did not differ among groups and sexes. We also hypothesized that more toes clipped would reduce survival in toe clipped individuals, but no correlation between survival and the number of toes clipped was found. Based on the cumulative AICc weights, none of the covariates had a strong effect on the apparent survival probability in our model set. Two out of six covariates were important in describing the variation on the recapture probability. The most important was sex, which carried out the most cumulative AICc weight.

As mentioned before, males and females *H. faber* present clear behavioral differences (Duellman, 1986; Martins and Haddad, 1988; Martins 1993). Because females are more mobile, their recapture probabilities were lower, which indicates that pooling the sexes in the analysis would lead to biased results. Besides, if we had considered just the return rate as a survival estimate, estimates would be biased low (0.39 and 0.17, averaged among groups) for males and

females, respectively, leading to erroneous conclusions. As noted before, biased results may be obtained if not correctly accounting for the probability of detection (Mazzerole et al., 2005).

Effects of time were important on recapture probability. The substitution of individuals in the pond could account for this trend, since individuals stay at the breeding site for a limited amount of time, being substituted by new ones throughout the breeding season (Martins, 1993). Such permanent emigration will likely bias survival estimates low, since estimates of apparent survival are a product of true survival and site fidelity. In this study, groups presented similar apparent survival estimates, showing that emigration rates may be similar among groups. Accounting for permanent emigration in the field includes the use of radio telemetry and known fate models where fates of all marked individuals are known (Williams et al., 2002). On the other hand, if individuals of the population leave the site temporarily, the robust design approach is a good alternative to account for temporary emigration (Pollock, 1982; Kendall et al., 1997).

We included rainfall in the models as an attempt to account for the weather variability, since amphibians present a strict relation to water availability. However, in this study rainfall did not come up as an important covariate. Then, the substitution of individuals in the pond highlights the importance of considering time variation effects in the model set, besides other related covariates, whenever possible.

Invasive marking methods can cause negative effects for individuals, and toe clipping is a stressor for amphibians when compared to handling only (Narayan et al., 2011). Other studies have already reported negative or neutral effects of toe clipping on frog survival and capturing (Lemckert, 1996; Van Gelder and Strijbosch, 1996; McCarthy and Parris, 2004; Hartel and Nemes, 2006; Liner and Smith, 2007; Schmidt and Schwarzkopf, 2010; Grafe et al., 2011). In our study, the removal of toe pads was quicker than marking with the PIT tag, and bleeding usually

did not occur. The application of the PIT tag took from two to four times longer (pers. obs.), and possibly increased handling stress. Many males, especially from toe clipped groups, were seen in normal reproductive activities right after being manipulated and no inflammation was observed. Phillott et al. (2011) reported that 1.3% of individuals of four hylid species genus *Litoria* and *Nyctimystes* presented toe inflammation, which may suggests that toe clipping could be a safe method for marking hylids. Stress response should be included as an important trait to be measured in individuals, but few studies considered this characteristic when testing the impacts of different invasive marking techniques on amphibians.

However, despite its low cost and ease of use, the number of individuals to be marked using toe clipping is limited. In our study we failed to find evidence of toe regeneration, but in case it occurs, as described by Hoffmann et al. (2008), the important mark-recapture assumption of not losing the marks in the population will be violated, biasing survival estimates low (Lebreton et al., 1992; Williams et al., 2002). The use of PIT tag is not as common as toe clipping, but may be a reliable method and has not generally been demonstrated to cause serious problems for tagged anurans, such as detrimental effects on body condition or mortality (Christy, 1996; Brown, 1997; Jehle and Hodl, 1998; McAllister et al., 2004; but see Scherer et al., 2005). However, PIT tagging is more costly, increases handling time, requires more skill from the researcher to use, and may be unfeasible in small frogs. In addition, even being considered a permanent marking method (Gibbons and Andrews, 2004), PIT tags could be expelled from (Roark and Dorcas, 2000) or migrate to another location in the body (Tracy et al., 2011) causing tag loss.

In general, studies looking at the impacts of different marking methods on vital rates of wild populations are scarce. Works comparing toe clipping and PIT tagging have shown similar

effects on survival and growth rates of salamanders (Ott and Scott, 1999) and free-living naked mole rats (Braude and Ciszek, 1998). It is also important to note that the effects of marking methods vary by species, reproductive strategies, habitats (e.g. arboreal vs. fossorial), and behaviors (Liner and Smith, 2007). Frog species will respond in different ways to marking and investigators must consider the characteristics of each species, as well as the use of the most practical and least harmful method, evaluating all methods together, as suggested by Phillot et al. (2008). Additionally, we recommend using different temporal and individual covariates, depending on the motivation for the study, otherwise the results of the analysis may be biased.

Estimating the survival probability of a control group of non-marked individuals in the field would be ideal, as we did not have comparisons to survival of individuals that were not treated. Digital photography may be the best marking technique that might approach the condition of a control group for free ranging populations, but it also presents problems, like identifiable characteristics on the target species and obtaining good quality pictures without disturbing individuals. Controlled laboratory experiments may be useful for the inclusion of a non-marked group, for comparing survival (e.g. looking for inflammation) and for allowing estimation of tag loss (Brown, 1997). However, laboratory experiments are not a good solution to observe the effects of marking on species interactions (e.g. predation, competition) as well as the effects of weather variability on marked individuals.

In summary, both marking techniques tested performed equally well, with individuals showing similar survival responses. Thus, given the lack of comparisons among alternative marking techniques in the literature (e.g. visible implanted elastomer-VIE, natural marks), and logistical issues, such as budget and processing time, we recommend the use of toe clipping instead of PIT tagging.

TABLES

Table 1. Model notation and definition for the parameters apparent survival (Φ) and recapture probability (p).

