Abstract

Urinary cadmium (Cd) concentrations in the Strong Heart Family Study (SHFS) participants are higher than in the general US population. This difference is unlikely to be related to tobacco smoking. We evaluated the association of consumption of processed meats and other dietary products with urinary Cd concentrations in the SHFS, a family-based study conducted in American Indian communities. We included 1725 participants with urine Cd concentrations (standardized to urine creatinine) and food frequency questionnaire data grouped in 24 categories, including processed meat. Median (IQR) urinary Cd concentrations were 0.44 (0.20–0.85) $\mu\text{g/g}$ creatinine. The age, sex, smoking, education, center, body mass index, and total kcal adjusted geometric mean ratio (GMR) (95%CI) of urinary cadmium concentrations per IQR increase in each dietary category was 1.16 (1.04–1.29) for processed meat, 1.10 (1.00–1.21) for fries and chips, 0.87 (0.80–0.95) for dairy products, and 0.89 (0.82–0.97) for fruit juices. The results remained similar after further adjustment for the dietary categories associated with urinary Cd in the previous model except for fries and chips, which was no longer statistically significant. These findings revealed the potential importance of processed meat products as a dietary source of cadmium.

American Indians; Cadmium; Diet; Meat; Association Analysis; Epidemiology

1. Introduction

Cadmium is a toxic metal with multiple health effects including kidney disease, bone fragility, cardiovascular disease and several cancers even at low exposure levels (Tellez-Plaza et al., 2013a; Tellez-Plaza et al., 2013b; García-Esquinas et al., 2014). Cadmium half-life in the body is extremely long (20–35 years) due to its cumulative capacity and binding to different proteins, especially in the kidneys and liver (Jomova and Valko, 2011). Tobacco is a major source of cadmium exposure in humans (Gil et al., 2011), as tobacco leaves bio-concentrate cadmium, which is then absorbed through the lungs during smoking. In non-smokers, the diet is the main source of cadmium (ATSDR, 2012) including root and leafy vegetables (e.g. potatoes, lettuce or spinach) (EFSA, 2009; Llobet et al., 2003), shellfish (e.g. clams or mussels) (Olmedo et al., 2013) and organ meats (e.g. liver or kidneys) (Jokanovi et al., 2013).

The characterization and prevention of cadmium exposures are warranted, especially in disproportionately exposed populations. In the Strong Heart Study (SHS), a population-based prospective cohort study conducted in American Indian communities in Arizona, Oklahoma and North and South Dakota, baseline urinary cadmium concentrations were markedly higher in the study participants compared to the general US population, even among never smokers (Tellez-Plaza et al., 2013b, Pang et al., 2016). These findings suggest there are unaccounted sources of cadmium exposure in the SHS population. Fretts et al. (2012) have reported a high consumption of processed meats in the SHS communities (68% participants consumed at least 3 servings of processed meats per week). Processed meat products, commonly consumed by low-income families due to its low price, could constitute

a relevant source of cadmium exposure as they contain heavily processed animal tissues, some of them potentially including organ meats. Several types of processed meats have historically been distributed free of charge by U.S. Department of Agriculture food assistance program in some Indian reservations and this distribution influences their diet (Smith et al., 1996; Taylor et al., 2006; Vaughan et al. 1997).

Baseline urinary cadmium concentrations, a biomarker of long-term exposure, were positively associated with incident cardiovascular disease in the SHS, even among non-smokers (Tellez-Plaza et al., 2013b). The goal of this study was to assess the association of different foods, with a specific interest on processed meat products, with urinary cadmium concentrations in the Strong Heart Family Study (SHFS), a family-based extension of the SHS that included a detailed food frequency questionnaire and urinary cadmium measures during the 2001–2003 visit. Our main hypothesis was that higher frequency and amount of processed meat consumption is associated with higher cadmium concentrations in urine. Given relatively high urinary cadmium concentrations in the SHS communities and its associated health effects, identifying relevant sources of exposure is critical for the development of prevention interventions.

