

HOMOTOPY TECHNIQUES FOR TENSOR DECOMPOSITION AND PERFECT IDENTIFIABILITY

JONATHAN D. HAUENSTEIN, LUKE OEDING, GIORGIO OTTAVIANI,
AND ANDREW J. SOMMESE

ABSTRACT. Let T be a general complex tensor of format (n_1, \dots, n_d) . When the fraction $\prod_i n_i / [1 + \sum_i (n_i - 1)]$ is an integer, and a natural inequality (called balancedness) is satisfied, it is expected that T has finitely many minimal decomposition as a sum of decomposable tensors. We show how homotopy techniques allow us to find all the decompositions of T , starting from a given one. Computationally, this gives a guess regarding the total number of such decompositions. This guess matches exactly with all cases previously known, and predicts several unknown cases. Some surprising experiments yielded two new cases of generic identifiability: formats $(3, 4, 5)$ and $(2, 2, 2, 3)$ which have a unique decomposition as the sum of 6 and 4 decomposable tensors, respectively. We conjecture that these two cases together with the classically known matrix pencils are the only cases where generic identifiability holds, i.e., the only *identifiable* cases. Building on the computational experiments, we use algebraic geometry to prove these two new cases are indeed generically identifiable.

1. INTRODUCTION

Tensor decomposition is an active field of research, with many applications (see, e.g., [49] for a broad overview). A tensor T of format (n_1, \dots, n_d) is an element of the tensor space $\mathbb{C}^{n_1} \otimes \dots \otimes \mathbb{C}^{n_d}$. The *rank* of T is the minimum r such that

$$(1) \quad T = \sum_{i=1}^r v_1^i \otimes \dots \otimes v_d^i$$

where $v_j^i \in \mathbb{C}^{n_j}$. This reduces to the usual matrix rank when $d = 2$.

The space $\mathbb{C}^{n_1} \otimes \dots \otimes \mathbb{C}^{n_d}$ contains a dense subset where the rank is constant. This constant is called the *generic rank* for tensors of format (n_1, \dots, n_d) . By a simple dimensional count, the generic rank for tensors of format (n_1, \dots, n_d) is at least

$$(2) \quad R(n_1, \dots, n_d) := \frac{\prod_{i=1}^d n_i}{1 + \sum_{i=1}^d (n_i - 1)} = \frac{\prod_{i=1}^d n_i}{1 - d + \sum_{i=1}^d n_i}.$$

The value $[R(n_1, \dots, n_d)]$ is called the *expected generic rank* for (n_1, \dots, n_d) .

A necessary condition for a general tensor T of format (n_1, \dots, n_d) to have only finitely many decompositions (1) is that the number $R(n_1, \dots, n_d)$ is actually an integer. Such formats are called *perfect* [15, 68]. Moreover, if a general tensor is known to have finitely many decompositions (1), then the generic rank is equal to the expected generic rank $R(n_1, \dots, n_d)$.

Date: October 31, 2016.

A tensor format is said to be *generically identifiable* if a generic tensor of that format has a unique decomposition (up to global rescaling and permutation of the factors). A tensor format is said to satisfy *perfect identifiability* if the format is perfect and generically identifiable. The main goal of this paper is to study the number of decompositions of perfect formats (n_1, \dots, n_d) when the generic rank is indeed equal to the generic expected rank.

The main tool for inquiry is numerical algebraic geometry, a collection of algorithms to numerically compute and manipulate solutions sets of polynomial systems. Numerical algebraic geometry, named in [65], grew out of numerical continuation methods for finding all isolated solutions of polynomial systems. For a development and history of the area, see the monographs [10, 66] and the survey [70]. The monograph [10] develops the subject using the software package `Bertini` [9], which is used to perform the computations in this article. For understanding the relation between numerical approaches and the more classical symbolic approaches to computational algebraic geometry, see [7].

Numerical algebraic geometry has proven useful in many other applications. A small subset of such applications include computing the initial cases for equations of an infinite family of Segre-Grassmann hypersurfaces in [24]; numerically decomposing a variety in [11] which was a crucial computation leading to a set-theoretic solution of the so-called *salmon problem* [2] improving upon a previous result of Friedland [27], and inspiring a later result of Friedland and Gross [28]; solving Alt's problem [5] which counts the number of distinct four-bar linkages whose coupler curve interpolates nine general points in the plane, namely 1442 [69]; finding the maximal likelihood degree for many cases of matrices with rank constraints [45] and observing duality which was proven in [26]; a range of results in physics such as [40, 41, 54, 55]; and numerically solving systems of nonlinear differential equations [32–39].

We consider the equation (1) where r is the generic rank and the v_j^i 's are unknowns. Starting from one decomposition for T , we can move $T(s)$ along a loop, for $0 \leq s \leq 1$, such that $T(0) = T(1) = T$. This consequently defines corresponding vectors $v_j^i(s)$ which satisfy

$$T(s) = \sum_{i=1}^r v_1^i(s) \otimes \cdots \otimes v_d^i(s).$$

The decompositions of T at the end values, $s = 0$ and $s = 1$, may be different. Since this process is computationally cheap, it can be repeated with random loops a considerable number of times and one can record all of the distinct decompositions found. Moreover, in the perfect case, where decompositions correspond to solutions to system of polynomial equations with the same number of variables, i.e., a square system, one can use α -theory via `alphaCertified` [42, 43] to prove lower bounds on the total number of decompositions. Theory guarantees that all decompositions can be found using finitely many loops while experience shows that all decompositions of T can be found after a certain number of attempts using random loops. When the number of decompositions is small, this process stabilizes quickly to the total number of decompositions. We describe using this process on some previously known cases and predict several unknown cases. In particular, the values reported in Section 3 are provable lower bounds that we expect are sharp.

To put these results in perspective, we recall that finding equations that detect tensors of small rank is a difficult subject. Recent progress is described in [3], which gives a semi-algebraic description of tensors of format (n, n, n) of rank n and multilinear rank (n, n, n) . In addition, several recent algorithms and techniques are available to find best rank-one approximations [57] or even to decompose a tensor of small rank [12, 14, 58, 67]. However, the problem generally becomes more difficult as the rank increases so that decomposing a tensor which has the generic rank is often the hardest case.

The formats $(3, 4, 5)$ and $(2, 2, 2, 3)$ were exceptional in our series of experiments since our technique showed that they have a unique decomposition (up to reordering). Indeed, an adaptation of the approach developed in [58] allowed to us to confirm our computations.

Theorem 1.1. *A general tensor of format $(3, 4, 5)$ has a unique decomposition (1) as a sum of 6 decomposable summands.*

Theorem 1.2. *A general tensor of format $(2, 2, 2, 3)$ has a unique decomposition (1) as a sum of 4 decomposable summands.*

These theorems are proved in Section 5. The proofs provide algorithms for computing the unique decomposition, which we have implemented in `Macaulay2` [31]. Based on the evidence described throughout, we formulate the following conjecture.

Conjecture 1.3. *The only perfect formats (n_1, \dots, n_d) , i.e., $R(n_1, \dots, n_d)$ in (2) is an integer, where a general tensor has a unique decomposition (1) are:*

- (1) $(2, k, k)$ for some k — matrix pencils, known classically by Kronecker normal form,
- (2) $(3, 4, 5)$, and
- (3) $(2, 2, 2, 3)$.

We would like to contrast the tensor case to the symmetric tensor case, where the exceptional cases were known since the 19th century, as well as the following recent result.

Theorem 1.4 (Galuppi–Mella [30]). *The only perfect formats (n, d) , i.e., $n^{-1} \cdot \binom{n+d-1}{d}$ is an integer, where a general tensor in $\text{Sym}^d \mathbb{C}^n$ has a unique decomposition are:*

- (1) $(2, 2k + 1)$ for some k — odd degree binary forms, known to Sylvester,
- (2) $(3, 5)$ — Quintic Plane Curves (Hilbert, Richmond, Palatini), and
- (3) $(4, 3)$ — Cubic Surfaces (Sylvester Pentahedral Theorem).