Model notation	Notation definition
(.)	parameter is constant
(t)	parameter varies with time
(g)	parameter varies with groups
(sex)	parameter varies with sex
(rain)	parameter varies with rainfall
(toe_chip)	parameter varies by marking method
(toe_lin)	parameter varies with linear trend effect on toe clipping

Table 2. Top 15 models of the candidate model set. AICc=Akaike's information criteria with small sample size correction, ΔAICc =difference between top model and the current model, w_i =AICc weights, K =number of parameters, Deviance=difference of the current model and the saturated model.

Model	AICc	ΔAICc	w_i	K	Deviance
Phi(.) p (toe_lin+time+sex)	847.40	0	0.05	12	822.90
Phi(.) p (toe_chip+time+sex)	847.71	0.31	0.04	12	823.22

ABSTRACT. Knowledge about many snake species' vital rates is lacking because of the difficulty in data collection. To provide guidelines for conservation efforts, we used a robust design mark-recapture model to estimate survival, behavioral effects on capture probability, temporary emigration, abundance and population growth rate for the golden lancehead pitviper, *Bothrops insularis*, an endemic and endangered species from southeastern Brazil. We collected data irregularly over ten occasions from 2002 to 2010. Annual survival was low and slightly positively correlated with average temperature. No behavioral effects were detected on capture probability. Temporal emigration was high, indicating the importance of accounting for this parameter both in the sampling design and modeling. On average, the population increased 9% per year during the study fluctuating between periods of increase and decrease, which might be attributed to natural oscillations, although illegal trade may also be responsible for declines.

Key words: endangered species, Huggins Closed Capture model, imperfect detection, pitviper population dynamics.

INTRODUCTION

In the last decades efforts to understand and preserve natural populations have increased because diseases, climate change, and other human-induced threats have become more pervasive (Sala et al., 2000). Despite such efforts, information on the life history of most taxonomic groups is still lacking. This knowledge deficiency not only results in poor understanding of the impacts of anthropogenic and non-anthropogenic stressors, but also in possibly poor management actions (Greene, 2005).

Snake populations have been suffering great impacts and declines around the world (Gibbons et al., 2000; Reading et al., 2010; Bohm et al., 2013). For many decades, this group was thought to be difficult to study in the field and partly because of their natural history characteristics, which includes elusive habits, cryptic behaviors, and low densities (Parker and Plummer, 1987; Dorcas and Willson, 2009). Furthermore, habitat heterogeneity and complexity of some systems make species difficult to find and study. As a consequence, most information on snake population biology is anecdotal and characterized by basic descriptions of vital rates and relative abundance indices (Parker and Plummer, 1987). Robust quantitative estimates of population vital rates, such as survival, are generally difficult to obtain (Dorcas and Willson, 2009).

When considering studies that account for detection probability in the estimation of vital statistics, the scarcity of reliable information is even greater. Fortunately, in the last decade there has been a growing number of field studies and application of novel analytical techniques leading to robust estimates (Schmidt, 2003; Altwegg et al., 2005; Mazerolle et al., 2007; Dorcas and Willson, 2009; Christy et al., 2010; Durso et al., 2011; Breininger et al., 2012; Hyslop et al., 2012; Maritz and Alexander, 2012; Prival and Schroff, 2012). The improvement of detection

probability through good sampling designs and explanatory covariates (Parker and Plummer, 1987; Hyslop et al., 2012) is important because it will provide support for the evaluation of all other parameters, increasing precision and accuracy (Pollock et al., 1990). This, in turn, will enable effective guidelines for management actions on population dynamics to be implemented (Dorcas and Willson, 2009; Breininger et al., 2012).

In the face of the difficulty of sampling elusive species, model-based approaches are valuable tools that help improve quality of population ecology studies. Mark-recapture is a well-known technique used for the assessment of important population estimates such as survival and transition probabilities. Additionally, mark-recapture allows the estimation of temporary emigration, an important parameter that influences vital rates (Kendall et al., 1997) and whose effects on snake populations are still unknown (Parker and Plummer, 1987; Dorcas and Willson, 2009). Similarly, behavioral effects of marking individuals are still undescribed for snakes and should be investigated since marking techniques may disturb individuals.

As an attempt to further advance the knowledge of Neotropical snake population ecology, we sampled the population of the insular and endemic golden lancehead pitviper, *Bothrops insularis* (Fig. 1), a critically endangered species (IUCN, 2012). The golden lancehead is a semi-arboreal, medium-sized pitviper with ambush behavior that feeds upon migratory passerine birds as adults (Martins et al., 2001; Marques et al., 2002; Marques et al., 2012). *Bothrops insularis* is mostly diurnal, but presents nocturnal activity as well (Marques et al., 2002). In 2008, Martins et al. (2008) raised a concern about population decline based on raw counts and suspicion of illegal trading. Here, for the first time we provide estimates of survival, behavioral effects on detection probability, temporary emigration, abundance and growth estimates for *B. insularis*.

METHODS

Study site

Bothrops insularis is restricted to the Queimada Grande Island ($24^{\circ} 29' S$, $46^{\circ} 40' W$), a small island (~ 43 ha) about 30 km south off the coast of São Paulo state, southeastern Brazil. The island consists of bare rocky areas, open grassy areas and lowland rainforest, which covers approximately 60% of the entire island, and is the habitat of the target species (Martins et al., 2008). Altitudinal variation in the island ranges from 0 to 200 m above sea level (Martins et al., 2008). The climate is subtropical with two prominent seasons; one rainy and warm (October to March) and the other dry and cold (April to September). Relative air humidity is always higher than 90%. The island serves as an important migration route for birds, which use the island to rest and feed and are preyed upon by the snakes (Marques et al., 2012).

Data collection

We used visual encounter surveys (VES) on each sampling occasion, where four to six trained observers searched for snakes on the ground and on the trees, during daylight, in a single 1370 x 3-meters linear transect that crosses the island in the north-south direction. Due to weather and logistical restrictions, we visited the island 10 times (primary sampling occasions) irregularly from 2002 to 2010 in different periods of the year. Each visit varied from two to four days (secondary sampling occasions), resulting in 28 sampling occasions (Table 1). Because our samples were composed almost entirely by adults (juveniles are difficult to spot in the field), we decided to restrict our analysis only to this age class (snout-vent length of mature males > 505 mm, and mature females > 555 mm; Marques et al., in press).