2. Materials and methods

2.1. Study population

The SHFS is a multigenerational cohort recruited from the SHS (North et al., 2002). Families were eligible if they had a core sibship consisting of 3 original SHS participants and at least 5 additional living family members. During the 2001–2003 baseline visit, 2474 SHFS participants (15 years of age and older) were recruited who were free of diabetes at baseline and had urine metal concentrations measured as part of an ancillary study to evaluate gene-environment interactions for incident diabetes. We only included participants with dietary data available (n=2188). We excluded 1 participant with missing urinary creatinine, 3 participants with abnormal concentrations of creatinine-corrected urine cadmium (concentrations 24, 30 and 200 times higher than the 90th percentile), and participants with missing values of educational level (n=8), body mass index (n=7), and smoking status (n=1). We further excluded 443 participants from a community that has withdrawn their permission to conduct research in 2016, leaving a total of 1725 participants in this analysis (see participant flow chart in Supplemental Figure 1).

The study protocol was approved by the institutional review boards of the Indian Health Service, the participating institutions and the participating tribes. All participants provided written informed consent.

2.2. Food frequency questionnaire

An interviewer-administered Block 119-item Food Frequency Questionnaire (FFQ) was used to measure usual food intake as previously described (Fretts et al., 2012). Serving sizes, described as standard units (e.g., 1 banana, 2 eggs, etc.) or standard volume/weight portions, were assessed using photographs of various portions as visual aids. Each participant was asked how often, on average, a particular food was consumed during the past year. The

quantity was assessed using frequency measures of consumption (seasonally, never, a few times per year, once per month, 2–3 times/mo, once per week, twice per week, 2–3 times/wk, 5–6 times/wk, daily) and adjusted for portion size (small, medium, or large). In addition to standard Block FFQ food items, the FFQ included foods commonly consumed among American Indians such as menudo, pozole, guysava, red or green chili, Indian taco, fry bread, corn tortilla, flour tortilla, and “spam” (a term that refers to canned meats, usually a combination of heavily processed beef or pork meats, salt, sodium nitrate, potato starch and water).

Average daily energy and macronutrient intakes were calculated for each study participant by using the Block database (Block Dietary Systems). To obtain measures of average daily energy and nutrient intake, the frequency response for each food on the FFQ and American Indians supplementary foods questionnaire was multiplied by the nutrient content of the documented portion size of the food, then summed for all foods (Block et al., 1998).

The food items in the FFQ were grouped in 24 different categories according to their potential cadmium content based on data on cadmium concentrations in US foods from the Total Diet Study Market Baskets 2006 through 2011 conducted by the US Food and Drug Administration (FDA, 2014). As an example, leafy vegetables, fries and chips, nuts and seeds, organ meat and processed meat had their own categories. For instance, the classification of fries and chips together and separated from boiled or baked potatoes is due to different levels of cadmium concentrations in these modalities of potato preparation. The specific food stuffs included in each category is displayed in Supplemental Table 1. For processed meats, for instance, our goal was to include meats made of mixed parts of the animal and for that reason we did not include bacon or hamburgers. Total intake for each food category was expressed as grams (g) consumed per day (Supplemental Figure 2).

2.3. Urine cadmium

Spot urine samples from baseline were collected in polypropylene tubes, frozen within 1 to 2 hours of collection, shipped buried in dry ice and stored in freezers at -70°C in the Penn Medical Laboratory, MedStar Research Institute, Washington, DC. Strict controls on the sampling, transport and storage of urine were conducted to ensure study quality (Strong Heart Study, 1991). The analyses of cadmium and other metals were performed by Inductively Coupled Plasma Mass Spectrometry ICP-MS (Agilent 7700x ICP-MS, Agilent Technologies, Waldbronn, Germany) and urine samples have already been used to measure creatinine and albumin (Tellez-Plaza et al, 2013b; Scheer et al., 2012). The inter-assay and the intra-assay coefficients of variation for urinary cadmium concentrations were 8.7% and 4.5%, respectively. Standard reference materials (National Institute of Standards and Technology, NIST 1640a and 1643e) were used to test the accuracy of the analyses. The limit of detection for urine cadmium was $0.015\ \mu\text{g/L}$ (and the corresponding limit of quantification is $0.050\ \mu\text{g/L}$), but our limit of detection is estimated conservatively so we kept all values provided by the method above the limit of detection. A total of 87 (5.05%) samples were below the limit of detection and were replaced by the limit of detection divided by the square root of two.

