### Abstract

**Background**—Environmental tobacco smoke (ETS) exposure is hypothesized to influence survival after breast cancer, but few studies have examined this association.

**Methods**—A population-based cohort of women (N=1,508) diagnosed with first primary invasive or *in situ* breast cancer in 1996–1997 was interviewed shortly after diagnosis and again approximately 5 years later to assess ETS exposure, and women were followed for over 18 years using the National Death Index; 597 deaths (237 associated with breast cancer) were identified. Multivariable Cox regression was used to estimate adjusted hazard ratios (HR) and 95% confidence intervals (CI) for mortality among women with breast cancer as related to at-diagnosis and at-/post-diagnosis changes in ETS exposure.

**Results**—There was little or no association between at-diagnosis ETS exposure and all-cause (HR=1.04, 95% CI=0.78–1.40) or breast cancer-specific (HR=0.98, 95% CI=0.63–1.52) mortality. Mortality was elevated among women who reported cessation in post-diagnosis ETS exposure up to one year before the follow-up assessment, for all-cause (HR=1.81, 95% CI=0.87–3.74) and breast cancer mortality (HR=1.89, 95% CI=0.68–5.24); however, estimates were imprecise.

**Conclusions**—We found little evidence of an association between at-diagnosis ETS exposure and mortality after breast cancer. Post-diagnosis cessation of ETS exposure was positively

Conflicts of interest: None declared

associated with mortality, although we could not rule out chance and reverse causation as possible explanations.

**Impact**—Exposure to ETS does not appear to influence mortality after breast cancer.

environmental tobacco smoke; second-hand smoke; passive smoke; breast cancer; mortality; survival analysis

---

## Introduction

Few studies (1–4) have examined whether environmental tobacco smoke (ETS) exposure increases the risk of mortality among women with breast cancer and no studies to date have prospectively examined the impact of post-diagnosis changes in ETS exposure on mortality. This study examined whether ETS exposure was associated with long-term all-cause and breast cancer-specific mortality among a population-based sample of women.

## Materials and Methods

Participants of the Long Island Breast Cancer Study Project (LIBCSP), a population-based cohort of women newly diagnosed with breast cancer, were interviewed shortly after diagnosis and again about 5 years later, and now continue to be followed for vital status. Details of the LIBCSP have been published previously (2,5). Institutional Review Board approval was obtained from all participating institutions.

### Environmental Tobacco Smoke Exposure Assessment

ETS exposure was determined via structured interviews (2). Women were asked to report whether any members of the household smoked in their presence, the relationship of the smoker, the participant's ages at first/last exposure, and any time periods the household member did not smoke. Duration of exposure was categorized as <15 years, 15–<30 years, and 30 years of exposure. Recency of exposure was categorized as <5 years, 5–<10 years, and 10 years.

### Covariate assessment

Covariates assessed via questionnaire included: age, menopausal status, annual household income, education, marital status, body mass index, physical activity, intake of alcoholic beverages, cigarette smoking, and treatment. Estrogen receptor status and nodal involvement were determined by medical record. Tumor size was obtained from the NY State Cancer Registry.

### Outcome Assessment

Vital status of the 1,508 women diagnosed with breast cancer was determined using the National Death Index. Follow-up for mortality occurred from the date of diagnosis in 1996–1997 until December 31, 2014 (median=17.61 years). We identified 597 deaths; 234 were associated with breast cancer.

## Statistical Analysis

Using multivariable Cox proportional regression models, we estimated hazard ratios (HR) and 95% confidence intervals (CI) for the associations between at-diagnosis as well as at-/post-diagnosis changes in ETS exposure and mortality following breast cancer. Models restricted to women with invasive cancer only yielded similar results from those of all women; only the latter are shown. All analyses were conducted using IBM SPSS Statistics Version 22.0 (IBM Corp., Armonk, NY).

In analyses of at-diagnosis ETS exposure, survival time began at the date of breast cancer diagnosis and ended on the date of death or, if alive, December 31, 2014. In analyses examining post-diagnosis ETS exposure, survival time began at the date of completion of the follow-up questionnaire and ended on the date of death or, if alive, December 31, 2014. Missing covariates were imputed in SPSS using 25 imputations with 1,000 iterations. The imputation models included age at diagnosis, menopausal status, income, education, marital status, BMI, physical activity, and alcohol intake, smoking status, post-diagnosis ETS exposure, disease characteristics (stage, tumor size, nodal involvement estrogen receptor status), treatment (radiation, chemotherapy, and hormone therapies), and the outcome (the event indicator and the Nelson-Aalen cumulative hazard estimator).

## Results

Approximately 15% of women reported ETS exposure in the year before diagnosis and 14% reported current exposure at the follow-up questionnaire.

### At-Diagnosis Environmental Tobacco Smoke Exposure

There was little or no association between current ETS exposure and all-cause (HR=1.04, 95% CI=0.78–1.40) or breast cancer-specific (HR=0.98, 95% CI=0.63–1.52) mortality after adjustment for covariates (Table 1). Risk of mortality was slightly elevated for all-cause (HR=1.17, 95% CI=0.74–1.86) and breast cancer-specific (HR=1.13, 95% CI=0.57–2.27) mortality when we restricted the analyses to never smokers, though the corresponding estimates imprecise.

### At-/Post-Diagnosis Environmental Tobacco Smoke Exposure

Though no associations were observed among women with ongoing ETS exposure, HRs were elevated 81% (HR=1.81, 95% CI=0.87–3.74) for all-cause mortality and 89% (HR=1.89, 95% CI=0.68–5.24) for breast cancer-specific mortality among women who reported cessation in post-diagnosis ETS exposure up to the year before the follow-up assessment (Table 2).

## Discussion

Exposure to the constituents of tobacco smoke, either through active smoking or exposure to ETS, is hypothesized to influence breast cancer progression through several mechanisms, including directly by influencing cell proliferation and metastasis (6), and indirectly by disrupting the endocrine system (7). Additionally, because up to 70% of tar in ETS is in the

vapor phase, whereas all of the tar in direct smoking is in the particulate phase, ETS may be an important source of exposure to carcinogens since particulate smoke is cleared into the mouth and swallowed, but vapor phase constituents are inhaled and absorbed into the bloodstream and lymph system (8). Despite these hypothesized mechanisms, the few studies conducted to date (1–4), including the sufficiently powered study reported here, provide limited or no evidence of an association between ETS exposure and survival after breast cancer. While we observed an elevated risk of mortality among women with post-diagnosis cessation of ETS exposure, we could not rule out chance and reverse causation as possible explanations.

## Acknowledgments

### Grant Support

The Long Island Breast Cancer Study Project was funded by the National Cancer Institute and the National Institutes of Environmental Health Sciences grants UO1CA/ES66572 and UO1CA66572 awarded to M.D. Gammon. H. Parada was supported by T32 ES007018 and R25 CA057726.