Each individual sighted was hand-captured and marked using passive integrated transponders (PIT tags) injected in the latero-posterior region of the body with sterilized needles. We obtained sex and measured the snout-vent length (SVL) of each individual using a flexible tape (to the nearest cm). Afterwards, we released the individuals at the same place we sighted them. We also measured monthly air temperature to include in the analysis since temperature predicts ectothermic's activity, even in subtropical regions (Gibbons and Semlitsch, 1987; Lillywhite, 1987).

Mark-recapture modeling

To estimate the population vital rates, we used the Huggins closed capture model, (Huggins 1989, 1991) in a robust design, to obtain maximum likelihood estimates of apparent survival probability (Φ), temporary emigration (γ), capture (p) and recapture probability (c) using program MARK (White and Burnham, 1999). We adjusted the time interval between visits because they were irregular.

The robust design incorporates aspects of closed models and open population models. In the former, the population is assumed to be biologically and geographically closed (neither births/deaths nor immigration/emigration are allowed) within primary sampling occasions and the model provides estimates of abundance and recapture probability. In the latter, the model relaxes the closure assumption between primary occasions and is used primarily to estimate survival (Pollock, 1982). The assumption of closure within each primary occasion is based on pitviper's biology, which are usually sedentary and sit-and-wait predators that remain in the same foraging and resting area for many days to weeks (Mushinsky, 1987; Sazima, 1992; Greene, 1997; pers.

obs. on radio-tagged *B. atrox* and *B. insularis*). Survival was assumed to be at or near 100% over the short period of the secondary sampling occasions.

Besides the estimation of Φ , which is a product of true survival and permanent emigration (thus, permanent emigration and death are confounded), one great advantage of the robust design is the estimation of temporary emigration, the animal movement that leads to temporary unavailability of individuals for capture in the sampling area (Kendall et al., 1997). Since open and closed models assume that all animals are always available for capture, failing to meet this assumption may bias the estimates (Kendall et al., 1997). Temporary emigration is provided by two parameters, γ^t and γ^r . The parameter γ^t represents the probability that an individual is a temporary emigrant on primary occasion t given it was alive and available for capture on primary occasion $t - 1$. The parameter γ^r represents the probability of an individual that was a temporary emigrant on primary occasion $t - 1$ remains as a temporary emigrant on primary occasion t . We used these parameters because we suspect that movement in and off the sampled area occurred during our study period.

The dissociation between capture (p) and recapture (c) probabilities allows for testing positive or negative behavioral responses to capturing and marking individuals (i.e., trap-shy and trap-happy effects, Nichols et al., 1984). Since we physically captured and marked individuals with PIT tags, the recapture probability could be lower (e.g., due to stress). Conversely, if $p = c$, no capture effect on behavior is assumed.

The Huggins closed capture robust design also provides an estimate of the population abundance for each primary occasion as a derived parameter, which means that the model does not contain abundance as an explicit parameter and calculates it based on the estimated capture

probabilities and obtained data. We used the estimates of the population abundance to obtain the finite population growth rate $\lambda = \bar{N}_{t+1}/\bar{N}_t$ for each one of the primary occasions of the study, where λ is a positive number that measures the proportional population increase/decrease from N_t to N_{t+1} . To obtain sampling variances and derive standard errors and confidence intervals for the estimated λ , we used the delta method (Powell, 2007).

We constrained each parameter to be a logit-linear function of individual and temporal covariates. We kept a simple parameterization and did not include time effects on parameters because we anticipated poor support for complex models due to our limited data set. We modeled survival as a function of sex (SEX) because we suspected of differences between males and females, and monthly air temperature (TEMP) because of ectothermic activity. We also included a model that considered apparent survival as constant over time (.). We tested for a random emigration pattern of movement among individuals ($\gamma^r=\gamma^d$), meaning individuals move on and off the study area randomly. Conversely, we tested for a first-order Markov process of emigration, where the state of the individual at $t - 1$ influences the state at t . For the detection process (capture and recapture probabilities) we tested for a positive effect of body size (snout-vent length, SVL), because larger snakes may be more detectable, monthly air temperature (TEMP), as well as no time variation (.).

We built 64 models representing hypotheses about the effects of the covariates on the parameters running all possible additive combinations of factors to obtain a balanced model set (Doherty et al., 2010). Our most parameterized model (i.e., the global model) assumed that apparent survival, initial capture probability and recapture probabilities were additive functions of temperature and sex, and allowed for Markovian time-constant temporary emigration,

$\varPhi(\text{temp+sex})$ $\gamma^r(\cdot)$ $\gamma^l(\cdot)$ $p(\text{temp+svl})$ $c(\text{temp+svl})$. We did not test for model fit, since the robust design has no standard goodness-of-fit test available. However, based on our experience about snake biology, we think we included important covariates for the parameters and we assume that the follow assumptions - same recapture probability within groups on $t+1$ and same survival probability within groups on $t+1$ - were respected.

We selected and ranked models using the principle of parsimony through the Akaike Information Criterion (Akaike, 1973) corrected for small sample sizes (AICc, Burnham and Anderson, 2002). Estimates were model averaged in order to include model uncertainty (Burnham and Anderson, 2002) and all parameters are reported with the 95% unconditional variance confidence intervals. We then calculated the relative importance of each covariate through the cumulative AICc weights (Burnham and Anderson, 2002). Following Berger and Barbieri (2004) we considered covariates with cumulative AICc weight > 0.5 to be important.