2.4. Other variables

Study visits were performed by trained and certified staff following a standard protocol (Lee et al., 1990). Sociodemographic (age, sex, region and education) and lifestyle information (smoking status) were obtained by questionnaire during the interview. Body mass index was calculated from measured weight (kg) divided by measured height (m^2). Kcal per day were obtained from the FFQ based on total grams of food estimated per day. To account for urine dilution, urine cadmium was divided by urine creatinine (μg per g of urine creatinine). Urine creatinine was measured at the Laboratory of the National Institute of Diabetes and Digestive and Kidney Disease, Epidemiology and Clinical Research Branch (Phoenix, AZ) by an alkaline picrate rate method (Lee et al., 1990).

2.5. Statistical analysis

Urine cadmium corrected for urinary creatinine and intake of dietary variables were right-skewed and log-transformed to improve normality. We described the participant characteristics across urine cadmium quartiles and assessed the differences between groups using Kruskal-Wallis tests for continuous variables and χ^2 tests for categorical variables.

To assess the association between cadmium exposure and the different food categories, including processed meats, we estimated geometric mean ratios (GMRs) and corresponding 95% confidence intervals (95% CI) of urinary cadmium concentrations for an interquartile range increase in daily intake for each food type modeled. We used generalized estimating equations (GEE) to account for the lack of independence among family members. We presented the results in two models progressively adjusted. Model 1 was initially adjusted for age (continuous), gender (male/female), educational level (more/less than 12 years or education), body mass index (continuous), smoking status (never/former/current), center (Arizona/Oklahoma/North and South Dakota) and total Kcal per day (continuous). Model 2 was further adjusted for other foods showing a significant association with urinary cadmium concentrations in Model 1 as well as with other food categories established as potential sources of cadmium exposure (see Supplemental Table 2), independently of statistical significance. To allow for a flexible evaluation of the dose-response, we also graphically described the association between cadmium and the food type based on restricted quadratic splines with knots at 10th, 50th, and 90th percentiles of each intake distribution, with the 10th percentile as the reference.

To evaluate the robustness of the results, we re-run the analyses with the dietary variables in the original scale instead as of log-transformed, with essentially identical results. We also run additional sensitivity analyses further adjusting for cigarette pack-years, smokeless tobacco products and exposure to secondhand tobacco smoke, with similar findings (Supplemental Table 3). We also conducted analyses stratified by sex and smoking status. All analyses were conducted with R software, version 3.1.2, the significance level was set at 0.05 and all tests were two-sided.

3. Results

Median (IQR) urinary cadmium concentrations were 0.44 (0.20–0.85) $\mu\text{g/g}$ creatinine (0.31 (0.15–0.58) for men and 0.56 (0.27–1.02) for women). Participants with higher urinary cadmium concentrations were more likely to be older, women, more educated, current smokers, consume less Kcal per day and to be from North and South Dakota (Table 1). Before any adjustment, the food categories positively associated with urinary cadmium concentrations ($p < 0.05$) were organ meat, leafy vegetables, root vegetables, non-alcoholic drinks, and oil and fat; food categories negatively associated with urinary cadmium concentrations were dairy products and fruit juices. Medians (IQR) intake in g/day were 23 (11–49) for processed meat, 27 (11–63) for fries and chips, 108 (38–268) for dairy products, and 140 (47–356) for fruit juices. Processed meat intake was weakly positively correlated with the intake of fries and chips (Spearman correlation coefficient of 0.20) (Supplemental Table 4). Dairy products and fruit juice intake were weakly positively correlated (Spearman correlation coefficient 0.24). Median (IQR) processed meat consumption was 20.9 (9.9, 41.0) for never smokers and 26.9 (11.9, 55.2) for ever smokers, respectively (p -value < 0.001).