Theorem 1.4 was still stated as a conjecture (following [53] and [52]) in the first preprint of the present article. See [53] and [60] for classical references. In [58, § 4.4], two of the authors showed that the Koszul flattening method predicts exactly the cases listed in Theorem 1.4 and no others.

2. SOME KNOWN RESULTS ON THE NUMBER OF TENSOR DECOMPOSITIONS

2.1. General tensors. The following summarizes some known results about tensors of format (n_1, \dots, n_d) . For any values of r smaller than the generic rank, which was defined in the introduction, the (Zariski) closure of the set of tensors of rank r is an irreducible algebraic variety. This variety is identified with the cone over the r^{th} secant variety to the Segre

variety $\mathbb{P}(\mathbb{C}^{n_1}) \times \cdots \times \mathbb{P}(\mathbb{C}^{n_d})$ of decomposable tensors, e.g., see [16, 49]. In particular, it is meaningful to speak about a general tensor of rank r .

Throughout this section, we consider cases where $d \geq 3$ and, without loss of generality, assume that $2 \leq n_1 \leq n_2 \leq \cdots \leq n_d$. First, we review the known results on the so-called unbalanced formats.

Theorem 2.1. *For formats (n_1, \dots, n_d) , suppose that $n_d \geq \prod_{i=1}^{d-1} n_i - \sum_{i=1}^{d-1} (n_i - 1)$.*

- (1) *The generic rank is $\min\left(n_d, \prod_{i=1}^{d-1} n_i\right)$.*
- (2) *A general tensor of rank r has a unique decomposition if $r < \prod_{i=1}^{d-1} n_i - \sum_{i=1}^{d-1} (n_i - 1)$.*
- (3) *A general tensor of rank $r = \prod_{i=1}^{d-1} n_i - \sum_{i=1}^{d-1} (n_i - 1)$ has exactly $\binom{D}{r}$ different decompositions where*

$$D = \frac{\left(\sum_{i=1}^{d-1} (n_i - 1)\right)!}{(n_1 - 1)! \cdots (n_{d-1} - 1)!}.$$

This value of r coincides with the generic rank in the perfect case: when $r = n_d$.

- (4) *If $n_d > \prod_{i=1}^{d-1} n_i - \sum_{i=1}^{d-1} (n_i - 1)$, a general tensor of rank $r > \prod_{i=1}^{d-1} n_i - \sum_{i=1}^{d-1} (n_i - 1)$, e.g., a general tensor of format (n_1, \dots, n_d) , has infinitely many decompositions.*

Proof. When $n_d > \prod_{i=1}^{d-1} n_i - \sum_{i=1}^{d-1} (n_i - 1)$, Item 1 follows from [18, Thm. 2.1(1-2)] (see also [13, Prop. 8.2]). In the perfect case, i.e., $n_d = \prod_{i=1}^{d-1} n_i - \sum_{i=1}^{d-1} (n_i - 1)$, Item 1 follows from [13, Prop. 8.3]. Items 2 and 3 follow from [13, Prop. 8.3, Cor. 8.4]. When $n_d - 1 > \prod_{i=1}^{d-1} n_i - \sum_{i=1}^{d-1} (n_i - 1)$, Item 4 follows from [1, Lemma 4.1]. If $n_d - 1 = \prod_{i=1}^{d-1} n_i - \sum_{i=1}^{d-1} (n_i - 1)$, then $\prod_{i=1}^{d-1} n_i = \sum_{i=1}^d (n_i - 1)$. Hence, $1 + \sum_{i=1}^d (n_i - 1)$ cannot divide $\prod_{i=1}^d n_i$ and so the format cannot be perfect. \square

The case $(2, n, n)$, corresponding to pencils of square matrices, is the only case for which the binomial coefficient $\binom{D}{r}$ in Theorem 2.1(3) is equal to 1. The unique decomposition is a consequence of the canonical form for these pencils, found by Weierstrass and Kronecker [15].

For convenience, Table 1 lists some perfect cases coming from Theorem 2.1(3), namely when $n_d = \prod_{i=1}^{d-1} n_i - \sum_{i=1}^{d-1} (n_i - 1)$ with generic rank $r = n_d$.

After Theorem 2.1, the only open cases are when the balancedness condition is satisfied:

$$(3) \quad n_d < \prod_{i=1}^{d-1} n_i - \sum_{i=1}^{d-1} (n_i - 1).$$

A seminal identifiability result for general tensors up to a certain rank is [68, Cor. 3.7]. In [20], based on weak defectiveness introduced in [19], there are techniques to check the number of decompositions of a general tensor of rank r , generalizing Kruskal's result [48].

De Lathauwer's condition (mentioned after equation (1.7) in [25]) can guarantee uniqueness up to rank

$$(4) \quad \sum_{i=1}^{d-1} n_i - d + 1$$

(n_1, \dots, n_d)	gen. rank	# of decomp. of general tensor
$(2, n, n)$	n	1
$(3, 3, 5)$	5	6
$(3, 4, 7)$	7	120
$(3, 5, 9)$	9	5005
$(3, 6, 11)$	11	352716
$(4, 4, 10)$	10	184756
$(2, 2, 2, 5)$	5	6
$(2, 2, 3, 8)$	8	495

TABLE 1. Generic ranks and numbers of decompositions for perfect formats (Thm. 2.1).

In the $3 \times 4 \times 5$ the bound (4) is 5. In the $2 \times 2 \times 2 \times 3$ the bound (4) is 3. Indeed De Lathauwer considers only “tall” tensors when the rank is no larger than the dimension of any mode, so his methods don’t apply to the perfect case. However if you ignore this assumption (rank $R \leq n_3$) in [25, Theorem 2.5], the second inequality

$$R(R - 1) \leq \frac{n_1(n_1 - 1)n_2(n_2 - 1)}{2}$$

becomes $30 \leq 36$, which is valid in the $3 \times 4 \times 5$ case. So the previous bound just misses our results.

For all formats such that $\prod_{i=1}^d n_i \leq 15,000$ which satisfy the inequality (3), a general tensor of rank r which is strictly smaller than the generic rank has a unique decomposition except for a list of well understood exceptions, e.g., see [20, Thm. 1.1]. These results support the belief that, other than some exceptions, a general tensor of rank r smaller than the generic rank has a unique decomposition. When r is the generic rank, since the techniques in [20] cannot be applied, we apply numerical algebraic geometry to such cases in Section 3.

2.2. The symmetric case. The following summarizes results about symmetric tensors to contrast with the general case. Recall that symmetric tensors of format (n, d) are tensors $T \in \text{Sym}^d \mathbb{C}^n$, which can be identified with homogeneous polynomials of degree d in n variables. The (symmetric) rank of T is the minimum r such that there is an expression

$$T = \sum_{i=1}^r v^i \otimes \dots \otimes v^i$$

with $v^i \in \mathbb{C}^n$. If T is identified with a polynomial, then each summand $v^i \otimes \dots \otimes v^i$ is the d -power of a linear form. By a naive dimension count, a general tensor in $\text{Sym}^d \mathbb{C}^n$ has rank at least $n^{-1} \cdot \binom{n+d-1}{d}$. When this fraction is an integer, the symmetric format (d, n) is called *perfect*. As in the general case, perfectness is a necessary condition in order for a general tensor in $\text{Sym}^d \mathbb{C}^n$ to have only finitely many decompositions.

The following is the basic result about decomposition of symmetric tensors that we state for perfect formats.

d	gen. rank	# of decomp. of general tensor
4	6	∞
5	7	1
7	12	5
8	15	16

TABLE 2. Generic ranks and numbers of decompositions for general tensors in $\text{Sym}^d \mathbb{C}^3$ [60].

