Abstract— The purpose of this study is to investigate the fatigue behaviour of the aluminium alloy 6082 by a finite element analysis (FEA). The tests are released for various specimens subjected to cyclic tensile loading in order to characterize the damage evolution and the fatigue strength of the aluminium alloy 6082. The results show the Wöhler curves (S-N curves) for the tested specimens under various stress amplitude levels and for different stress ratios values ($R=0$, $R=0.5$, $R=-1$). The obtained data highlights the strong influences of the stress ratios R and the effects of high cyclic loading on the decreasing of aluminium alloys 6082 life and performances. Afterward, fatigue crack growth under tensile loading was investigated, in this way fatigue tests have been performed on specimens with different pre-cracks sizes to underline the influences of the crack growth on the lifetime and fatigue behaviour of the tested specimens. The predicted fatigue life and the results obtained for the different loading conditions presented in this study were found to be in good agreement with the experimental fatigue investigations published in the literature

Keywords— Fatigue; Aluminium alloy; S-N curve; FEA, Specimen; Stress ratios

I. INTRODUCTION

The application of aluminium alloys in many mechanical components has been increasingly employed especially in automotive, rail vehicles and aeronautical industry, due to their good mechanical properties and low specific weight, also is related to recycling, as all kinds of aluminium alloys can be reused in different products. Aluminium alloy has a density around one third that of steel (around 2700 kg/m³), and it is often used advantageously in applications where low weight and high strength are required. We can find two main classes of aluminium alloys: Cast alloys and Wrought. The increasing use of aluminium alloys in various fields and for high performance products in severe environments requires the complete understanding and knowing of their properties to ensure the best performances and avoid defects, micro-structural features, and any type of damage.

Among all these factors which could fail structures in different modes, fatigue can be the principal cause in the presence of defects and reducing the life of any components. The fatigue can produce larger strain deformation, crack initiation and growth, which can lead to the rupture and the destroying of structures. Wang et al [1] have studied the fatigue and fracture behaviour of structural Al-alloys up to very long life regimes, during cyclic tests they observed a significant interfacial voids were in the Al-alloys during

crack initiation and early fatigue crack growth process. Suresh [2] shows that the fatigue crack growth is typically governed by the crack tip stress intensity. Many Studies have been conducted on the fatigue and deformation behavior of aluminum alloys with different heat treatments (over, under and peak aged), and specifically the interactions between dislocations, slip band structures and precipitates [3-8].

Other studies have been carried out on the influences of microstructure and micro-porosity on the mechanical properties of aluminium cast alloys [9-11]. The fatigue crack propagation can be separated into three stages [12-14]. Stage I crack growth is usually limited to within a single grain and is generally characterized by crack propagation through shear decohesion on a single slip system. The crack will transition to Stage II type growth at higher stress intensities where two slip systems will be active and multiple grains will be located within the crack tip plastic zone. Stage II crack growth is characterized by crack growth normal to the loading direction and the formation of fatigue striations on the fracture surface. The final step in the fatigue process is overload fracture (Stage III crack propagation), which leads to the complete failure of the material.

In that reason, the present study deals with the fatigue damage progression, the effects of high cyclic loading and crack growth on the decreasing of the mechanical properties of aluminium alloy (6082).

Static and cyclic tensile tests have been performed, first on normal specimens and after on pre-cracked specimens to identify the influences of crack initiation and growth on the fatigue life of aluminium alloy (6082). The Results of the S-N curves for the different loading conditions and under the various stress ratios values are presented in this study.

II. FEA PROCEDURES

During FEA an aluminium alloy (6082) is used and its mechanical properties and chemical composition are presented in Table I and Table II. The main characteristics of this alloy are good mechanical strength, high resistance to corrosion, thermal treatability and weldability.

TABLE I
CHEMICAL COMPOSITION OF THE USED ALUMINIUM ALLOY 6082

Chemical Composition	
Al	96,41%
Cr	0,23%
Cu	0,08%
Fe	0,4%
Mg	0,8%
Si	0,9%
Ti	0,08%
Zn	0,17%
Mn	0,8%
Others	0,13%

TABLE II
MECHANICAL PROPERTIES OF THE USED ALUMINIUM ALLOY 6082

Mechanical Properties	
Density	2,71 g/cm ³
Young's Modulus	71 GPa
Yield Strength	280 MPa
Ultimate tensile strength	310 MPa
Thermal Expansion	23.1 μm/m-K.