As seen in Table 2, after adjustment for sociodemographic and other participant characteristics (Model 1) the GMR (95% CI) of urinary cadmium for an interquartile range in log-transformed g/day for each food group was 1.16 (1.04, 1.29) for processed meat products, 1.10 (1.00, 1.21) for fries and chips, 0.87 (0.80, 0.95) for dairy products and 0.89 (0.82, 0.97) for fruit juices. After further adjustment for the food categories associated with urinary cadmium in model 1 (processed meat products, fries and chips, dairy products and fruit juices) and for food categories known to have higher cadmium concentrations (organ meat, leafy vegetables, and baked and mashed potatoes) processed meat products remained associated with higher urinary cadmium concentrations (GMR 1.15, 95% CI 1.03–1.28), while dairy products (GMR 0.88, 95% CI 0.80–0.97) and fruit juices (GMR 0.91, 95% CI 0.83–0.99) remained associated with lower urinary cadmium concentrations (Model 2). In analysis stratified by sex (Table 3), the association of urinary cadmium with processed meat consumption was higher in males (GMR 1.31 95% CI 1.08–1.60) than in females (GMR 1.07 95% CI 0.95–1.20) (p -value for interaction 0.05). The negative associations between urinary cadmium concentrations and dairy products and fruit juices was also stronger in males compared to females. In analyses stratified by smoking status (Table 3), the association between cadmium and processed meat was stronger in ever smokers (GMR 1.23 95% CI 1.06–1.44) compared to never smokers (GMR 1.07 95% CI 0.92–1.25) although the interaction was not significant (p -value 0.46), while dairy products and fruit juices displayed similar results in ever and never smokers.

In flexible evaluations of the dose-response, processed meat intake was associated with increased urinary cadmium concentrations only at levels of consumption higher than 9.6 g/day (Figure 1). Dairy products and fruit juice showed an inverse association throughout the range of intake, although the decrease in urinary cadmium concentrations became more accentuated after around 180 g/day for dairy products and 206 g/day of fruit juices. The associations of cadmium with processed meats, dairy products and fruit juice remained

similar in analyses allowing for effect modification by sex and smoking status (Supplemental Figure 3).

4. Discussion

The findings of this study support that the consumption of processed meat products are associated with higher cadmium concentrations in urine. The association was non-linear, being observed at a daily intake of processed meats above 9.6 g/day but not below that level. Other meat products evaluated (poultry, red meat, and organ meat) were not associated with higher urinary cadmium concentrations, supporting the specificity of the association with processed meat, not with other types of meat. The association was stronger among men and ever smokers, compared to women and never smokers, respectively, although the interaction by smoking status was not statistically significant. In this respect, the markedly weaker and non-statistically significant association among never smokers prevents this study to reach firm conclusions regarding the association between processed meat and cadmium exposure. Additional research is needed to assess whether our findings are due to confounding, maybe by smoking status or other sources of cadmium that could correlate with processed meat intake or whether high intake of this type of product contributes to cadmium exposure in the population. Dairy products and fruit juices, on the other hand, were associated with lower urinary cadmium concentrations.

Typically, organ meat (especially kidneys and liver) have been identified as the major type of meat products associated with cadmium exposure due to their capacity to accumulate cadmium (Hassan et al., 2012; López-Alonso et al., 2007). After adjustment for participant characteristics, we found no association between the consumption of organ meat and urinary cadmium concentrations. This can be explained by the relatively low consumption of organ meats in the study population (Table 1). Several studies have also found that despite the high concentration of cadmium in organ meats, their contribution to dietary cadmium is small due to their infrequent consumption. In Sweden, offal products provided only 4% of the total cadmium dietary intake in a postmenopausal women cohort (Julin et al., 2012), and in another Swedish study for nonsmoking participants living on farms, offal products contributed only 0.3% (range 0.5–3.6%) of dietary cadmium (Olsson et al., 2002).

Very few studies have evaluated the association between processed meat products or other types of meat and cadmium biomarkers. In Swedish adults, total meat intake, measured through a food frequency questionnaire, was related to blood cadmium concentrations, although the study did not distinguish between processed and non-processed meats (Bjermo et al., 2013). In children from the US, beef consumption (measured through a food frequency questionnaire which included hot dogs as one of the beef food items), was associated with blood cadmium concentrations (Davis et al., 2014). In 3 year-old children from Ukraine, on the other hand, eating one sausage or more per week was not associated with higher blood cadmium concentrations (Friedman et al., 2006). Our study constitutes one of the first studies specifically evaluating the potential importance of these processed meat products in cadmium exposure. It is unclear, however, why we observed a non-linear dose-response relationship or why the association was stronger in men and ever smokers. On one hand, this could be related to residual confounding by smoking, although our analyses

were robust to additional adjustment for cigarette pack-years, smokeless tobacco products, and secondhand smoke exposure. On the other hand, these differences could also be related by differences in the types of processed meats consumed, as it is possible that not all types of processed meats contribute to increased cadmium exposure.