RESULTS

We marked 291 adult individuals (126 males, 165 females) and recaptured 46 of them at least once. In general, models presented similar weights resulting in high uncertainty in model selection (Table 2). Model averaged survival probability was slightly different among years based on temperature, but confidence intervals overlapped (Fig. 2). Air temperature had a marginal positive correlation with survival probability ($\beta_{\text{temp}} = 0.29$, CI = -0.04 - 0.62; cumulative AICc weight of 0.50; Table 3). Sex was uncorrelated with survival ($\beta_{\text{sex}} = 0.69$, CI = -0.6 - 2.0; cumulative AICc weight of 0.42; Table 3).

Model-averaged estimates suggested a slightly higher probability of being out of the study area (an emigrant) during period t if the individual was an emigrant during the previous period $t - 1$ ($\gamma^e \geq \gamma^n$), but the confidence intervals for these parameters overlapped (Fig. 3), and a random pattern of movement on and off the study area was most supported by the data (Table 2). Still, these estimates suggested there is a high probability that any marked snake may be outside of the sampled transect, and thus unavailable for detection, during a given sampling period.

Conditional on individuals being available for detection, the capture and recapture probabilities were constant and similar for all individuals and sampling occasions (Fig. 4), and therefore behavioral effects on recapturing individuals were not supported (Tables 2, 3). Similarly, air temperature and body size were not important predictors in the detection process, capture and recapture probabilities (Tables 2, 3).

The derived population abundance for the sampling area varied between sampling periods from 80 to 220 individuals (Table 4). From 2002 to 2010 the population showed an average annual finite population growth rate of 1.09 ranging from 0.4 to 2.1 (Fig. 5).

DISCUSSION

Shine and Charnov (1992) suggested a high survival pattern for viperids, although most previous estimates of survival for other viperids did not account for detection probability (Turner, 1977; Parker and Plummer, 1987; Shine and Charnov, 1992). We found that *B. insularis'* annual adult apparent survival was relatively low, ranging from 0.27 to 0.50, similar to another tropical viper, the African namaqua dwarf adder *Bitis schneideri* (Maritz and Alexander, 2012).

The low annual survival observed here may be best explained by individuals that were captured just once, being outside the study area in the next occasions. Similarly, illegal removal of individuals, suggested by Martins et al. (2008), could cause the same pattern, characterizing permanent emigration, since the estimation of apparent survival makes no distinction between true survival and permanent emigration (Lebreton et al., 1992). Alternatively, if the illegal trade targets the largest individuals of the population, fewer snakes survive long enough to reach higher age classes and thus, the population will present higher proportion of younger snakes (e.g., Prival and Schroff, 2012, study on *Crotalus pricei*). Body size is usually positively related with fecundity in reptiles, including snakes (Seigel and Ford, 1987), and if larger individuals are removed from the population, the average population fecundity could also decrease. Although it has been hypothesized that the study population has declined from the 1990's to the 2000's, our population growth estimates do not support this hypothesis (2002-2010; see below).

Another potential cause to be considered for the low apparent survival is prey availability. As adults, the golden lancehead preys upon usually only two out of 50 migratory birds that are seasonally present on the island (Marques et al., 2012). Food shortages may depend on weather stochasticity and dynamics of migratory bird movement. In contrast to its mainland sister species, *B. jararaca*, the golden lancehead breeds biannually and produces a low number of viable vitellogenic follicles (Marques et al., in press). Such seasonal prey availability may impose a trade off between reproduction and survival.

Temperature slightly positively correlated with survival, an expected pattern since reptile activity usually correlates with weather variability (Gibbons and Semlitsch, 1987). Temperature and other weather covariates such as rainfall may affect age classes of a population in different ways, but the role of weather on age classes of ectothermic population demography is almost

unknown. Altwegg et al. (2005) showed that survival was lower during harsh winters for juvenile asp vipers in Switzerland, but did not affect adults. The ability of finding shelter or the level of body fat reserves may be crucial to determine survival.

Differential activity and behavioral patterns would be expected for males and females with impacts on survival (Gibbons and Semlitsch, 1987). Due to mate search, males move longer distances and may be more exposed to predation (Gibbons and Semlitsch, 1987; Andersson, 1994), while females may present decreased survival after parturition, because of the high amount of energy expended (Madsen and Shine, 1992; Andersson, 1994). Models that allowed for sex-specific differences in apparent survival were not strongly supported by our data (Table 2 and 3), still among models that included this covariate, males had higher apparent survival probabilities than females. This same pattern has been reported in the literature for adult viper populations, such as the asp viper *Vipera aspis* (Altwegg et al., 2005) and non-viper snakes such as the indigo eastern snake *Drymarchon couperi* (Breininger et al., 2012). *Bothrops insularis* may be prey of four raptors on the island (Marques et al., 2012), and juvenile individuals may be more vulnerable. However, if predation is not a strong pressure for the adult population, as suggested by Marques et al. (2002), females would pay a higher final cost to grow and breed than males. Then, this prediction would lead to a higher survival probability for males.

For most snakes, the importance of temporary emigration remains unknown, since no other studies have estimated the probability of temporary emigration (Dorcas and Willson, 2009). Maritz and Alexander (2012) recognized the importance of temporary movement when studying the namaqua dwarf adder and used a simulation method to estimate emigration, but they did not explicitly incorporate the movement probability in the model likelihood or provide a measure of error.

Temporary emigration was high in this study (~ 0.70) showing a high random probability of movement on and off the study area among primary occasions. The randomness of movement demonstrates sampling did not disturb animals. Additionally, this high temporary emigration might result from the small proportion of habitat we sampled, although movement even for sedentary vertebrates, such as pitvipers, is expected at some point. Without accounting for temporary emigration when it exists, the study will suffer with imprecise parameter estimates (Kendal et al., 1997) and investigators should be aware of that. Even if local conditions may difficult the use of alternative sampling designs, such as in the Queimada Grande island (Martins et al., 2008), we recommend hard thinking and planning to account for variability (Thompson, 2004).