Theorem 2.2 (Alexander-Hirschowitz [4]). *Let $d \geq 3$ and assume $r = n^{-1} \cdot \binom{n+d-1}{d} \in \mathbb{Z}$. A general tensor in $\text{Sym}^d \mathbb{C}^n$ has finitely many decompositions of rank r except in the following cases: $(n, d) = (3, 4)$, $(5, 3)$, or $(5, 4)$. In these three exceptional cases, a general tensor has no decomposition of rank r , but infinitely many decompositions of rank $r + 1$.*

When $n = 2$, note that $\frac{d+1}{2} \in \mathbb{Z}$ exactly when d is odd. In these cases, Sylvester proved that there is a unique decomposition with $\frac{d+1}{2}$ summands [60].

Theorem 1.4([30]) lists two other cases when a general tensor in $\text{Sym}^d \mathbb{C}^n$ has a unique decomposition, namely $\text{Sym}^3 \mathbb{C}^4$ where $(n, d) = (4, 3)$ and $\text{Sym}^5 \mathbb{C}^3$ where $(n, d) = (3, 5)$ [60].

When $n = 3$, note that $\frac{1}{3} \cdot \binom{d+2}{2} \in \mathbb{Z}$ is an integer exactly when $d = 1$ or $d = 2$ modulo 3. Table 2 records all the cases that can be found in [60] concerning $\text{Sym}^d \mathbb{C}^3$. The clever syzygy technique used in [60] seems not to extend to higher values of d .

Remark 2.3. Let $d = 1$ or $d = 2$ modulo 3. By [23, Thm. 4.2(vi)], the number of decompositions of a general symmetric tensor in $\text{Sym}^d \mathbb{C}^3$ is bounded below by the degree of the tangential projection from $r - 1$ points, where $r = \frac{(d+2)(d+1)}{6}$ is the generic rank. This latter degree is computed as the residual intersection of two plane curves of degree d having $r - 1$ double points, which is $d^2 - 4(r - 1) = d^2 - 4 \frac{(d-1)(d+4)}{6} = \frac{(d-2)(d-4)}{3}$.

An analysis of the degeneration performed in [23] suggests that actually the number of decompositions of general symmetric tensor in $\text{Sym}^d \mathbb{C}^3$ should be divisible by $\frac{(d-2)(d-4)}{3}$. This guess agrees, for $d \leq 8$, with the above table from [60] and the results for $d \leq 11$ in §3.3.

A general symmetric tensor of rank r which is strictly smaller than the generic rank has a unique decomposition except for a list of well understood exceptions, see [6, 21, 53].

3. HOMOTOPY TECHNIQUES FOR TENSOR DECOMPOSITION

In this section, we first describe the monodromy-based approach we use to determine the number of decompositions for a general tensor. The software `Bertini` [9, 10] is then used in the subsequent subsections to compute decompositions for various formats. In the perfect cases under consideration, the number of decompositions can be certifiably lower bounded via `alphaCertified` [42, 43]. In particular, for the two cases $(3, 4, 5)$ and $(2, 2, 2, 3)$ which are discovered here to have a unique decomposition, we provide theoretical proofs in Section 5. Our computational methods include probabilistic reductions (e.g. cutting by random hyperplanes and choosing random points) and numerical computations which are always subject to round-off errors in any finite computation (e.g. numerical path tracking).

Even though these methods are now completely standard, have been carefully and repeatedly tested, and yield completely reproducible results, they are technically only true with high probability, or up to the numerical precision of the computers we use. Recently results whose proofs partially rely on such methods have been denoted Theorem* (see [59]). In this article we say that these results hold *with high confidence*.

3.1. Decomposition via monodromy loops. In numerical algebraic geometry, monodromy loops have been used to decompose solution sets into irreducible components [64]. Here, we describe the use of monodromy loops for computing additional decompositions of a general tensor. For demonstration purposes, suppose that a general tensor of format (n_1, \dots, n_d) has rank r and finitely many decompositions.

The approach starts with a general tensor T of format (n_1, \dots, n_d) with a known decomposition (1) with $v_j^i \in \mathbb{C}^{n_j}$ for $i = 1, \dots, r$. In practice, one randomly selects the v_j^i first and then computes the corresponding T defined by (1). To remove the trivial degrees of freedom, we assume that $(v_j^i)_1 = 1$ for $i = 1, \dots, r$ and $j = 1, \dots, d - 1$. That is, we have a solution of

$$F_T(v_1^1, \dots, v_d^r) = \left[\begin{array}{c} T - \sum_{i=1}^r v_1^i \otimes \dots \otimes v_d^i \\ (v_j^i)_1 - 1, \quad i = 1, \dots, r, j = 1, \dots, d - 1 \end{array} \right] = 0.$$

The system F_T consists of $\prod_{j=1}^d n_j + r(d - 1)$ polynomials in $r \cdot \sum_{j=1}^d n_j$ variables. Since $r = R(n_1, \dots, n_d)$ in (2), the number of polynomials is equal to the number of variables meaning that F_T is a *square* system.

Now, suppose that $S \subset (\mathbb{C}^{n_1} \times \dots \times \mathbb{C}^{n_d})^r$ consists of the known decompositions of T . For a loop $\tau : [0, 1] \rightarrow \mathbb{C}^{n_1 \dots n_d}$ with $\tau(0) = \tau(1) = T$, consider the homotopy

$$H(v_1^1, \dots, v_d^r, s) = F_{\tau(s)}(v_1^1, \dots, v_d^r) = 0.$$

The loop τ is selected so that the solution paths starting at the points in S when $s = 0$ are nonsingular for $s \in [0, 1]$. This is the generic behavior for paths τ since the singular locus is a complex codimension one condition while we are tracking along a real one-dimensional arc $\tau(s)$ for $0 \leq s \leq 1$. The endpoints, namely at $s = 0$ and $s = 1$, of these solution paths form a decomposition of T . If a new decomposition is found, it is added to S . The process is repeated for many loops τ . We leave many details about path tracking to [10, 66].

Since F_T and the homotopy H is naturally invariant under the action of the symmetric group on r elements, we only need to track one path starting from one point from each orbit. Each loop is usually computationally inexpensive so we can repeat this computation many times. Experience has shown that randomly selected loops are typically successful at generating the requisite monodromy action needed to obtain all decompositions starting from a single one in a relatively small number of loops.

In the subsequent subsections, when an exact value is reported, this means that at least 50 additional randomly selected loops failed to yield any new decompositions. Thus, we expect that these values are sharp. When a lower bound is reported, this means that we have terminated the computation with the last loop generating many new decompositions. Thus, these lower bounds are probably quite far from being sharp, but do show nonuniqueness.

3.2. The number of decompositions for perfect format tensors.

Computation 3.1. *Tables 3 and 4 summarize the results of our numerical computations which determine (with high confidence) the generic ranks and numbers of decompositions for general tensors $d \geq 3$ satisfying (3) with $\prod_{i=1}^d n_i \leq 100$. Table 5 records our results for symmetric tensors.*

The generic rank is known to be equal to the expected one for formats (n, n, n) [51], which is not perfect for $n \geq 3$, and $(2, \dots, 2)$ for at least $k \geq 5$ factors [17], which is perfect if $k + 1$ is a power of 2. A numerical check for $k = 7$ shows it is not identifiable.

3.3. The number of decompositions for symmetric tensors. We highlight a few cases for computing the number of decompositions of symmetric tensors.

In the cases of this table, Theorem 1.1 in [52] and the recent [30] imply that the number of decompositions of a general tensor is at least 2.

For $\text{Sym}^d \mathbb{C}^3$ and $d = 1$ or $d = 2$ modulo 3, the expectation stated in Remark 2.3 is that the number of decompositions is divisible by $\frac{(d-2)(d-4)}{3}$. This is confirmed for $d = 10$ with $320 = 20 \cdot 16$ and $d = 11$ with $2016 = 96 \cdot 21$.

