Abstract

We recently introduced a new approach to the evaluation of weight of evidence (WoE) for Y-chromosome profiles. Rather than attempting to calculate match probabilities, which is particularly problematic for modern Y-profiles with high mutation rates, we proposed using simulation to describe the distribution of the number of males in the population with a matching Y-profile, both the unconditional distribution and conditional on a database frequency of the profile. Here we further validate the new approach by showing that our results are robust to assumptions about the allelic ladder and the founder haplotypes, and we extend the approach in two important directions. Firstly, forensic databases are not the only source of background data relevant to the evaluation of Y-profile evidence: in many cases the Y-profiles of one or more relatives of the accused are also available. To date it has been unclear how to use this additional information, but in our simulation-based approach its effect is readily incorporated. We describe this approach and illustrate how the WoE that a man was the source of an observed Y-profile changes when the Y-profiles of some of his male-line relatives are also available. Secondly, we extend our new approach to mixtures of Y-profiles from two or more males. Surprisingly, our simulation-based approach reveals that observing a 2-male mixture that includes an alleged contributor's profile is almost as strong evidence as observing a matching single-contributor evidence sample, and even 3-male and 4-male mixtures are only slightly weaker.

Y-profile evidence: close paternal relatives and mixtures

Abstract

We recently introduced a new approach to the evaluation of weight of evidence (WoE) for Y-chromosome profiles. Rather than attempting to calculate match probabilities, which is particularly problematic for modern Y-profiles with high mutation rates, we proposed using simulation to describe the distribution of the number of males in the population with a matching Y-profile, both the unconditional distribution and conditional on a database frequency of the profile. Here we further validate the new approach by showing that our results are robust to assumptions about the allelic ladder and the founder haplotypes, and we extend the approach in two important directions. Firstly, forensic databases are not the only source of background data relevant to the evaluation of Y-profile evidence: in many cases the Y-profiles of one or more relatives of the accused are also available. To date it has been unclear how to use this additional information, but in our simulation-based approach its effect is readily incorporated. We describe this approach and illustrate how the WoE that a man was the source of an observed Y-profile changes when the Y-profiles of some of his male-line relatives are also available. Secondly, we extend our new approach to mixtures of Y-profiles from two or more males. Surprisingly, our simulation-based approach reveals that observing a 2-male mixture that includes an alleged contributor's profile is almost as strong evidence as observing a matching single-contributor evidence sample, and even 3-male and 4-male mixtures are only slightly weaker.

Introduction

In [1], we presented a radically simple new approach to the evaluation of weight of evidence (WoE) for Y-chromosome profiles. We showed using simulation that sets of males with the same Y-profile typically number up to a few tens, and rarely more than a few hundreds, almost all of them related within a few tens of meioses. Our simulation model is implemented in open-source and easy-to-use R software `malan` [2], allowing these distributions to be approximated under different assumptions about the variance in reproductive success (VRS) and the population size and growth rate. We also showed how the distribution of $|\Omega|$, the number of males with the same Y-profile as an alleged source Q , is affected by conditioning on a database count of the profile. In particular, we noted that a zero count in a database of up to a few thousand profiles conveys little information, since

29 from the mutation rate we expect any profile to be rare, which is reflected in the unconditional
30 distribution of $|\Omega|$.

31 In some cases the Y-profiles of one or more male-line relatives of Q may also be available.
32 This information also affects the distribution of $|\Omega|$, and here we use a simple modification of our
33 simulation model to investigate its effect on the WoE. Any patrilineal relative observed to have a
34 Y-profile not matching that of Q decreases $|\Omega|$ in distribution, and hence tends to increase the WoE
35 for Q to be the source of the evidence profile. Conversely a matching relative tends to increase $|\Omega|$
36 and so weaken the WoE. Note that if the relative's Y-profile differs from that of Q at multiple loci
37 then the proposed biological relationship may be called into question; we do not consider further
38 here the possibility of a mis-specified relationship.

39 Suppose that, rather than observing a profile matching that of Q, we observe a mixture of
40 the Y-profiles of two or more males such that the profile of Q is "included in the mixture" (every
41 allele in the profile of Q is observed in the mixed profile). Then, because there can be millions of
42 distinct profiles that are included in the mixture, it is typically assumed that the WoE for Q to
43 be a contributor is correspondingly weaker than in a single-contributor case. We show that this
44 intuition is incorrect. This is because the number of distinct Y-profiles that actually arise in a
45 real human population is only a minuscule fraction of the possible profiles given the alleles at each
46 locus. Therefore, although there are many alternative profile combinations that could explain the
47 observed mixture, the great majority of these combinations do not exist in the population, whereas
48 the profile of Q has been observed and is likely to also exist in his close relatives. We show that a
49 2-male mixture that includes Q has almost exactly the same evidential value as a single-contributor
50 match, and 3-male and 4-male mixtures are only slightly weaker.