Brown et al. (2007) reported trap-shyness in the rattlesnake *Crotalus horridus*, where snakes abandoned their shelters and became less prone to be recaptured. Prival and Schroff (2012) suggested that capture might disturb *C. pricei* individuals. The low detectability (0.05) of the aquatic viperid *Agkistrodon piscivorus* was partly attributed to the capture method used (Durso et al., 2011). Field procedures, such as marking or examining for prey or pregnancy information may reduce subsequent detection probability by means of altering normal activity, home ranges and increasing individual stress levels. Here, behavioral effects were negligible (AICc cumulative weight was 0.40) showing the species may be indifferent to our manipulation. Nonetheless, we are unaware of the effects of marking juveniles. Also, populations may respond differently and thus information on natural history is essential for the use of any marking method.

We did not observe any effect of temperature on detection probability. Since survival was marginally correlated with temperature, the same pattern could be expected for detection. Bovo et al. (2010) found no correlation of postprandial or gravid snakes and thermoregulatory behavior in

B. insularis. Snakes on the island are found almost exclusively inside the forest (Martins et al., 2008). Although reptile activity is related to temperature (Pough et al., 2004), the forest might lessen the heat gains and losses, protecting individuals from extreme temperatures and windy conditions of the grassy areas.

Body size did not correlate with detection probability, differently from other snake population studies (Koops et al., 2009; Maritz and Alexander, 2012). Adults may move at similar rates and detection of adult *B. insularis* may be unrelated with body size since they are relatively large (500-800 mm snout-vent length) and pale yellowish to brownish cream. Such traits would reduce heterogeneity in detectability among adult individuals. On the other hand, we are aware that newborns and juveniles are harder to detect because of their small size, potential reduced movement and elusive behavior, which may generate detection probability estimates close to 0 (Christy et al., 2010).

Detection probability only applies to individuals with a non-zero probability of being detected (available to be detected), which lead us to conclude that we did not sight all individuals available. Because of life history traits, snakes are difficult to find in the field, and different studies report relatively variable and low detection probabilities (Altweig et al., 2005; Lind et al., 2005; Brown et al., 2007; Maritz and Alexander, 2012). *Bothrops insularis* occurs in relatively high densities (Marques et al., 2002) but detection, even with a relatively large and trained search team, was low. Christy et al. (2010) fenced a 5-ha area and obtained a detection probability estimate of 0.07 for the brown tree snake, *Boiga irregularis*. Similarities on habitat (tropical systems) and habit (arboreal) of both snakes, *B. insularis* and *B. irregularis* might preclude low detection since spotting individuals in 3-dimensional habitats could be challenging due to the complex architecture of the forest. Thus, we suggest reducing the studied area to the minimum

acceptable (depending on the species' biology), since detectability might be an inverse function of the size of the study area (Prival and Schroff, 2012), and also increase sampling effort as a strategy to increase detection in future studies.

We estimated that from 80 to 220 adult individuals were available to be captured on each primary occasion in the sampling area. The finite population growth rate of *B. insularis* was also variable among years, but on average we observed a slightly decrease in the abundance ($\lambda = 0.94$) across years. Understanding the elements that contribute for population dynamics may clarify such patterns and reveal trends, allowing for precise management actions. As suggested, prey availability may influence the population growth and individuals in low body condition were seen in the island with certain frequency (pers. obs.). Similarly, weather stochasticity can restrict snake activity, affecting physiological processes and increasing mortality.

Illegal trade and, less importantly, habitat reductions were hypothesized to be the potential causes for *B. insularis* decline from 1995 to 2007 (Martins et al., 2008). However, natural oscillations such as those cited above or detectability issues might mask a real trend (Parker and Plummer, 1987) making the distinction between a real and an apparent decline hard. Such hypothesis decline were based on raw counts made in plots and pointed to a population size of about 2000 individuals (Martins et al., 2008), besides that speculations in a previous study based on counts in the same transect we used here varied from 2000 to 4000 individuals (Marques et al., 2002). Nevertheless, due to the habitat heterogeneity in the island, we believe that extrapolation methods, as used before (Martins et al., 2008), would provide naïve estimates of population size. Regardless of the methods used to estimate *B. insularis* population size before, we should be cautious that severe natural or man-induced oscillations in a potential small population could drive it rapidly to an extinction threshold.

We presented here the first population rates for an endangered Neotropical pitviper. Since snakes are among the least studied vertebrates in relation to population ecology (IUCN, 2012) it will take some time until we reach a good comprehension about Neotropical systems and be able to make good predictions about snake population dynamics in these habitats. Despite the biological difficulties in searching for such an elusive vertebrate, we believe we have taken the first step towards understanding neotropical pitviper populations.

ABSTRACT. In many lizards, polygyny is the common mating system, and males guard females in order to prevent access of competitors. Males use biting as weapon and display status badges, in these guarding behaviors, presenting potential lower survival because of costs of reproduction. Females, in turn, take advantage of mate guarding presenting higher value as they grow. Here, we applied a mark-recapture study in the whiptail lizard to test for variations in male and female survival with respect to two important attributes for mating, head size and badge size, the latter defined here as the relative amount of bright coloration. Males with larger heads had lower survival than males with smaller heads, whereas female survival increased with head size. Badge size was not associated with survival of either males or females. We hypothesize that males with larger heads may be more vulnerable to sources of mortality, such as predation and fighting for females. On the other hand, females may become more attractive to males as they grow and hence survive better by benefitting from male guarding behavior.

Key words: mate guarding, mark-recapture, polygyny, sexual selection, survival probability.

INTRODUCTION

One of the most striking features of animal species is the frequent difference in morphology, physiology and behavior between males and females known as sexual dimorphism (Andersson, 1994). Different hypotheses have been proposed to explain the occurrence of sexual dimorphism, including sexual selection (Darwin, 1859), which is the evolution of characters that confers advantage to one sex, usually males, in competition for mates (Andersson, 1994; Emlen, 2008). Under sexual selection, female preference may drive male traits to levels of exaggeration that are costly to maintain (Cotton et al., 2004). These traits settle where sexual selection is balanced by natural selection, and under this assumption, a cost for displaying honest signals of quality (Zahavi and Zahavi, 1997) would be expected for males with possible effects on fitness components, such as survival.