4. PSEUDOWITNESS SETS AND VERIFICATION

The approach discussed in Section 3 uses random monodromy loops to attempt to generate new decompositions. Clearly, when showing that a format is not identifiable, one simply needs to generate some other decomposition. We can use the numerical approximations to generate a proof that it is not identifiable in the perfect case using, for example, `alphaCertified` [42, 43]. However, to determine the precise number of decompositions, we simply run many monodromy loops and observe when the number of decompositions computed stabilize. In this section, we describe one approach for validating the number of decompositions and demonstrate this approach in Section 4.2 for counting the number of decompositions for a general tensor of format $(3, 6, 6)$ of rank 8.

4.1. Using pseudowitness sets. For demonstration purposes, consider counting the number of decompositions of a general tensor of format (n_1, \dots, n_d) of rank r . Consider the following where we have removed the trivial degrees of freedom by selecting elements to be 1:

$$G := \left\{ (T, v_1^1, \dots, v_d^1, \dots, v_1^r, \dots, v_d^r) \mid \begin{array}{l} T = \sum_{i=1}^r v_1^i \otimes \dots \otimes v_d^i, \\ (v_j^i)_1 = 1 \text{ for } i = 1, \dots, r \text{ and } j = 1, \dots, d-1 \end{array} \right\}.$$

The graph G is clearly an irreducible variety. Hence, the image $\overline{\pi(G)}$ is also irreducible where $\pi(T, v_1^1, \dots, v_d^1, \dots, v_1^r, \dots, v_d^r) = T$. If $\dim G = \dim \overline{\pi(G)}$, then we know that a general tensor T of format (n_1, \dots, n_d) of rank r has finitely many decompositions, namely

$$\frac{|\pi^{-1}(T) \cap G|}{r!}.$$

In particular, $|\pi^{-1}(T) \cap G|$ is the degree of a general fiber of π with respect to G and the denominator $r!$ accounts for the natural action of the symmetric group on r elements.

Using numerical algebraic geometry, computations on G will be performed using a *witness set*, e.g., see [10, 66], and on $\overline{\pi(G)}$ using a *pseudowitness set* [46, 47]. A byproduct of computing a pseudowitness set for $\overline{\pi(G)}$ is the degree of a general fiber.

Suppose that $X \subset \mathbb{C}^N$ is an irreducible variety of dimension k and f is a system of polynomials in N variables such that X is an irreducible component of the solution set defined by $f = 0$. Then, a witness set for X is the triple $\{f, \mathcal{L}, V\}$ where $\mathcal{L} \subset \mathbb{C}^N$ is a general linear space of codimension k and $V = X \cap \mathcal{L}$. Here, “general linear space” means that \mathcal{L} intersects the smooth points of the reduction of X transversely so that $|V| = \deg X$.

To focus only on the case of interest, we assume that $\pi : \mathbb{C}^N \rightarrow \mathbb{C}^m$ is the projection map onto the first m coordinates such that π is generically ℓ -to-one on X , i.e., $\dim X = \dim \pi(X)$. Then, a pseudowitness set for $\overline{\pi(X)}$ is the quadruple $\{f, \pi, \mathcal{M}, W\}$ where $W = X \cap \mathcal{M}$ and $\mathcal{M} = \mathcal{M}_\pi \times \mathbb{C}^{N-m}$ with $\mathcal{M}_\pi \subset \mathbb{C}^m$ being a general linear space of codimension k . Here, “general linear space” means that \mathcal{M}_π intersects $\overline{\pi(X)}$ transversely, so that $|\pi(W)| = |\overline{\pi(X)} \cap \mathcal{M}_\pi| = \deg \overline{\pi(X)}$, and, for each $T \in \overline{\pi(X)} \cap \mathcal{M}_\pi$, $|\pi^{-1}(T) \cap X| = \ell$. Therefore, π is an ℓ -to-one map on W with $|W| = \ell \cdot \deg \overline{\pi(X)}$.

Returning to the problem at hand, since we aim to compute a pseudowitness set for $\overline{\pi(G)}$, we can simplify this computation by only considering the fiber over a general curve section of $\overline{\pi(G)}$. If $k = \dim \overline{\pi(G)}$, let $\mathcal{A} \subset \mathbb{C}^{n_1} \otimes \cdots \otimes \mathbb{C}^{n_d}$ be a general linear space of codimension $k - 1$. Then, $C = \pi^{-1}(\overline{\pi(G)} \cap \mathcal{A}) \cap G$ and $\overline{\pi(C)} = \overline{\pi(G)} \cap \mathcal{A}$ are both irreducible curves, e.g., see [62, Thm. 3.42] and [66, Thm. 13.2.1], respectively. Moreover, $\deg \overline{\pi(G)} = \deg \overline{\pi(C)}$ and the degree of a general fiber for C and G with respect to π are equal.

With this, we now aim to compute a pseudowitness set for the curve $\overline{\pi(C)}$. Since C is a curve, we compute a pseudowitness set for $\overline{\pi(C)}$ by intersecting C with a hyperplane of the form $\pi^{-1}(\mathcal{H})$ where $\mathcal{H} \subset \mathbb{C}^{n_1} \otimes \cdots \otimes \mathbb{C}^{n_d}$ is a general hyperplane. Since $\pi^{-1}(\mathcal{H})$ is invariant under the natural action of the symmetric group on r elements, we will first consider the intersection of C with a general element of an irreducible family of hypersurfaces that are invariant under the same action and contains hyperplanes of the form $\pi^{-1}(\mathcal{H})$. This is sufficient by the results of [56] and simplifies the computation since only one point in each orbit needs to be computed, i.e., only one point out of every $r!$ based on the natural action of the symmetry group on r elements.

Remark 4.1. At first sight, by reducing down to the curve case, it might seem that some technicalities could be avoided by choosing a general hyperplane among the hyperplanes invariant under the symmetric group and only needing to compute one point in each orbit. However, there could be some difficulties that arise with this.

The first difficulty is that the set of hyperplanes invariant under a finite group does not have to be irreducible. For example, let $G \subset \mathbb{C}^*$ denote the sixth roots of unity. Consider the action of G on \mathbb{C}^2 defined by $g \cdot (z, w) \mapsto (g^2 z, g^3 w)$. In this case, the set of invariant hyperplanes consists of two points, i.e., the z axis and the w axis.

Even when there is a large family of invariant hyperplanes that make sense, the second difficulty is that none of them need be invariant enough to intersect the algebraic set of interest transversely in the degree number of points. For example, let $X \subset \mathbb{C}^2$ be the solution set of $z^2 - w^3$ which is a curve of degree 3. Let G denote $\{1, -1\}$ which acts on \mathbb{C}^2 by $g \cdot (z, w) \mapsto (gz, w)$. Note that X is invariant under G . The G -invariant hyperplanes consist of two components. One component is made up of the fibers of the projection map $(z, w) \mapsto w$ which meet X in two points. The other component consists of the w axis which is not transversal to X .

To avoid these potential difficulties, we first define an irreducible family of hyperplanes that contains the invariant hyperplanes of interest. Then, the general theory in [56] shows that this process computes the requisite points needed in the construction of a pseudowitness set.

4.2. Tensors of format (3, 6, 6) of rank 8. The tensors of format (3, 6, 6) have generic rank 9 in which a general tensor of this format has infinitely many decompositions. In [22], the open problem of computing the number of tensor decompositions of a general tensor of rank 8 of format (3, 6, 6) was formulated. To the best of our knowledge, this is probably the last open case when a generic tensor of some rank strictly smaller than the generic one is not identifiable. Theorem 3.5 of [22] proved that the number of decompositions is ≥ 6 . Moreover, [22] showed that the number of decompositions of format (3, 6, 6) of rank 8 is equal to the number of decompositions of a general tensor in $\text{Sym}^3 \mathbb{C}^3 \otimes \mathbb{C}^2 \otimes \mathbb{C}^2$, which is perfect with generic rank 8. We use the approach from §4.1 to show exactly 6 decompositions. Another approach based on a multihomogeneous trace test in [44] confirms this result.