51 Before tackling the above two major goals of this paper, we provide further support for our
52 simulation-based approach by showing that our results are robust to assumptions about the allelic
53 ladder of the mutation model, and the method of allocation of haplotypes to founders. In [1] we
54 assumed an unbounded allelic ladder and that all founders were assigned the same haplotype. Here
55 we adopt more realistic assumptions, but first confirm that this change makes little difference to
56 the results.

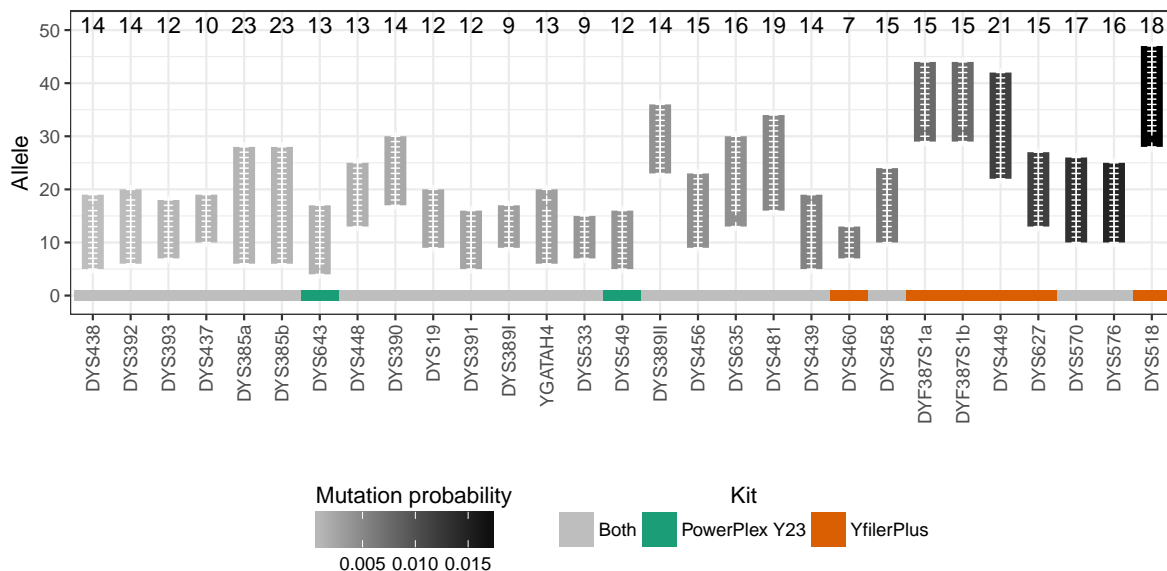

57 **Methods and materials**58 **Profiling kits, allelic ladders and founder haplotypes**

Figure 1: **Profiling kits and allelic ladders.** Only integer alleles are included, not alleles with partial repeats. Vertical bars indicate the ladders, with a “+” for each observed allele, shaded according to the estimated locus mutation rate per generation as indicated in the legend. The size of each allelic ladder is given above the bar. Data are from YHRD.org release 55 [3].

59 We consider two Y-chromosome short tandem repeat (STR) profiling kits: PowerPlex Y23
 60 (23 loci) and Yfiler Plus (27 loci). As in [1], we continue to consider only integer alleles in our
 61 simulations, but they are now bounded by L (lower) and U (upper). An L allele can only mutate
 62 to $L+1$, while a U allele can only mutate to $U-1$. All other alleles remain equally likely to increase
 63 or decrease at a mutation, and the mutation rate is the same for all alleles at a locus. The values
 64 of L and U are specified at each locus corresponding to the integer alleles in YHRD.org release 55
 65 [3] (see Fig. 1). For comparison, we also considered a tiny ladder of size 3 (alleles -1 , 0 and 1).

66 In [1], all founders in the population simulation got the same haplotype. This implied that if
 67 few mutations occurred since their founders, two live individuals could have matching haplotypes
 68 despite descending from distinct founders. We set the number of generations such that this was

69 very unlikely, but for further realism we consider here two different ways of assigning haplotypes
70 to founders:

- 71 • Uniformly random choices from the (integer) allelic ladder, independently at each locus.
- 72 • Haplotypes sampled at random with replacement from a contemporary Danish database of
73 185 males [4]. We removed profiles with three alleles at D_{YF}387S1, non-integer alleles, or
74 null alleles, leaving 181 PowerPlex Y23 profiles and 171 Yfiler Plus profiles.