The tests were performed on cylindrical specimens that had a gauge diameter of 10 mm and a gauge length of 50 mm as shown in figure 1. The specimens for static and fatigue tests have been axially loaded on one side and fixed in the other.

The following fatigue parameters were employed during cyclic tests: sinusoidal load cycles with constant amplitude (Fig 2), test frequency of 10Hz, three stress ratios (R1 = -1; R2= 0; R3= 0.5), and under an ambient temperature.

Fig 1 Specimens dimensions

Fig 2..Applied Loading

The finite element analysis was realized using a technique known as Rainflow counting [16-18]. This technique is used in the fatigue analysis by converting the random loading to simple cycles. Algorithm of this method was developed by Endo and Matsuishi [19] and it's allows the application of Miner's rule and strain-life approach to compute fatigue damage on each cycle (Fig 3).

Fig.3. Strain-Life approach [20]

The strain-based approach is a comprehensive approach which can be applied to both low cycle and high cycle fatigue regimes. For long life applications where the plastic strain term is negligible, the total strain-life equation reduces to Basquin's formula which was also used for the stress-life (S-N) approach. The equation relating total strain amplitude ϵ_a and life (N) is as follows (Eq 1):

$$\epsilon_a = \frac{\sigma'_f}{E} (2N)^b + \epsilon'_f (2N)^c \quad (1)$$

Where:

- σ'_f is the "Strength Coefficient", E is the Young's Modulus
- b is the "Strength Exponent"
- ϵ'_f is the "Ductility Coefficient"
- c is the "Ductility Exponent"

Figure 4 present the basic workflow used during the finite element analysis. The simulation process flows from left to right across the schematic. This configuration is analogous with the normal workflow of a typical finite element (FE) based simulation (pre-processing, followed by solving, followed by post-processing). For the 5-box trick, the three boxes on the left (FE Input, Material Mapping, and Load Mapping) entail pre-processing activities, the center box (CAE Fatigue Analysis) entails solving actions, and the box on the right (Fatigue Results Display) entails post-processing activities.

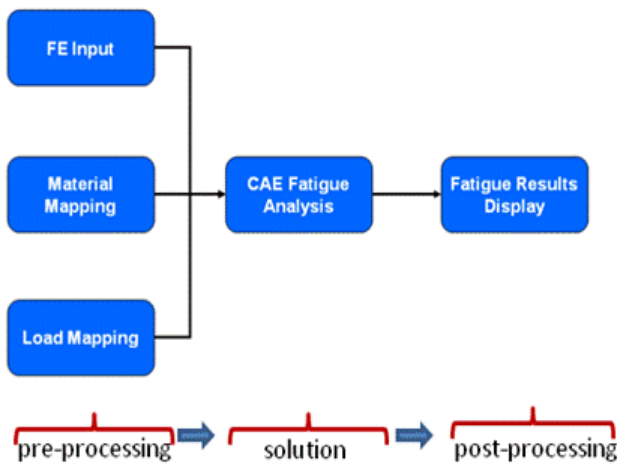

Fig 4 Workflow used during the FEA

The fatigue tests were carried out until total failure of the specimens. The results lead us to determine the S-N curves under the various stress ratios values, the endurance limit and the influences of the crack growth in the fatigue life of the pre-cracked specimens.

Afterwards, it is possible to verify the Basquin relation (Eq 2) that can be used to adequately fit the obtained data correlating alternating stresses and number of cycles to failure, as expressed in Eq. 1.

$$S_a = A \times N^b \quad (2)$$

Where S_a is the applied stress, A and b are respectively the constant and the curve exponent and N is number of cycles.

III. RESULTS AND DISCUSSION

A. Static Tests

The proposed results in Fig.5 depict the typical tensile stress versus strain curves obtained under static loading. It's observed that in the elastic region stress is linearly proportional to strain. When the load exceeds a value corresponding to the yield strength, the specimen undergoes gross plastic deformation. We can notice that the ultimate strength is equal to 310Mpa and the elastic limit is equal to 283Mpa.