To use the approach from §4.1, consider the Veronese embedding

$$v_3 : \mathbb{C}^3 \rightarrow \mathbb{C}^{10} \text{ where } (x, y, z) \mapsto (x^3, x^2y, x^2z, xy^2, xyz, xz^2, y^3, y^2z, yz^2, z^3).$$

We picked a random line $\mathcal{L} \subset \mathbb{C}^{40}$ and consider the irreducible curve

$$C := \left\{ (T, a_1, b_1, c_1, \dots, a_8, b_8, c_8) \mid \begin{array}{l} T = \sum_{i=1}^8 v_3(a_i) \otimes b_i \otimes c_i \in \mathcal{L} \\ (a_i)_1 = (b_i)_1 = 1 \text{ for } i = 1, \dots, 8 \end{array} \right\} \subset \mathcal{L} \times (\mathbb{C}^3 \times \mathbb{C}^2 \times \mathbb{C}^2)^8.$$

To compute a pseudowitness set for $\overline{\pi(C)}$, we need to compute $C \cap (\mathcal{M}_\pi \times (\mathbb{C}^3 \times \mathbb{C}^2 \times \mathbb{C}^2)^8)$ where $\mathcal{M}_\pi \subset \mathbb{C}^{40}$ is a general hyperplane. Consider the irreducible family of hyperplanes defined by the vanishing of linear equations of the form

$$(5) \quad \sum_{j=1}^{40} \alpha_j T_j + \sum_{j=1}^3 \beta_j \sum_{k=1}^8 (a_k)_j + \sum_{j=1}^2 \gamma_j \sum_{k=1}^8 (b_k)_j + \sum_{j=1}^2 \delta_j \sum_{k=1}^8 (c_k)_j = \epsilon.$$

By construction, this family is invariant under the natural action of the symmetric group S_8 and contains all hyperplanes of the form $\mathcal{M}_\pi \times (\mathbb{C}^3 \times \mathbb{C}^2 \times \mathbb{C}^2)^8$. After picking a random hyperplane \mathcal{H} of the form (5) and starting with one point on $C \cap \mathcal{H}$, we used monodromy loops via **Bertini** to compute additional points in $C \cap \mathcal{H}$ which stabilized to $1020 \cdot 8! = 41,126,400$. The trace test [63] confirms that this set of points is indeed equal to $C \cap \mathcal{H}$. After selecting a random hyperplane \mathcal{M}_π , we then computed $W = C \cap (\mathcal{M}_\pi \times (\mathbb{C}^3 \times \mathbb{C}^2 \times \mathbb{C}^2)^8)$ by deforming from $C \cap \mathcal{H}$ which yielded $|W| = 6 \cdot 8! = 241,920$. Since $\overline{\pi(C)} \cap \mathcal{M}_\pi = \mathcal{L}$ which has degree 1, $|\pi(W)| = 1$ thereby showing exactly 6 decompositions.

We summarize the result of this computation.

Computation 4.2. *Numerical algebraic geometry together with randomly selected linear spaces show (with high confidence) that a general tensor in $\text{Sym}^3 \mathbb{C}^3 \otimes \mathbb{C}^2 \otimes \mathbb{C}^2$ has exactly 6 decompositions.*

5. TENSOR DECOMPOSITION VIA APOLARITY

In [58], a technique generalizing Sylvester's algorithm was implemented by considering the kernel of the catalecticant map, which in turn is a graded summand of the apolar ideal. In principle, this apolarity technique can be used for any algebraic variety.

5.1. A uniform view of (Koszul) flattenings. Let V and V_i be arbitrary finite dimensional vector spaces over \mathbb{C} of dimensions n and n_i , respectively. For $-n \leq p \leq n$, let $\bigwedge^p V$ denote fundamental representations of $GL(V)$ where we interpret $\bigwedge^p = \bigwedge^{-p} V^*$ when $p < 0$. For a multi-index $I \in \mathbb{Z}^d$, let V_I denote the tensor product of fundamental representations

$$V_I := \bigwedge^{i_1} V_1 \otimes \bigwedge^{i_2} V_2 \otimes \dots \otimes \bigwedge^{i_d} V_d.$$

Note that $V_{1^d} := V_1 \otimes \dots \otimes V_d$. We may assume, up to reordering, that $i_j \geq 0$ for $j = 1, \dots, h$, $i_j < 0$ for $j = h+1, \dots, d$. We obtain linear maps $K_p: \bigwedge^p V \rightarrow \bigwedge^{p+1} V$ that depend linearly on V by way of the Koszul complex. Specifically, for $v \in V$ and $\varphi \in \bigwedge^p V$ define

$$\begin{aligned} K_p(v)(\varphi) &= \varphi \wedge v \text{ for } p \geq 0, \\ K_p(v)(\varphi) &= \varphi(v) \text{ for } p < 0. \end{aligned}$$

Now we consider the tensor product of many Koszul maps, which are linear maps on tensor products of fundamental representations that depend linearly on $T \in V_{(1, \dots, 1)} := V_1 \otimes \dots \otimes V_d$:

$$K_I(T): V_I \rightarrow V_{I+1^d}.$$

For indecomposable elements $v_1 \otimes \dots \otimes v_d \in V_1 \otimes \dots \otimes V_d$ and $\varphi_1 \otimes \dots \otimes \varphi_d \in V_I$ define

$$(6) \quad K_I(v_1 \otimes \dots \otimes v_d)(\varphi_1 \otimes \dots \otimes \varphi_d) = \bigotimes_{j=1}^h (\varphi_j \wedge v_j) \otimes \bigotimes_{j=h+1}^d (\varphi_j(v_j)).$$

The definition of K_I is extended by bi-linearity. We often drop the argument (v) or (T) of K_p or K_I when the tensor to be flattened is not specified and the linear dependence is understood. From this definition it is clear that the image of $K_I(v_1 \otimes \dots \otimes v_d)$ is isomorphic to

$$\bigotimes_{j=1}^h \left(\bigwedge^{i_j} (V_j / \langle v_j \rangle) \otimes (v_j) \right) \otimes \bigotimes_{j=h+1}^d \left(\bigwedge^{-i_j-1} (v_j^\perp) \right).$$

A consequence of dimension counting, bi-linearity of K_I , and sub-additivity of matrix rank is the following, which is essentially described in [50, Prop. 4.1].

Proposition 5.1. *Suppose $T \in V_{1, \dots, 1}$ has tensor rank r . Let $i_j \geq 0$ for $j = 1, \dots, h$, $i_j < 0$ for $j = h+1, \dots, d$. Then the Koszul flattening $K_I(T): V_I \rightarrow V_{I+1^d}$ has rank at most*

$$r_I := r \cdot \prod_{j=1}^h \binom{n_j - 1}{i_j} \cdot \prod_{j=h+1}^d \binom{n_j - 1}{-i_j - 1}.$$

In particular, the $(r_I + 1) \times (r_I + 1)$ minors of $K_I(T)$ vanish. This is meaningful provided that $r_I < \min\{\dim V_I, \dim V_{I+1^d}\}$.

Let $m = \prod_{j=1}^h \binom{n_j - 1}{i_j} \cdot \prod_{j=h+1}^d \binom{n_j - 1}{-i_j - 1}$. The proposition says that for all tensors T with $\text{rank}(T) = r$ we have $\text{rank}(K_I(T)) \geq r \cdot m$. Thus, Koszul flattenings potentially provide the most useful information whenever the following ratio is maximized:

$$\min \{ \dim V_I, \dim V_{I+1^d} \} / m.$$

When $rm \leq \min \{ \dim V_I, \dim V_{I+1^d} \}$ we say that the flattening can detect rank r since we expect that the flattening $K_I(T)$ will have different ranks when T has rank either $r - 1$ or r

(this is true in all the examples we have tried, including the ones occurring in Theorems 1.1 and 1.2) and there is no obstruction to this based solely on the size of the flattening matrix.