75 Population simulations

76 We used our R package `malan` [1, 2, 5] to simulate 10 population genealogies: an initial population
77 of 5,000 Y chromosomes reproduces for 100 generations, followed by growth at a rate of 2% per
78 generation for 150 generations, creating a final population size of 102K. Thus, the number of
79 live males (total of final three generations) is close to 300K. The VRS was fixed here at 0.2; see
80 Fig. A1 for the distributions of the number of sons and brothers of each male. To each population
81 simulation we applied two allelic ladders (bounded/unbounded) for each of three assignments of
82 founder haplotypes (same/random/database) and each of two kits (PowerPlex Y23/Yfiler Plus).
83 Following [1], we used mutation count data [3] with a Beta(1.5, 200) prior distribution at each locus
84 to obtain a posterior distribution from which the mutation rate was sampled, independently over
85 loci. Mutations were simulated 10 times for each simulated population, with rates re-sampled each
86 time.

87 In each simulation 5,000 males (Q) were drawn at random and for each we recorded $|\Omega|$, the
88 number of live males with the same haplotype (including Q). Thus, for each of the 12 ladder /
89 founder / kit combinations, the distribution of $|\Omega|$ was estimated based on 10 (genealogies) \times
90 10 (mutation replicates) \times 5,000 (choices of Q) = 5×10^5 cases. In each simulation, information
91 about the profiles of close paternal relatives of Q was also recorded, so that we could approximate
92 the distribution of $|\Omega|$ conditional on the profile status of different relatives.

93 For comparison, we include below results from [1] which used a slightly different population
94 simulation that we now briefly recap: 250 generations; growth of 2% in all generations; initial
95 population size of 7,365 rising to 10^6 in the final generation (in our new simulations, the growth
96 rate is the same but for fewer generations, and initial and final population sizes are both smaller).
97 Ten genealogies were simulated; mutation rates were sampled 100 times per genealogy (c.f. 10 here);

98 only an unbounded allelic ladder was considered with the same haplotype for each founder, and
 99 1,000 Q were sampled per simulation.

100 Mixed profiles

101 In general, the preferred measure of the WoE for Q to be a contributor to an evidence sample
 102 is the likelihood ratio (LR) [6]. When the evidence sample shows exactly his profile q , the LR
 103 is the inverse of a (conditional) match probability, but if we know the Y-haplotype counts in the
 104 population of N alternative sources of the evidence profile, then the conditioning is irrelevant and
 105 the LR simplifies to

$$LR_1 = \frac{N}{n_q}, \quad (1)$$

106 where we introduce the notation n_a for the count of haplotype a in the population. In [1], we
 107 did not recommend reporting LR_1 , because the population size N relevant to a crime scenario is
 108 often highly uncertain. Instead we recommended reporting an estimate of the haplotype count
 109 $n_q = N/LR_1$.

110 Suppose now that the evidence profile m has two different alleles at h loci, and no more than
 111 two alleles at any locus. There are 2^{h-1} possible profile pairs that could have produced the mixture,
 112 which is the number of ways of choosing one allele from m at each locus, and ignoring the order of
 113 the resulting profile pair. Suppose also that an alleged contributor Q has profile q that is included
 114 in m . Then a relevant LR to consider compares the hypothesis H_p , that m arises from Q and an
 115 unknown male U, relative to the alternative H_d that m arises from two unknown males [6]. Under
 116 H_p the profile u of U can be inferred from q and m , without error if we assume no missing data or
 117 null alleles, and no duplications or heteroplasmy, so both q and u have exactly one allele at each
 118 locus. Still assuming that the n_a are known in the population of possible sources of m , we have:

$$LR_2 = \frac{P(m | H_p)}{P(m | H_d)} = \frac{n_u/N}{\sum_{r,s} (n_r/N)(n_s/N)} = \frac{Nn_u}{\sum_{r,s} n_r n_s} \quad (2)$$

119 where the summation is over the 2^{h-1} unordered pairs of profiles (r, s) that combine to give m . LR_2
 120 can be interpreted as the probability that two profiles drawn at random in the population form m ,
 121 divided by the probability that a single profile drawn at random forms m when combined with q .
 122 If n_q , n_r and n_s are all of comparable magnitude then $LR_2 \approx LR_1/2^{h-1}$. For current Y-profiles,
 123 2^{h-1} can exceed one million, and so the WoE from a mixed evidence profile is usually considered
 124 to be much weaker than from a single-contributor evidence profile.

125 [3, 7] compute (2) directly, using observed database fractions in place of population fractions of
126 the form n_a/N . However, databases are not large enough for accurate estimation of these, small,
127 fractions. More importantly, the relatedness of males with the same haplotype means that they
128 may be clustered geographically and socially, meaning that the available databases are unlikely to
129 accurately represent the population of possible sources of the evidence profile in a specific case.