Resource defense polygyny is the most common mating system in lizards (Pianka and Vitt, 2003; Calsbeek and Sinervo, 2008), and mate guarding is common in non-territorial lineages, such as the Teiidae family where males, by limiting the chances of other males, mate with females increasing their confidence of paternity (Censky, 1997; Ancona et al., 2010). Sexually dimorphic traits such as head shape and conspicuous coloration, commonly present in lizards, are usually honest signals attributed to reproductive success (Zahavi and Zahavi, 1997; Lopez et al., 2003; Whiting et al., 2003; Molnar et al., 2012).

Head width is a good predictor of dominance in staged encounters because it is influenced by muscle size, which predicts bite force (Herrel et al., 2001; Lappin and Hussak, 2005; Cox et al., 2007). Bite force, a measure of weapon performance, is positively correlated with reproductive output and males may present serious injuries from same-sex aggressive

competition, sometimes resulting in death (Cooper and Vitt, 2002; Lappin and Husak, 2005). Other costs are attributed to mate guarding such as reduced foraging time (Anderson, 1993).

The extent of the body covered by the conspicuous coloration, or badges-of-status size, has been related to dominance, aggressiveness, and mate acquisition in lizards (Pianka and Vitt, 2003; Whiting et al., 2003; Huyghe et al., 2005). On the other hand, nuptial color also brings costs to males (Clutton-Brock and Isvaran, 2007), attracting a predator's attention (Andersson, 1994; Stuart-Fox et al., 2003) exposing individuals to higher mortality, as in the guppy *Poecilia reticulata* (Godin and McDonough, 2003), or because males tend to behave more risky, as in the house sparrow *Passer domesticus* (Reyer et al., 1998). Badges may act as a proxy of male quality and are used to decide conflicts (reviewed in Whiting et al., 2003). Females, in turn, may benefit in the presence of a large male, with increased foraging time, reduction of harassment by single smaller males and lower predation (Anderson, 1994; Zaldívar-Rae and Drummond, 2007).

Although some papers suggest opposite survival estimates for males and females due to sexual selection, survival is usually inferred indirectly using some related measure, such as body condition or number of females in a territory (Sinervo and Lively, 1996). Mark-recapture methods allow for testing hypotheses and making direct inferences about how morphological traits such as weapons and ornaments are associated with vital rates, including survival, while accounting for detection probability (Lebreton et al., 1992).

In this work, we assessed the effects of head size and badge size in adult male and female survival of the teiid whiptail lizard, *Cnemidophorus* cf. *ocellifer*. We used mark-recapture models to test the hypothesis that males with larger heads and displaying more conspicuous coloration over the body have lower survival than smaller males and females, since the allocation of energy

for these traits and guarding females might have negative consequences to individuals, accumulating with age.

METHODS

Study site

We conducted the study in Estação Ecológica de Jataí ($21^{\circ}30' S$, $21^{\circ}40' W$), a conservation unit in the state of São Paulo, southeastern Brazil. The unit is located in a transitional area between the Atlantic forest and the Cerrado biomes, composed of open grassy areas and semi-deciduous forests. The area is characterized by an average temperature of $11^{\circ}C$ in the coldest months (June to August), and $30^{\circ}C$ in the hottest months (December to February). Annual rainfall is about 1500 mm, mostly concentrated in the rainy season (CEPAGRI, 2011).

Study species

We tested the proposed hypothesis using mark-recapture methods for a population of the Brazilian whiptail lizard, *Cnemidophorus* cf. *ocellifer* (Fig. 1). This is a small (30-78 mm snout-vent length in the study population), fast moving, diurnal lizard that occurs throughout Brazil (Mesquita and Colli, 2003). Most species of *Cnemidophorus* are polygynous, with non-territorial behavior, where males compete directly for access to mates and show pre- and post-copulatory female accompaniment (Anderson and Vitt, 1990; Zaldívar-Rae and Drummond, 2007; Ancona et al., 2010). Males prefer larger females because they are able to oviposit a larger number of eggs (Vitt and Breitenbach, 1993). Females, in turn, prolong courtship, inciting contests and providing higher quality males the opportunity to displace pursuing males (Pianka and Vitt, 2003). Sexual dimorphism is present in body morphology (Mesquita and Colli, 2003), with males

having larger heads and more conspicuous coloration (bright green colored spots on flanks and tail).

Study design

We set up a 250x250m trapping grid consisted of 121 pitfall traps. We captured adult males and females for seven consecutive days each month, from September 2010 through September 2011. Traps were opened early in the morning, before the species became active, and closed after the species became inactive, in late evening. We used digital photography as the primary method of individual identification but also batch marked individuals by toe clipping the third joint of the second toe of the right hand. On each capture we recorded weapon size, defined here as head width at the maximum lateral extent of the jaw adductor muscles (to the nearest 0.1 mm), total percentage of colored lateral area (badge size), snout-vent length and mass.

To identify individuals and measure badge size, we took four photographs of each lizard using a digital camera (Nikon Coolpix P6000, Nikon, Tokyo, Japan) that included the following views: dorsum, ventral, right and left flank. Pictures were always taken at the same distance from the lizard, using the macro mode and a circular external flash to standardize for light variation. The dorsum and ventral photographs were later used in the software Interactive Individual Identification System (I^3S classic version 2.0, Van Tienhoven et al., 2007) for individual recognition.

Flank photographs were used to measure the badge size of the individuals using the software ImageJ (Abramoff et al., 2004). We quantified individual badges by calculating the relative percentage of pixels covered by the conspicuous (green) color over the right flank of individuals (see Olsson et al., 2000), accounting for body size (Berglund et al., 1996). The total

lateral area covered by the badge did not vary among the reproductive and non-reproductive seasons on individuals (data not shown). Badge size may be fixed at birth, implying heritability (Whiting et al., 2003).