Fig 5 Stress-Strain curve

B. Fatigue Tests

During the past decades a number of models has been developed to study the fatigue behavior of materials. The most well know fatigue model is S-N curve, which was originally developed for metallic materials. Figure 6 displays the S-N curve for specimens under $R = -1$.

Three fatigue life behaviors namely low-cycle, high-cycle and infinite life can be distinguished. Low-cycle regime extends up to $16 \cdot 10^3$ cycles with the corresponding fatigue strength at 190 MPa, and the higher cycle life starts at $5 \cdot 10^6$ cycles. Depending on the amount of applied stress the degree and rate of damage varied consequently. A greater stress level causes more damage than that of low stress level.

Fig 6. S-N curve under $R = -1$

Comparison of the fatigue behaviour of the specimens under the three stress ratios levels is presented in figure 7. The obtained fatigue results for the tested specimens under considered three stress ratios are shown in Table .2.

It is observed that as the applied bending stress is increased, the life cycle of the specimen is decreased for all stress cycle of values. The fatigue strength increase with R values and the fatigue life decrease significantly as the stress ratio was lowered.

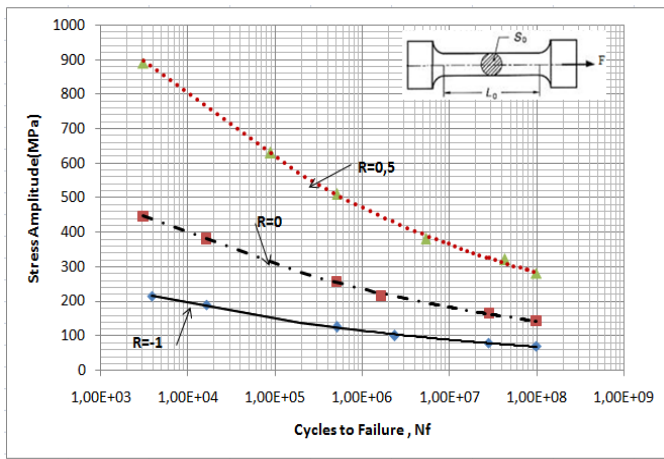

Fig 7 Comparison of the S-N curves under the three stress ratio

TABLE III
FATIGUE RESULTS FOR THE VARIOUS STRESS RATIOS

R= -1		R= 0		R= 0,5	
S _a	N _f	S _a	N _f	S _a	N _f
215	3882	445	3,09E+03	890	3087
190	16287	380	1,63E+04	630	89142
125	5,10E+05	255	5,13E+05	510	5,13E+05
100	2,38E+06	215	1,67E+06	380	5,42E+06
89	2,80E+07	165	2,87 E+07	320	4,35E+07
70	1,00E+08	143	1,00E+08	280	1,00E+08

When all predictions of S-N curves are rearranged into the form of Basquin's formula, the equations that best describe the obtained results can be represented by:

- For (R= -1): $S_a = 553,1 \times N^{-0,11}$ (3)
- For (R= 0): $S_a = 1087 \times N^{-0,11}$ (4)
- For (R= 0, 5): $S_a = 2188 \times N^{-0,11}$ (5)

Figures 8 and 9 present and compare the (S-N) curves for normal and pre-cracked specimens under a maximal stress equal to 80 Mpa. It's observed that the pre-cracked specimens have a very low fatigue life and an accelerate damage evolution due to the crack growth.