130 [8] used [9, 10] to obtain improved estimates of population fractions by modelling the haplotype
131 distribution as composed of clades of haplotypes each of which has arisen from one ancestral hap-
132 lotype by a small number of single-step mutations. Within each clade, independence is assumed
133 across loci and haplotype probabilities are computed using a mixture of discrete Laplace distribu-
134 tions. The population fraction of the haplotype is obtained as a weighted sum over the clades (the
135 weights correspond to the prior probability that a haplotype in the population originates from that
136 clade).

137 [11] further develop the clade idea, but recognise the importance of the fact that profile q has
138 been observed, which is typically not the case for other profiles included in the mixture. They
139 introduce a “haplotype centred” method to compute the LR, which uses the insight that, given the
140 observed profile of Q , the most likely source of a matching or similar profile is in a close patrilineal
141 relative of Q , as previously noted by [12].

142 The approach proposed here is different but based on a similar insight. We note that although
143 (q, u) is just one among many profile pairs that could contribute to the summation in (2), if q is
144 the only reference profile available to the investigation that is included in m , then (q, u) is expected
145 to provide the largest contribution to the sum. The number of different Y-profiles that actually
146 arise in any human population is a tiny fraction of the profiles that are possible. For example, just
147 the integer alleles of the 27 Yfiler Plus loci shown in Fig. 1 can generate more than 10^{31} distinct
148 profiles, whereas the worldwide human population is $< 10^{10}$. Thus, a random possible profile is
149 extremely unlikely to actually exist. In contrast, the fact that profile q has been observed in Q
150 implies that we expect it to exist in multiple male-line relatives of Q . Although we have no *a priori*
151 evidence for the existence of profile u , it is much more likely that one unobserved profile exists in
152 the population than that two unobserved profiles r and s both exist.

To quantify the extent to which the profile pair (q, u) dominates the summation in (2), we use
the 500K `malan` simulations described above in the case of bounded allelic ladder and database

founder haplotypes. From each simulation, we sample pairs of live males Q and U and form the mixed profile m . We then search the live population for other pairs of males whose mixed profile is also m . As for the single-contributor case, because of the problem of specifying N in practice, instead of LR_2 we recommend reporting

$$N/LR_2 = \frac{\sum_{r,s} n_r n_s}{n_u}.$$

Similarly we search for triples of males with mixed profile m matching that from Q and two other randomly-selected males, and report

$$N/LR_3 = \frac{\sum_{r,s,t} n_r n_s n_t}{\sum_{u,v} n_u n_v},$$

153 where each (r, s, t) in the sum is a triple of profiles that combine to form m , and (u, v) is a pair of
 154 profiles that when combined with q form m . The expression for N/LR_4 is analogous.

155 Results

156 Robustness to allelic ladder and founder haplotypes:

157 Quantiles of the distribution of $|\Omega|$, the number of males with the same Y-profile as Q, are shown
 158 in Table 1 for the different allelic ladders and methods of assigning founder haplotypes. See Fig. A2
 159 for plots. The distributions are similar for all conditions considered here. The biggest, but still
 160 small, impact arises from using a tiny ladder of size three at each locus. In the rest of the paper, we
 161 only show results for the bounded allelic ladder and database founder haplotypes unless otherwise
 162 noted.

163 Profiled male-line relatives:

164 If either the father or the paternal grandfather is observed not to match Q, then the distribution of
 165 $|\Omega|$ gives greatly increased support to low values, whereas a match shifts the distribution slightly
 166 towards higher values compared with the unconditional case (Fig. 2 and Table 2).

167 Fig. 3 and Table 2 describe the distribution of $|\Omega|$ given information about the match status of
 168 a specified patrilineal relative, or that there is no relative of the specified type. The effect of the
 169 latter information is seen to be intermediate between match and mismatch for that relative.

Allelic ladder	Founder haplotypes	95% quantile		99% quantile	
		PP23	YP	PP23	YP
Unbounded	Random	73	41	114	64
Unbounded	Same	73	41	114	64
	Previously published	73	41	115	63
Bounded	Random	73	41	115	64
Bounded	Database	73	41	115	64
Bounded	Same	74	41	115	63
$\{-1, 0, 1\}$	Random	77	42	120	65

Table 1: **Estimated quantiles of the distribution of $|\Omega|$, the number of males with the same Y-profile as Q.** See text for explanation of the allelic ladders (column 1) and the methods of assigning founder haplotypes (column 2). Row 3 gives results previously published in [1], similar to the case of Row 2 but with a slightly different demographic model as discussed in the text. PP23 = PowerPlex Y23; YP = Yfiler Plus.