Occasionally, we captured males and females together in the same trap during the mating season. Then we compared body size (snout-vent length), relative mass (mass standardized by body size) and head width of these males and females to the rest of male and female population, using t-tests with unequal variances, to check if those individuals were morphologically different from those caught alone - assuming males caught in the traps with females were guarding the respective females. Such comparison provides an opportunity of comparing traits of potential pairing individuals with traits of the whole population. Finally, we recorded minimum temperature and total rainfall during trapping activities as weather covariates because reptile activity, and thus detection probability, might be influenced by weather conditions. For the few occasions when these covariate data were missing (eight individual captures), we used averaged values of the data set.

Survival analysis with imperfect detection

We used the Cormack-Jolly-Seber model (CJS; Cormack, 1964; Jolly, 1965; Seber, 1965), implemented in program MARK (White and Burnham, 1999), to estimate apparent survival probability (Φ), which is the product of true survival and site fidelity, and recapture probability (p) (Lebreton et al., 1992). We pooled the seven capture days each month to form encounter histories. Using these data, we constructed a set of 14 *a priori* models representing different hypotheses about the interaction effects of head size and badge size on male and female

apparent monthly survival probability. We also included a null model with no variation on monthly survival. For the recapture probability we constructed additive and interactive combinations of sex and time, and also included the weather covariates rainfall, minimum temperature, as well as a null model (being constant).

Goodness-of-fit and a variance inflation factor (i.e., median \hat{c}) were assessed for our general model excluding individual covariates ($\Phi_{\text{sex} \times \text{time}} p_{\text{sex} \times \text{time}}$) since there is currently no goodness-of-fit test for CJS models with individual covariates. Models were selected and ranked based on Akaike Information Criterion adjusted for small sample sizes and corrected for over dispersion (QAICc, Burnham and Anderson, 2002). We considered the model with the smallest QAICc value as the most parsimonious model (Burnham and Anderson, 2002).

RESULTS

We captured a total of 162 adult males and 159 adult females during the study period. Males presented larger weapons ($t = 10.19$, $df = 276$, $p < 0.01$; Fig. 2) and greater badge sizes ($t = -27.35$, $df = 284$, $p < 0.01$; Fig. 2) than did females. We captured 12 couples together during the reproductive season. Companion males were larger ($p < 0.01$) and heavier ($p = 0.04$) but did not have larger heads ($p = 0.29$) than unaccompanied adult males. Accompanied females were larger ($p < 0.01$), but did not differ in relative mass ($p = 0.12$) and head size ($p = 0.26$) from unaccompanied females.

We adjusted the statistics due to some lack of fit of the general model to our data ($\hat{c} = 1.13$). The top model in our analysis included an interaction effect between sex and weapon size for apparent survival probability (Table 1). Weapon was negatively and positively associated

with survival in males and females, respectively (Fig. 3). The second top model also included an interaction between sex and weapon size on apparent survival probability (Table 1). The third best model had QAICc weight of 0.14 and represents the interaction effect between sex and badge size (Table 1, Fig. 3). In this model survival and badge size were negatively correlated, however, the 95% confidence interval for the estimated interaction included zero ($\beta_{\text{sex} \times \text{color}} = -0.05$, CI -0.35 to 0.24).

The top model included a time effect in recapture probability (Table 1) and indicated that it varied from 0 to 0.25 for males and from 0 to 0.20 for females (Fig. 4). In general, recapture probability was higher during the breeding season. The difference between the top-ranked model and the second top model was the inclusion of an extra parameter, sex as an additive effect on time, but Qdeviance was very similar suggesting that sex was an unimportant variable (Arnold, 2010). Recapture probability on the third model was again only a function of time.

DISCUSSION

As expected for polygenic species, males presented larger heads and larger badges than females. When examining the individuals (i.e., pairs) captured together in the traps, males had a larger averaged body size and were heavier than males captured alone. Females captured with males in the traps also had larger body sizes than females captured alone. Larger and heavier males may present advantages because of the higher levels of testosterone and increased aggressiveness towards other males during mate guarding (Andersson, 1994; Zaldívar-Rae and Drummond, 2007). Males in turn, may target better-quality females, i.e., larger and older ones, since reptiles present indeterminate body growth and litter size is positively related to body size (Vitt and Caldwell, 2009).

We noted that the second and the fourth top models presented very similar QDeviance values when compared with the first and third top models, respectively. Structurally, the only difference among these models is the addition of sex as an additive effect to time in the recapture parameter. Although the second and fourth models encompassed 26% of the total variation in the candidate model set, the inclusion of sex did not improve the power of explanation, and consequently, sex should not be interpreted as having an important effect (Arnold, 2010), being considered a “pretending variable” (Anderson, 2008). Disregarding these two models, the top model (i) would have a three-fold evidence ratio in relation to the third top model (j) ($\text{QAICc weight}_i/\text{QAICc weight}_j$), and more than 0.8 of weight.

In an attempt to model the recapture probability with weather covariates, we included rainfall and minimum temperature that are usually associated with reptile activity (Vitt and Caldwell, 2009). However, models containing weather covariates had low QAICc weights, $w_i < 0.01$. Time was the only important variable associated with recapture, with higher probabilities of capturing individuals in the breeding season (August to December). Weather variability may not be extreme and other covariates, such as reproductive activity already noticed or prey availability may be more related to recapture probability.

The lower survival of larger-headed males might be linked to the investment in reproduction, resulting in cumulative phenotypic damage over life. Weapons are generally used to defend critical resources, with its benefits usually outweighing potential costs (Andersson, 1994). The competing sex evolves in an intense and directional sexual selection for increased abilities, leading to the evolution of exaggerated structures, such as those seen in scarab beetles or cervid mammals (Emlen, 2008). Game theory predicts that conflicts will only escalate to fights when contestants are about the same size (Emlen, 2008), but individuals are constantly testing

opponents. Thus, despite the larger heads, individuals could often face pursuing rivals that are testing their abilities, and seeking sneaky copulations, which may increase conspicuousness to predators as well (Marler and Moore, 1988). All of these factors might increase energy expenditure and reduce survival.