5.2. Apolarity Lemma for Koszul flattenings. Recall from (6) that

$$K_I(v_1 \otimes \dots \otimes v_d) \equiv 0 \iff \bigotimes_{j=1}^h (\varphi_j \wedge v_j) \otimes \bigotimes_{j=h+1}^d (\varphi_j(v_j)) = 0$$

for all pure tensors $\varphi \in V_I$.

It is useful to look at tensors in the kernel of $K_I(T)$ as linear maps. With this aim, we need to distinguish the negative and nonnegative parts of $I \in \mathbb{Z}^d$. So let $N \sqcup P = \{1, \dots, d\}$ be the set partition such that $-I_N \in \mathbb{Z}_{>0}^d$, $I_P \in \mathbb{Z}_{\geq 0}^d$ and the notation I_P (resp. I_N) is the vector in \mathbb{Z}^d gotten by keeping the elements of I in the positions P (resp. N) and setting the rest of the entries to zero. We also let 1_P denote the vector with ones in the positions denoted by the index P (and zero elsewhere), and similarly for 1_N . With this, we may identify $V_I = V_{I_P+I_N} = \text{Hom}(V_{-I_N}, V_{I_P})$, and consider the Koszul flattening of $T \in V_{(1, \dots, 1)}$ as

$$K_I(T): \text{Hom}(V_{-I_N}, V_{I_P}) \rightarrow \text{Hom}(V_{-I_N+1_N}, V_{I_P+1_P}).$$

Up to reordering the factors, $K_I(T)$ is defined on decomposable elements $\left(\bigotimes_{j \in I_N} w_j\right)$ by

$$K_I(v_1 \otimes \dots \otimes v_d)(\psi) \left(\bigotimes_{j \in I_N} w_j\right) = \psi \left(\bigotimes_{j \in I_N} (w_j \wedge v_j)\right) \wedge \left(\bigotimes_{j \in I_P} v_j\right) \quad \forall \psi \in \text{Hom}(V_{-I_N}, V_{I_P}).$$

In our setting, [50, Prop. 5.4.1] yields the following lemma (see (9) for a concrete case). Since this technique refers to a vector bundle, it could be called “nonabelian” apolarity, in contrast with classical apolarity which refers to a line bundle (see [50, Ex. 5.1.2] and [58, § 4]).

Lemma 5.2 (Apolarity Lemma). *Suppose $T = \sum_{s=1}^r v_1^s \otimes \dots \otimes v_d^s$.*

$$\ker K_I(T) \supset \left\{ \psi \in \text{Hom}(V_{-I_N}, V_{I_P}) \mid \psi \left(V_{-I_N+1_N} \wedge \bigotimes_{j \in N} v_j^s \right) \wedge \left(\bigotimes_{j \in P} v_j^s \right) = 0 \text{ for } s = 1, \dots, r \right\}.$$

Proof. Pick ψ in the space on the right hand side of the inclusion. Choosing any $w_j \in V_{-I_N+1_N}$ for every $j \in I_N$, we have

$$K_I \left(\sum_{s=1}^r v_1^s \otimes \dots \otimes v_d^s \right) (\psi) \left(\bigotimes_{j \in I_N} w_j \right) = \sum_{s=1}^r \psi \left(\bigotimes_{j \in I_N} (w_j \wedge v_j^s) \right) \wedge \left(\bigotimes_{j \in I_P} v_j^s \right)$$

and each summand vanishes by the assumption. \square

5.3. The $3 \times 4 \times 5$ case. Let us denote the three factors as $A = \mathbb{C}^3$, $B = \mathbb{C}^4$, $C = \mathbb{C}^5$. The following are all possible relevant non-redundant Koszul flattenings (up to transpose), which all depend linearly on $A \otimes B \otimes C$.

$$\begin{aligned} K_{(0,-1,-1)}: (B \otimes C)^* &\rightarrow A, & K_{(-1,0,-1)}: (A \otimes C)^* &\rightarrow B, & K_{(-1,-1,0)}: (A \otimes B)^* &\rightarrow C \\ K_{(1,0,-1)}: C^* \otimes A &\rightarrow B \otimes \wedge^2 A, & K_{(-1,0,2)}: A^* \otimes \wedge^2 C &\rightarrow B \otimes \wedge^3 C \\ K_{(0,1,-1)}: C^* \otimes B &\rightarrow A \otimes \wedge^2 B, & K_{(-1,1,0)}: A^* \otimes B &\rightarrow C \otimes \wedge^2 B, \end{aligned}$$

$$K_{(-1,0,1)}: A^* \otimes C \rightarrow B \otimes \Lambda^2 C \quad , \quad K_{(0,-1,1)}: B^* \otimes C \rightarrow A \otimes \Lambda^2 C,$$

Consider

$$K_u(T): \Lambda^{u_1} A \otimes \Lambda^{u_2} B \otimes \Lambda^{u_3} C \rightarrow \Lambda^{u_1+1} A \otimes \Lambda^{u_2+1} B \otimes \Lambda^{u_3+1} C,$$

where, for any vector space V , we interpret negative exterior powers by asserting that $\Lambda^s V = \Lambda^{-s} V^*$ if $s < 0$.

For example $K_{0,-1,-1}(a \otimes b \otimes c)$ has image

$$(\Lambda^0 A \wedge a) \otimes (B^*(b)) \otimes (C^*(c)) \subset \Lambda^1 A \otimes \Lambda^0 B \otimes \Lambda^0 C.$$

The factor $(B^*(b)) \otimes (C^*(c))$ is just any scalar, obtained by contracting b with B^* , and c with C^* . We are left with $(\Lambda^0 A \wedge a) = \langle a \rangle$, which is 1-dimensional.

Another example is $K_{0,1,-1}(a \otimes b \otimes c)$ which has image

$$(\Lambda^0 A \wedge a) \otimes (\Lambda^1 B \wedge b) \otimes (C^*(c)) \subset \Lambda^1 A \otimes \Lambda^2 B \otimes \Lambda^0 C.$$

The factor $C^*(c)$ is a scalar obtained by contracting c with C^* . This leaves $(\Lambda^0 A \wedge a) = \langle a \rangle$ tensored with $(\Lambda^1 B \wedge b) \subset \Lambda^2 B$, but $(\Lambda^1 B \wedge b) \cong (B/b) \otimes \langle b \rangle$, which is 3-dimensional.

In general, the image of $K_u(a \otimes b \otimes c)$ has dimension

$$(7) \quad \binom{\dim A - 1}{f(u_1)} \binom{\dim B - 1}{f(u_2)} \binom{\dim C - 1}{f(u_3)}.$$

where $f(x) = \begin{cases} x & \text{if } x \geq 0 \\ -x - 1 & \text{if } x < 0 \end{cases}$. On the other hand, the maximum rank that K_u can have is the minimum of the dimensions of the source and the target, or

$$(8) \quad \min \left\{ \binom{\dim A}{|u_1|} \binom{\dim B}{|u_2|} \binom{\dim C}{|u_3|}, \binom{\dim A}{|u_1 + 1|} \binom{\dim B}{|u_2 + 1|} \binom{\dim C}{|u_3 + 1|} \right\}.$$

Since the matrix rank of a Koszul flattening of a tensor T is bounded above by a multiplicative factor (7) of the tensor rank of T , the maximum tensor rank that a Koszul flattening can detect by a drop in matrix rank is the ratio of (8) and (7). For convenience we record the dimensions and the multiplication factor (7) for each flattening.

map	size	mult-factor	max tensor rank detected
$K_{(0,-1,-1)}$	3×20	1	3
$K_{(-1,0,-1)}$	4×15	1	4
$K_{(-1,-1,0)}$	5×12	1	5
$K_{(1,-1,0)}$	15×12	2	6
$K_{(1,0,-1)}$	12×15	2	6
$K_{(0,1,-1)}$	18×20	3	6
$K_{(-1,1,0)}$	12×30	3	4
$K_{(-1,0,1)}$	40×15	4	4
$K_{(0,-1,1)}$	30×20	4	5
$K_{(-1,0,2)}$	40×30	6	5
$K_{(0,-1,2)}$	30×40	6	5
$K_{(0,-1,2)}$	30×40	6	5

We see that the only maps that might distinguish between tensor rank 5 and 6 are $K_{(1,-1,0)}$, $K_{(1,0,-1)}$, and $K_{(0,1,-1)}$. Since $\wedge^2 A \cong A^*$, the first two maps are transposes of each other:

$$K_{(1,-1,0)} = (K_{(1,0,-1)})^t.$$

Thus, we proceed by considering $K_{(1,0,-1)}$ and $K_{(0,1,-1)}$.