170 While broadly in line with intuition, these results hold some surprises. In general, the closer
 171 the relative the greater is the effect of a mismatch in decreasing the distribution of $|\Omega|$, but the
 172 direction in time of the relationship is also important: a mismatching father is more important
 173 than a mismatching son, because the father has more descendants. Similarly, a grandfather is more
 174 informative than a brother. Moreover, a mismatching brother has only slightly greater impact
 175 on the quantiles of $|\Omega|$ than a mismatching cousin: a brother relationship is closer but a cousin
 176 relationship traverses one extra generation backward in time and is informative about the grandfa-
 177 ther. For matches, more distant relatives are more informative, with a matching cousin being most
 178 informative among the relationships considered here, but because a cousin is expected to match
 179 the impact of this information on the distribution of $|\Omega|$ is modest.

180 In Fig. 4 the match/mismatch information comes from all the brothers of Q, for Q with between
 181 one and three brothers. For Q with two or three brothers, all of them with a Y-profile different
 182 from Q, the distribution of $|\Omega|$ is similar to the case that Q is found not to match his father.

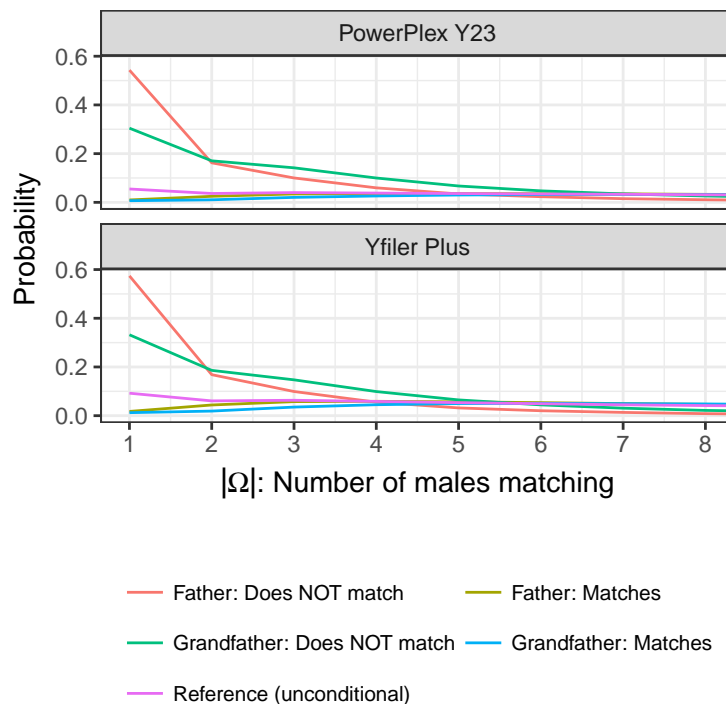

Figure 2: **Distribution of $|\Omega|$ given father/grandfather profile match information.** “Unconditional” means without information about the Y-profile of any relative of Q . The other lines correspond to match/mismatch information as indicated in the legend.

183 Mixed profiles:

184 For 97% of 2-male Yfiler Plus (YP) mixed profiles, the mixture cannot be formed from any other
 185 pair of profiles that actually exists in the population (Table 3, second row). In that case, a mixed
 186 evidence profile is equivalent to an evidence profile exactly matching q . This equivalence holds for
 187 93% of 2-male PowerPlex Y23 (PP23) mixtures; for 56% (YP) and 42% (PP23) of 3-male mixtures
 188 and for 20% (YP) and 10% (PP23) of 4-male mixtures, respectively.

189 To explain this startling result in simpler terms, imagine a mixture in which alleles 1 and 2
 190 are observed at each of 25 loci and an alleged contributor Q has allele 1 at every locus. Then the
 191 number of possible distinct profile pairs contributing to the mixture is 2^{24} or almost 17 million.
 192 However, under our simulation model, it is highly probable that the two profiles contributing to the
 193 mixture are $(1, 1, \dots, 1)$ and $(2, 2, \dots, 2)$: the other 17 million possible profile pairs are collectively