On the other hand, smaller males may not present enough large and strong heads to win contests. In species where only a few individuals control all mating opportunities sneaky tactics, usually displayed by smaller individuals, are expected to take place (Andersson, 1994). Sneak behavior is known for teiid whiptail lizards, such as *Aspidoscelis costata*, where smaller males do not engage in fights; instead, they access females furtively and try to force copula, running away if the guarding male detects their presence (Zaldívar-Rae and Drummond, 2007). This strategy may ensure higher survival to individuals that present smaller weapons and has no other choice to mate but furtively. However, sneaky males may not sire many offspring. These two different strategies may occur along the male's reproductive life, investing in growth and trying furtive copula when low fighting ability is present (small weapon), and defending females aggressively when large and strong. Large males may sire more offspring, but with higher costs, translated in higher mortality probability (Ancona et al., 2010). This two-phased strategy may not generate a bimodal size of body or head size, because it would be just part of the development of individuals.

Contrary to our predictions, badge size uncorrelated with survival. This result leads us to refute the prediction that mortality increases with larger badges because of predation (Magnhagen, 1991), a pattern already showed for the collared lizard, *Crotaphytus collaris*. Extravagant characteristics such as badges of status are said to reduce longevity (Promislow, 2003; Preston et al., 2011) and leads to immunosuppression (Olsson et al., 2000; Preston et al.,

2011), being negatively correlated with survival. However, our data does not support this prediction and similar results were found for the lacertid lizard, *Psammodromus algirus*, where testosterone, responsible for the conspicuous coloration, did not preclude body growth and body mass gain (Salvador and Veiga, 2000).

Badges of status are used by females to obtain information about male quality, and also may serve to signal to other males. Females may choose males based on badges at first place and then expose these males to other competitors (Pianka and Vitt, 2003) in order to test the honesty of signaling (Johnstone and Norris, 1993). A high risk of injury from fighting larger-headed individuals could be the cost of displaying a dishonest signal. Hennigsem and Irschick (2011) experimentally reduced badge size (dewlap) in the anole, *Anolis carolinensis*, and found that smaller badges did not change the outcome of male-male interactions. Bite force, an intrinsically measure of performance, was the main factor to determine the winner in the conflicts.

Larger-headed females in turn presented higher survival. Larger-bodied females may be able to avoid predation, by means of increased experience and escaping behavior, and this holds true for both sexes. However, larger females are preferred as mates (Ancona et al., 2010), and this may reduce mortality through lower harassment (Zuk, 2011), since males generally display risky behaviors, presumably attracting more attention and giving females the opportunity to escape (Censky, 1997). Badges in females were not correlated with survival and their function is not clear. Female ornamentation might be related to resources, suggesting some sort of intrasexual competition (LeBas, 2006) or individual differences in fecundity, suggesting differences in female quality, as demonstrated for the striped plateau lizard *Sceloporus virgatus* (Weiss, 2006)

and for the collared lizard (Baird, 2004). The hypotheses surrounding female ornamentation must be further explored.

In summary, we partially corroborated our hypothesis since larger heads had opposite effects on male and female survival, but conspicuous coloration did not correlate with survival. Larger males, who may invest more in the acquisition of mates, may have reduced life span due to reproductive activity. Females may gain a higher value as they grow, having higher survival probability. Despite the higher mortality in larger males, the costs associated to reproduction might be worth it, with evolutionary advantages for high investment in sexual traits.

SÍNTESE

Observamos que a probabilidade de detecção individual nos sistemas estudados foi baixa e condizente com a detecção de vertebrados em ambientes tropicais. O emprego de covariáveis individuais e temporais ajudará a aumentar a precisão das estimativas dos parâmetros vitais, incluindo a probabilidade de detecção.

No capítulo 1, concluímos que as taxas de retorno, índices brutos de sobrevivência, são subestimados em relação as estimativas de sobrevivência que incorporam a detecção imperfeita. Além disso, as estimativas de parâmetros populacionais resultantes do esforço de coleta no campo dependem da detecção.

Recomendamos o emprego da ablação de artelhos em vez da marcação por *microchip* para anfíbios anuros considerando os resultados obtidos, os custos e o tempo envolvidos na aplicação de ambas técnicas. Lembramos que as técnicas de marcação podem ser invasivas e os casos devem ser avaliados individualmente.

Bothrops insularis apresentou baixa probabilidade de sobrevivência anual e alta probabilidade de emigração temporária de nossa área de estudo. Detectamos um crescimento anual médio negativo da população adulta, salientando a importância da identificação das causas e do monitoramento da população.

No capítulo 4 observamos que os custos de sobrevivência foram mais elevados em machos adultos com maior tamanho de cabeça e concluímos que estes provavelmente investem mais energia na reprodução. Fêmeas, por sua vez, apresentaram sobrevivência maior conforme o aumento do tamanho da cabeça, e com isso concluímos que elas adquirem maior valor com a idade. Não encontramos relação entre ornamentação e sobrevivência.

Demonstramos aqui a eficiência do método de marcação e recaptura como uma abordagem eficiente na estimativa de parâmetros populacionais e questões relacionadas a história de vida das espécies. Consideramos que um bom desenho amostral deve ser prioritário no planejamento de um estudo pois permitirá captar todas as variações necessárias para responder as questões propostas, além de assegurar uma boa estimativa da probabilidade de detecção para a espécie/população. Caberá ao pesquisador que detêm o conhecimento sobre a história natural do grupo em questão, elevar a probabilidade de detecção, por meio do desenho amostral e esforço de campo, empregando métodos probabilísticos para a estimativa dos parâmetros.