In our case, Apolarity Lemma 5.2 says that

$$(9) \quad \ker K_{1,0,-1}(\sum_{i=1}^s a_i b_i c_i) \supset \{\varphi \in \text{Hom}(C, A) \mid \varphi(c_i) \wedge a_i = 0 \text{ for } i = 1, \dots, s\}.$$

and

$$\ker K_{0,1,-1}(\sum_{i=1}^s a_i b_i c_i) \supset \{\varphi \in \text{Hom}(C, B) \mid \varphi(c_i) \wedge b_i = 0 \text{ for } i = 1, \dots, s\}.$$

Equality should hold for honest decompositions, see [50, Prop. 5.4.1].

With this setup, we now present a proof of Theorem 1.1.

Proof of Theorem 1.1. For general $f \in A \otimes B \otimes C$, $K_{1,0,-1}(f)$ is surjective and $\ker K_{1,0,-1}(f)$ has dimension $\dim \text{Hom}(C, A) - \dim \wedge^2 A \otimes B = 15 - 12 = 3$. To complete the proof we interpret the linear map $K_{1,0,-1}(f)$ as a map between sections of vector bundles. Let $X = \mathbb{P}(A) \times \mathbb{P}(B) \times \mathbb{P}(C)$, endowed with the three projections π_A, π_B, π_C on the three factors. We denote $\mathcal{O}(\alpha, \beta, \gamma) = \pi_A^* \mathcal{O}(\alpha) \otimes \pi_B^* \mathcal{O}(\beta) \otimes \pi_C^* \mathcal{O}(\gamma)$. Let Q_A be the pullback of the quotient bundle on $\mathbb{P}(A)$.

Let $E = Q_A \otimes \mathcal{O}(0, 0, 1)$ and $L = \mathcal{O}(1, 1, 1)$. Note that E is a rank two bundle on X . As in [50, 58], the map $K_{1,0,-1}(f)$ can be identified with the contraction

$$K_{1,0,-1}(f): H^0(E) \longrightarrow H^0(E^* \otimes L)^*$$

which depends linearly on $f \in H^0(L)^*$.

The general element in $H^0(E)$ vanishes on a codimension two subvariety of X which has the homology class $c_2(E) \in H^*(X, \mathbb{Z})$. The ring $H^*(X, \mathbb{Z})$ has three canonical generators t_A, t_B, t_C and it can be identified with $\mathbb{Z}[t_A, t_B, t_C]/(t_A^3, t_B^4, t_C^5)$. Since the rank of Q_A is 2 and $\mathcal{O}(0, 0, 1)$ is a line bundle, we have the well known formula $c_2(E) = c_2(Q_A) + c_1(Q_A)c_1(\mathcal{O}(0, 0, 1)) + c_1^2(\mathcal{O}(0, 0, 1))$. We have $c_1(Q_A) = t_A$, $c_2(Q_A) = t_A^2$, $c_1(\mathcal{O}(0, 0, 1)) = t_C$ and we compute $c_2(E) = t_A^2 + t_A t_C + t_C^2$. Hence three general sections of $H^0(E)$ have their common base locus given by $c_2(E)^3 = (t_A^2 + t_A t_C + t_C^2)^3 = 6t_A^2 t_C^4$. This coefficient 6 coincides with the generic rank and it is the key of the computation. Terracini's lemma (see [49, Cor. 5.3.1.2]), using a simple tangent space computation, verifies that the generic rank is indeed 6. We pick a tensor $f = \sum_{i=1}^6 a_i b_i c_i$ constructed with six random points $(a_i, b_i, c_i) \in \mathbb{P}(A) \times \mathbb{P}(B) \times \mathbb{P}(C)$ for $i = 1, \dots, 6$. By using Macaulay2 (see the Macaulay2 file attached at the arXiv version of this paper) we may compute that the variety

$$\{(a, c) \in \mathbb{P}(A) \times \mathbb{P}(C) \mid \varphi(c) \wedge a = 0 \quad \forall \varphi \in \ker K_{1,0,-1}(f)\}$$

consists of the union of six points (a_i, c_i) for $i = 1, \dots, 6$, and this holds even scheme-theoretically. It follows that equality holds in (9) with $s = 6$, indeed $K_{1,0,-1}(f)$ is surjective and has 3-dimensional kernel, while the right-hand side of (9) has dimension at least $\dim \text{Hom}(C, A) - 6 \cdot 2 = 3$. Moreover the common base locus of $\ker K_{1,0,-1}(f)$ is given by 6 linear spaces $\{a_i\} \times \mathbb{P}(B) \times \{c_i\}$ for $i = 1, \dots, 6$.

We claim that the common base locus of $\ker K_{1,0,-1}(f)$ is given by 6 linear spaces as above for general tensor f . Indeed, the common zero locus of three sections of E can be seen

as the zero locus of a section of $E^{\oplus 3}$. The dimension of the zero locus of a section of $E^{\oplus 3}$ is at least $9 - 6 = 3$ and it is upper semicontinuous with respect to the section, hence the common base locus of $\ker K_{1,0,-1}(f)$ is a pure-dimensional 3-fold for general f . Since the top Chern class of $E^{\oplus 3}$ is $c_2(E)^3$, which we computed to be $6t_A^2 t_C^4$, we know that the common base locus of $\ker K_{1,0,-1}(f)$ comes from a 0-dimensional scheme of degree 6 on $\mathbb{P}(A) \times \mathbb{P}(C)$, after a pullback with π_B , by [29, Prop. 14.1 (b)]. Since this 0-dimensional scheme consists of 6 distinct points for the tensor f that we have picked, this property remains true for general f .

In particular, the decomposition $f = \sum_{i=1}^6 a_i \otimes b_i \otimes c_i$ has a unique solution (up to scale) for a_i and c_i . After a_i, c_i have been determined, the remaining vectors b_i can be recovered uniquely by solving a linear system. \square

Remark 5.3. If we attempt to repeat the same proof using $K_{0,1,-1}$ in place of $K_{1,0,-1}$ most parts go through unchanged. The map $K_{0,1,-1}(T): C^* \otimes B \rightarrow A \otimes \wedge^2 B$ is 18×20 , and general element T produces a 2-dimensional kernel. Then, we consider the intersection of two general sections of $H^0(E) = \text{Hom}(C, B)$, where now $E = Q_B \otimes \mathcal{O}(0, 0, 1)$. The top Chern class of E is (by a similar calculation as in the proof of Theorem 1.1)

$$4t_B^3 t_C^3 + 3t_B^2 t_C^4.$$

This gives that the common base locus of $\ker K_{0,1,-1}(T)$ is given by a degree 7 curve on the Segre product $\text{Seg}(\mathbb{P}(C) \times \mathbb{P}(B))$. This curve necessarily contains the 6 points needed to decompose T , but information from another Koszul flattening is needed to find them.

Remark 5.4. For the $(3, 4, 5)$ format, we can even decompose a general tensor T of any rank r between 1 and 6. The trick is to add to T the sum of $6 - r$ general decomposable tensors, find the unique decomposition with the algorithm described in the proof of Theorem 1.1, and subtract the $6 - r$ tensors that have to appear in the decomposition. Unfortunately, this technique cannot work in other cases if we do not have a tensor decomposition to start with.