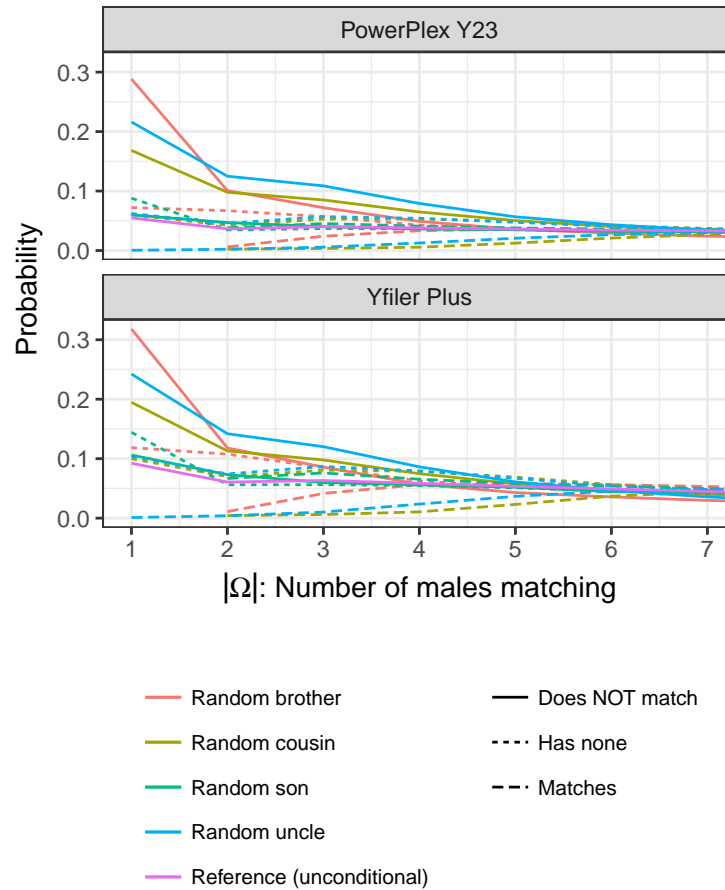

Figure 3: **Distribution of $|\Omega|$ given that Q has no son, brother, patrilineal cousin or paternal uncle, or match information from a random one of them.** Each curve is coded by its colour and line type (see legend); no information is available about male-line relatives other than the one specified. The reference line corresponds to no information from relatives of Q .

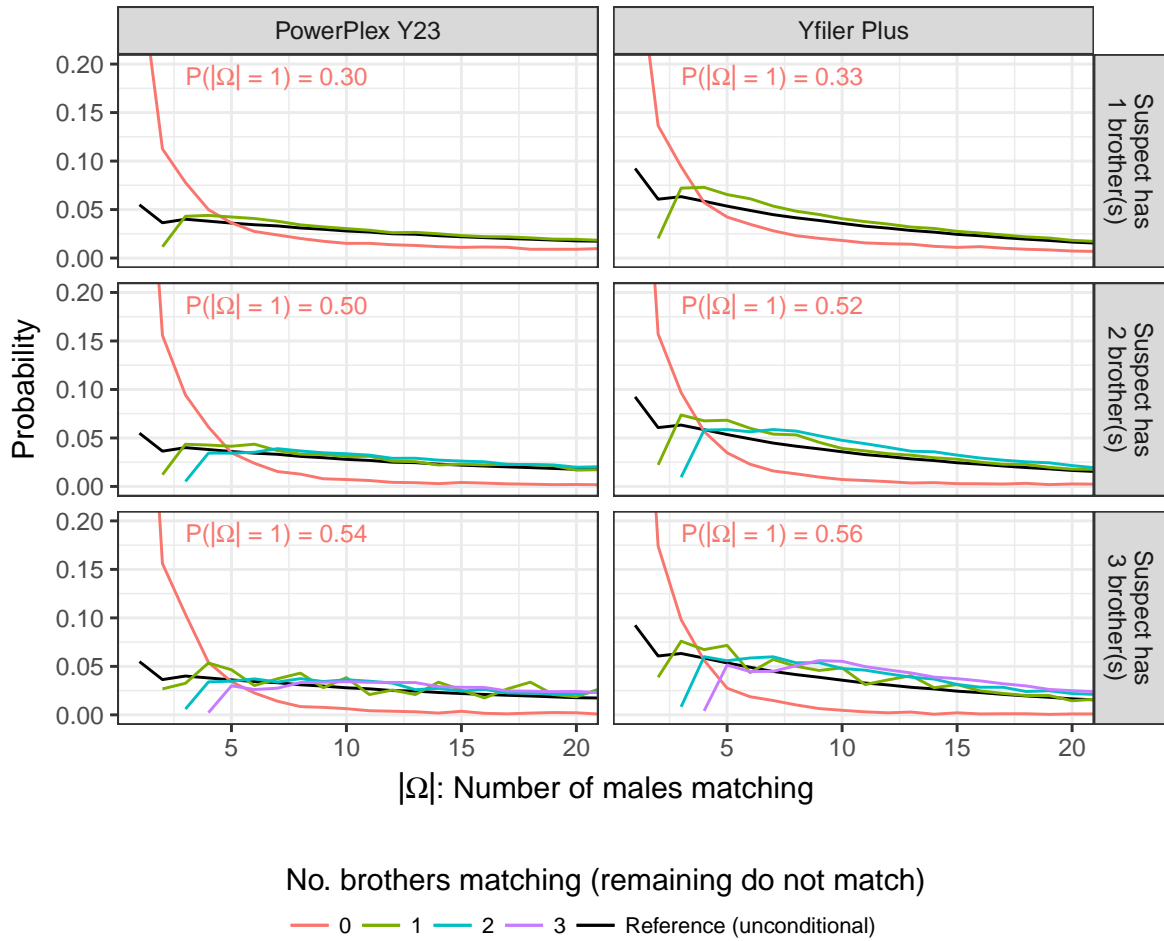

Figure 4: **Distribution of $|\Omega|$ given match information for all brothers when Q has up to three brothers.** The value of $P(|\Omega|=1)$ when all brothers mismatch is off the plot and is given numerically.