Food categories that were associated with higher urinary cadmium concentrations in this study before adjustment for other foods included fries and chips. Several studies have identified potatoes and root vegetables as an important dietary contributor to cadmium exposure. In Sweden, a study in nonsmoking men and women living on farms estimated that potatoes and other roots provided 24% of the total dietary cadmium (Olsson et al., 2002), while a study in Swedish postmenopausal women estimated that potatoes provided 18% of total dietary cadmium intake (Julin et al., 2012). In the Total Diet Study by the FDA, fries and chips show higher concentrations of cadmium as compared to potatoes cooked with other cooking methods (FDA, 2014), which could be related to the lower water content of fries and chips. In our study, cereals such as wheat and rice, leafy vegetables, and nuts and seeds, foods that have been commonly reported as dietary sources of cadmium (FDA, 2014; Olsson et al., 2002, Tsukahara et al., 2003, Baldantoni et al., 2016), were not associated with increased urinary cadmium concentrations.

Dairy products and fruit juices showed an inverse association with urinary Cd concentrations. Drinking milk has also been identified as inversely associated with urinary cadmium concentrations in a study in premenopausal women aged 40–45 years from the US (Adams et al., 2011). A similar inverse association of urinary cadmium with dairy products and fruit juices has been reported in US adults in a Dietary-Wide Association Study (DWAS) using NHANES and USDA data (Davis et al., 2014). Milk, cheese and yogurt were associated with lower urinary or blood cadmium concentrations. Similarly, orange juice and apple juice (this one just with blood cadmium) were associated with lower blood and urinary cadmium concentrations (Davis et al., 2014). The reasons behind these inverse associations are unknown. Potentially, these products could decrease the gastro-intestinal absorption of cadmium. This is well known, for instance, for dairy products and lead, which is also a toxic divalent metal (de Almeida Lopes et al., 2015). An adequate supply of calcium can protect against cadmium toxicity symptoms (Peraza et al., 1998). Regarding fruit juices, one possible explanation could be related to increased vitamin C and the activation of the iron transporter which could result in increasing iron while decreasing cadmium uptake (Fox et al., 1980). Interestingly, vitamin C supplementation has been observed to reduce elevated cadmium concentrations in the kidneys and liver of pigs fed a copper-rich diet (Peraza et al., 1998). Unfortunately in our study we have no information on ferritin levels or iron stores.

This study has several strengths. The SHFS represents a unique resource to evaluate the dose-response relationship between processed meat consumption and urine cadmium concentrations due to the wide range of levels of processed meat consumption in the study population. Strengths of the study include state-of-the art methods to measure cadmium in urine with low limits of detection and the availability of dietary information (Scheer et al., 2012). The Block FFQ is one of the most widely used food questionnaires, showing reliability and validity (Block et al., 1992; Boucher et al., 2006; Caan et al., 1998; Subar et al., 2001). The inclusion of an ethnic foods section on the FFQ contributes considerably to

increase group mean nutrient estimates and can contribute to better food and energy intake estimates (Block et al., 2004).

A possible limitation is the lack of blood cadmium, a cadmium biomarker that has a shorter half-life than urine cadmium and that could be useful to evaluate together with urine cadmium concentrations. In the Strong Heart Family Study, however, only urine cadmium is available. Other limitations include the use of a single spot urine sample of cadmium determination as a biomarker of exposure and the lack of tobacco biomarkers. Regression-dilution bias due to non-differential measurement error in dietary assessment may have resulted in an underestimation of the associations. We also lack information on other environmental or occupational sources of cadmium in the population. Studies of other Native American populations from the US, Canada and Mexico have suggested that sources of cadmium include nearby contaminating factories and mining (Schmitt et al., 2006; Moon et al., 1986), and surface dust in jewelry-making homes (Gonzales et al., 2004). Another activity that could be relevant for cadmium exposure in our population is small-scale-motor vehicle repair (Yassin and Martonik, 2004).