5.4. The ≥ 4 factor case. We have seen that general tensors of format $(2, n, n)$ and $(3, 4, 5)$ are identifiable. We asked if there are other formats with this property when there are ≥ 4 factors. To our surprise, the numerical homotopy method predicted an additional case where identifiability holds. Our construction of Koszul flattenings and multi-factor apolarity above allows us to prove this fact, which we prove next.

5.5. The $2 \times 2 \times 2 \times 3$ case. For this part, let $A \cong B \cong C \cong \mathbb{C}^2$ and $D \cong \mathbb{C}^3$. Because of the small dimensions we are considering, the number of interesting Koszul flattenings for tensors in $A \otimes B \otimes C \otimes D$ is limited to the following maps, which depend linearly on $A \otimes B \otimes C \otimes D$.

The 1-flattenings (and their transposes):

$$\begin{aligned} K_{-1,0,0,0}: A^* &\rightarrow B \otimes C \otimes D, & K_{0,-1,0,0}: B^* &\rightarrow A \otimes C \otimes D, \\ K_{0,0,-1,0}: C^* &\rightarrow A \otimes B \otimes D, & K_{0,0,0,-1}: D^* &\rightarrow A \otimes B \otimes C, \end{aligned}$$

which detect a maximum of rank 2 in the first 3 cases and a maximum of rank 3 in the last.

The 2-flattenings (and their transposes):

$$K_{0,0,-1,-1}: C^* \otimes D^* \rightarrow A \otimes B, \quad K_{0,-1,0,-1}: B^* \otimes D^* \rightarrow A \otimes C,$$

$$K_{-1,0,0,-1}: A^* \otimes D^* \rightarrow B \otimes C.$$

The maps are all 4×6 and detect a maximum of tensor rank 4.

Remark 5.5. For $(2,2,2,2)$, it is known that only two of the three 2-flattenings are algebraically independent, and the dependency of the third on the other two is “responsible” for the defectivity of the 3rd secant variety $\sigma_3(\mathbb{P}^1 \times \mathbb{P}^1 \times \mathbb{P}^1 \times \mathbb{P}^1)$. This secant variety has one dimension less than expected. This type of Segre variety was indeed studied by C. Segre [61].

The higher Koszul flattenings:

$$K_{-1,0,0,1}: A^* \otimes D \rightarrow B \otimes C \otimes \wedge^2 D, \quad K_{0,-1,0,1}: B^* \otimes C \rightarrow A \otimes C \otimes \wedge^2 D,$$

$$K_{0,0,-1,1}: C^* \otimes D \rightarrow A \otimes B \otimes \wedge^2 D$$

These maps are all 12×6 , and detect a maximum of rank 3.

We will proceed with the 2-flattenings in the following proof of Theorem 1.2 since they are the only flattenings that detect the difference between rank 3 and 4.

Proof of Theorem 1.2. Terracini’s lemma (see [49, Cor. 5.3.1.2]), using a tangent space computation, verifies the well known fact that the generic rank is 4. Suppose $T \in A \otimes B \otimes C \otimes D$ is general among tensors of rank 4 and write $T = \sum_{i=1}^4 a_i \otimes b_i \otimes c_i \otimes d_i$.

First consider the case $K_{0,0,-1,-1}: C^* \otimes D^* \rightarrow A \otimes B$. If T is general of rank 4, then $K_{0,0,-1,-1}(T)$ has rank 4, and must have a 2-dimensional kernel. Now, we apply (9). The points $\{c_i \otimes d_i\}$ must be contained in the common base locus of the elements in the kernel of $K_{0,0,-1,-1}(T)$. Let $X = \mathbb{P}(A) \times \mathbb{P}(B) \times \mathbb{P}(C) \times \mathbb{P}(D)$, endowed with the four projections $\pi_A, \pi_B, \pi_C, \pi_D$ on the four factors. We denote $\mathcal{O}(\alpha, \beta, \gamma, \delta) = \pi_A^* \mathcal{O}(\alpha) \otimes \pi_B^* \mathcal{O}(\beta) \otimes \pi_C^* \mathcal{O}(\gamma) \otimes \pi_D^* \mathcal{O}(\delta)$. Consider the line bundle $E = \mathcal{O}(0, 0, 1, 1)$ and $L = \mathcal{O}(1, 1, 1, 1)$ over X . The ring $H^*(X, \mathbb{Z})$ has four canonical generators t_A, t_B, t_C, t_D and it can be identified with $\mathbb{Z}[t_A, t_B, t_C, t_D]/(t_A^2, t_B^2, t_C^2, t_D^3)$. We have $c_1(E) = t_C + t_D$. As in the proof of Theorem 1.1, the common base locus of the 2-dimensional kernel of $K_{0,0,-1,-1}(T)$ may be seen as the zero locus of a section of $E^{\oplus 2} = \mathcal{O}(0, 0, 1, 1)^{\oplus 2}$, which has top Chern class $c_1^2(E)$. Since $c_1^2(E) = 2t_C t_D + t_D^2$, we get $c_1^2(E)t_C = 1 \cdot t_C t_D^2$, $c_1^2(E)t_D = 2 \cdot t_C t_D^2$. It follows that two general sections of E have common base locus given by a cubic curve, denoted $\mathcal{C}_{C,D}$ of bi-degree $(1, 2)$ on $\text{Seg}(\mathbb{P}(C) \times \mathbb{P}(D))$, pulled back to a codimension 2 subvariety of X . The projection to $\mathbb{P}(D)$ is a conic, which we denote \mathcal{Q}_C .

Similarly for the next 2-flattening, $K_{0,-1,0,-1}: B^* \otimes D^* \rightarrow A \otimes C$, we repeat the same process, where all the dimensions and bundles are the same except for a change of roles of C and B . By the same method we obtain another conic \mathcal{Q}_B in $\mathbb{P}(D)$.

Finally, if \mathcal{Q}_C and \mathcal{Q}_B are general, Bézout’s theorem implies that they intersect in 4 points in $\mathbb{P}(D)$, say $\{[d_1], [d_2], [d_3], [d_4]\}$. Like in the proof of Theorem 1.1 we can check, using a Macaulay2 script, that starting from $T = \sum_{i=1}^4 a_i b_i c_i d_i$ with $(a_i, b_i, c_i, d_i) \in X$ for $i = 1, \dots, 4$, we get that the conics found by the above procedure intersect exactly in $\{[d_1], [d_2], [d_3], [d_4]\}$. By semicontinuity, like in the proof of Theorem 1.1, we have that the intersection between the common base locus of the kernel of $K_{0,0,-1,-1}(T)$ and the common base locus of the kernel of $K_{0,-1,0,-1}(T)$, corresponding to the class $(2t_C t_D + t_D^2)(2t_B t_D + t_D^2) = 4t_B t_C t_D^2$, consists of the pullback under π_A of four distinct points on $\mathbb{P}(B) \times \mathbb{P}(C) \times \mathbb{P}(D)$, for general T , namely of the 4 linear spaces $\mathbb{P}(A) \times \{b_i\} \otimes \{c_i\} \times \{d_i\}$. In particular, the

decomposition $T = \sum_{i=1}^4 a_i \otimes b_i \otimes c_i \otimes d_i$ has a unique solution (up to scale) for b_i , c_i and d_i . After b_i , c_i , d_i have been determined, the remaining vectors a_i can be recovered uniquely by solving the linear system $T = \sum_{i=1}^4 a_i \otimes b_i \otimes c_i \otimes d_i$. \square

6. CONCLUSION

By using a numerical algebraic geometric approach based on monodromy loops, we are able to determine the number of decompositions of a general tensor. Since this approach determined that general tensors of format $(3, 4, 5)$ and $(2, 2, 2, 3)$ have a unique decomposition, we developed explicit proofs for these two special cases. With the classically known generically identifiable case of matrix pencils, i.e., format $(2, n, n)$, we conjecture these are the only cases for which a general tensor has a unique decomposition.

We are currently researching other applications of this monodromy-based approach, including determining identifiability in biological models [8].