PP23 = PowerPlex Y23; YP = Yfiler Plus.

194 unlikely to exist in the population.

195 Table 3 does not answer the WoE problem for mixed evidence profiles, but it helps explain
196 Fig. 5 (see Table 4 for key quantiles) which shows the distribution in our simulations of N/LR_k for
197 $k = 1, \dots, 4$ (ignoring the non-recognisable mixtures in the first row of Table 3). As expected, the
198 distribution is shifted towards higher values as k increases, reflecting reduced WoE as the number
199 of contributors to the evidence sample increases. What is striking and counter-intuitive is that the
200 reduction in WoE is so slight. One guide to the correct intuition is that, for example when $k = 4$,
201 if there are many quadruples of males in the population whose profiles combine to make m , then
202 there are also many triples that when combined with q also make m : the Spearman correlation
203 between the numbers of quadruples and triples is around 0.85 for both kits.

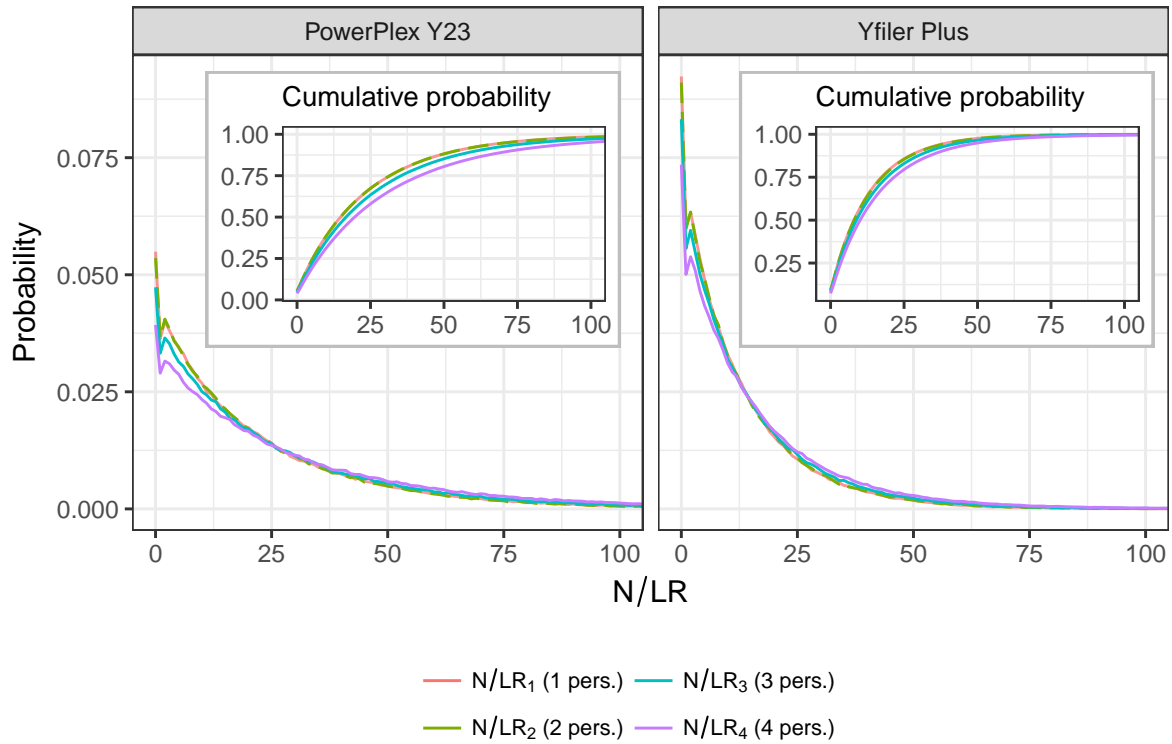

Figure 5: **The distribution of N/LR_k for $k = 1, \dots, 4$.** The case $k = 1$ corresponds to Fig. 4 of [1], and describes the distribution of the number of males with Y-profile matching that of a single-contributor evidence profile. The other curves describe the distribution of an analogous measure of WoE (see methods) when a reference profile q is included in a k -male mixture, $k = 2, 3, 4$. The red and green curves ($k = 1, 2$) are almost indistinguishable and are shown with alternating colours.