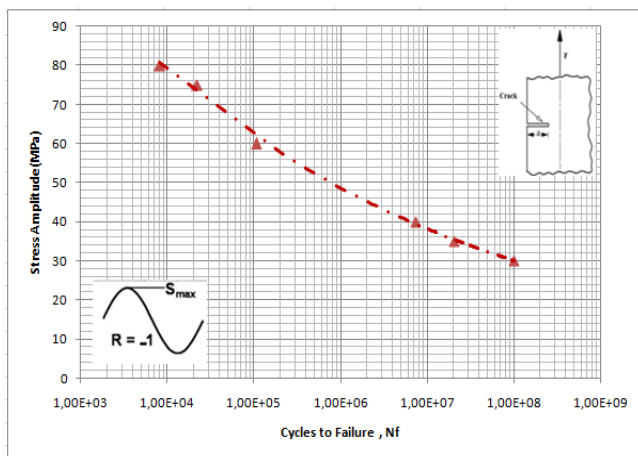

Fig 8 S-N curve for the pre-cracked specimen (crack length (a) =3mm and R= -1)

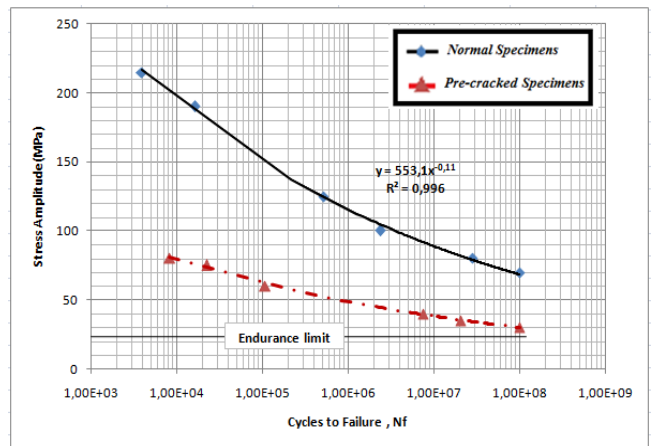

Fig 9 Comparison of S-N curves for the pre-cracked and normal specimen (R= -1, a=3mm)

The obtained effective endurance limit defined as the stress that causes failure at 10^8 cycles, is equal to 30MPa for pre-cracked specimens and about 70MPa for normal specimens under (R= -1). The results show how the crack growth and fatigue damage can modify the mechanical properties of the tested material.

Figure 10 presents the fatigue behaviour of four different pre-cracked specimens with various initial crack sizes. It's observed that the number of cycles to failure decreases when the crack length increases. For instance, when the crack length (a) is equal to 3mm, the number of cycles to failure is about 1728 cycles, and with a pre-crack length equal to 2 mm, the number of cycles to failure is equal to 2896 cycles.

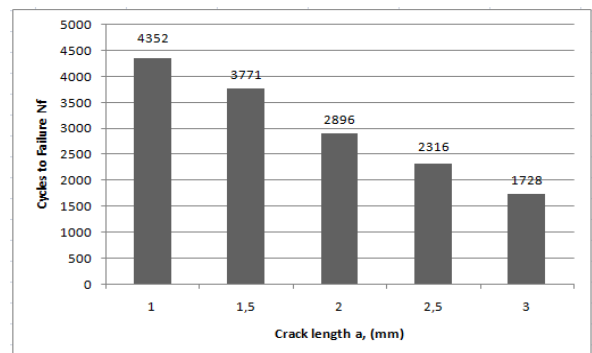

Fig 10. Crack length vs cycles to failure for different crack size

Figure 11 presents the result of the fatigue life of the pre-cracked specimen under an applied stress equal to 80 MPa and a stress ratio equal to -1, the figure shows the cracked area that is most affected by fatigue (fatigue life about 8200 cycles), as well as the blue areas in which we have a more important lifespan.

Figure 11 Fatigue behaviour of the cracked area during cyclic tests

IV. CONCLUSIONS

The fatigue behaviour and the influences of damage evolution and crack growth on the decreasing of aluminium alloys (6082) performance have been investigated. When the fatigue load level increases, the fatigue life decreases. Conversely, at low fatigue load level, the fatigue life is long and the damage evolution occurs slowly. The great danger that can be assigned to all structures due to fatigue and cracking can be noticed. This study was also carried out by a finite element analysis of the fatigue response of aluminium alloy 6082 under different stress ratios. Results demonstrate that the fatigue strength increase with R values. However, fatigue life decreases significantly as the stress ratio was lowered.

NOMENCLATURE

a	Crack length	mm
N	Number of cycles	
N_f	Number of cycles to failure	
R	Stress ratio ($R = \frac{S_{min}}{S_{max}}$)	
S_a	Stress amplitude	MPa