Number of k -sets	$k = 2$		$k = 3$		$k = 4$	
	PP23	YP	PP23	YP	PP23	YP
0	48 (0.01)	15 (0.00)	257 (0.05)	101 (0.02)	8,082 (1.62)	1,299 (0.26)
1	466,904 (93.38)	482,896 (96.58)	208,726 (41.75)	281,520 (56.30)	49,639 (9.93)	100,730 (20.15)
2	30,655 (6.13)	16,411 (3.28)	134,358 (26.87)	130,569 (26.11)	71,470 (14.29)	114,609 (22.92)
3-49	2,393 (0.48)	678 (0.14)	156,455 (31.29)	87,795 (17.56)	340,711 (68.14)	277,847 (55.57)
≥ 50	0	0	204 (0.04)	15 (0.00)	30,098 (6.02)	5,515 (1.10)

Table 3: **Distribution of the number of distinct k -sets of profiles yielding a given k -male mixed Y profile.** Each cell records the count (%) of 500K simulated k -male mixtures that could be obtained in the number of different ways indicated in the first column. The first row (0) corresponds to when the mixture is not recognised as a k -male mixture because no locus had k alleles. For $k = 2$ this only happens when the two contributors have the same profile. The second row (1) corresponds to cases when the profiles generating the mixture form the only k -set of profiles in the live population that combine to form that mixture. PP23 = PowerPlex Y23; YP = Yfiler Plus.

204 Discussion

205 We have further developed our new and powerful simulation-based approach to assessing the weight
 206 of Y-profile evidence [1]. We have extended it to allow conditioning on the profiles of some male-
 207 line relatives of the alleged contributor Q, and to evidence samples that include DNA from up to
 208 four males. The simulations underlying our results can be performed for any profiling kit, which is
 209 demonstrated in a vignette in the R package `malan` [2].

210 The results for conditioning on male-line relatives broadly match intuition though with some
 211 surprising aspects. If either the father or grandfather of Q is observed to have a Y-profile different
 212 from Q, then the number of matching males $|\Omega|$ is greatly reduced, and consequently the Y-profile
 213 evidence is strengthened in favour of Q being the source (Fig. 2). More generally, the distribution of
 214 $|\Omega|$ is reduced for any observed mismatch with a male-line relative of Q. The converse is also true:
 215 observed relative matches reduce the WoE. However, the magnitude of effect is not symmetric.
 216 From Table 2, we see that the observation of a mismatching father has the greatest impact on the

	95% quantile		99% quantile	
	PP23	YP	PP23	YP
N/LR_1	72	40	113	63
N/LR_2	72	41	119	64
N/LR_3	82	45	139	71
N/LR_4	99	51	177	83

Table 4: **Estimated quantiles of the distribution of N/LR_k for $k = 1, \dots, 4$.** See Fig. 5 for plots. PP23 = PowerPlex Y23; YP = Yfiler Plus.

217 distribution of $|\Omega|$, whereas a matching father has little impact.

218 Our most striking result is that the observation that the profile of Q is included in a mixed
 219 evidence profile with up to four contributors is almost as strong evidence for Q to be a contributor
 220 as is a match with a single-contributor evidence profile. In particular, being included in a 2-male
 221 mixture has virtually the same evidence value as a single-contributor match. This property was
 222 not apparent using previous approaches to evaluating mixtures. Although there are many other
 223 sets of profiles that could generate the mixture, if a possible profile has not been observed it is very
 224 unlikely to actually exist in the population. It follows that a 2-male mixed evidence profile can be
 225 presented to a court in terms of an equivalent single-contributor profile, using the suggestions we
 226 made in [1]. A similar approach may also be feasible for 3-male and 4-male mixtures.

227 The results reported here have been obtained using one model, but `malan` can be used to
 228 investigate alternative mutation models and demographic scenarios. As we noted in [1], almost all
 229 Y-profile matches are between males who are related to within a few tens of meioses. It follows that
 230 our results are robust to the mutation mechanism, with only the mutation rate being important.
 231 Moreover the number of matching males is typically up to a few tens, which is small relative to the
 232 population size and so our results are also reasonably robust to details of the demographic model
 233 [1]. We have confirmed here that the distribution of $|\Omega|$ is robust to assumptions about the allelic
 234 ladder and the allocation of founder haplotypes.

235 Overall, these results further advance the case for use of our new simulation-based paradigm
 236 for Y-profile evidence, introduced in [1]. We have demonstrated here that our approach is flexible

237 enough to incorporate new kinds of evidence, and it leads to important new insights about the
238 strength of Y-profile evidence.

- We show how observing the Y-profiles of male-line relatives affects the evidential weight of a matching profile.
- Mixtures: a mixed Y profile is almost as strong evidence as a single-contributor sample.
- Results are robust to assumptions about allelic ladder and founder haplotypes.