5. Conclusions

Increased consumption of processed meat products was associated with increased urinary cadmium concentrations in the SHFS participants, although the association was weaker and non-statistically significant among never smokers. Increased consumption of milk products and fruit juices, on the other hand, was associated with lower urinary cadmium concentrations. This study revealed the potential contribution of processed meat products to cadmium exposure and provides a possible explanation for the high concentrations of urinary cadmium in the population. Research is needed to confirm the association between processed meat products and cadmium biomarkers in other populations, as well as to evaluate the cadmium content of a diverse group of processed meat products, including those that are more frequently consumed in American Indian communities. Meanwhile, our findings support that promoting healthier dietary habits in American Indian communities, including the reduction of consumption of processed meats and increasing the intake of dairy and fruit juices, could contribute to reduce cadmium exposure.

HIGHLIGHTS

- We evaluated the association of foods with urinary Cd levels in American Indians.
- Higher processed meat intake was associated with higher urinary Cd concentrations.
- Higher intake of dairy products and fruit juices was associated with lower Cd levels.
- Processed meat products are a potential dietary source of cadmium.

Figure 1. Geometric mean ratio (95% confidence interval) of urine cadmium by daily intake of processed meat, dairy products and fruit juice

Lines represent the geometric mean ratio of urinary cadmium concentrations based on restricted quadratic spline models with knots at the 10th, 50th, and 90th percentiles of each log-transformed daily intake of each food type. Shaded areas surrounding the lines represent 95% confidence intervals. The reference was set at the 10th percentile of each dietary variable distribution. Solid lines (blue shaded areas) represent the cadmium geometric mean ratios (95% CI's) for each dietary variable by adjusting for age (continuous), sex (male/female), center (Arizona/Oklahoma/North and South Dakota), educational level (<12 years/12 years), smoking status (never/former/current), body mass index (continuous), and total kilocalories (continuous). Dotted lines (green shaded areas) represent the cadmium geometric mean ratios (95% CI's) in model further adjusted for additional food type variables (organ meat, processed meat, leafy vegetables, root vegetables, baked and mashed potatoes, fries and chips, dairy products, fruit juice and alcoholic drinks). Bars represent the distribution of processed meat, dairy products and fruit juice intake, respectively. The extreme tails of the histogram were truncated because 3 participants reported processed meat intake > 400 grams, and 6 reported dairy products intake < 1.3 grams.

Table 1

Participant characteristics by urine cadmium (µg/g) quartiles.^a (N=1725)

Table 2

Geometric Mean Ratios (95% confidence interval) of urine cadmium concentrations per interquartile range in daily food type intake (N=1725)

Food type	p75 vs. p25 (g/day)	Model 1	p-value	Model 2	p-value
Poultry	46.4 vs 11.7	1.03 (0.95, 1.12)	0.49	0.99 (0.91, 1.08)	0.80
Red meat	109.8 vs 30	1.06 (0.96, 1.18)	0.25	0.99 (0.89, 1.11)	0.90
Organ meat	5.9 vs 0.3	1.08 (0.95, 1.22)	0.24	1.06 (0.93, 1.20)	0.39
Processed meat	48.8 vs 11.4	1.16 (1.04, 1.29)	0.007	1.15 (1.03, 1.28)	0.01
Fish	10.8 vs 0.8	0.95 (0.85, 1.06)	0.38	0.94 (0.83, 1.05)	0.27
Shellfish	4.3 vs 1.1	1.01 (0.89, 1.15)	0.90	1.01 (0.88, 1.15)	0.94
Leafy vegetables	32.9 vs 4.6	1.02 (0.94, 1.10)	0.70	1.04 (0.95, 1.13)	0.40
Root vegetable	12.8 vs 2.5	1.00 (0.93, 1.08)	0.99	1.00 (0.93, 1.08)	0.96
Other vegetables	123 vs 33.4	0.97 (0.89, 1.06)	0.50	0.97 (0.89, 1.06)	0.52
Cereals	238.8 vs 85.4	0.97 (0.89, 1.06)	0.54	0.96 (0.87, 1.06)	0.46
Rice	25 vs 2.9	0.94 (0.86, 1.03)	0.21	0.93 (0.85, 1.03)	0.16
Corn	30.2 vs 7.4	0.98 (0.90, 1.07)	0.64	0.97 (0.88, 1.06)	0.49
Legumes	24.8 vs 3.8	1.00 (0.91, 1.09)	0.94	0.98 (0.89, 1.07)	0.64
Nuts and seeds	16.1 vs 1.7	0.94 (0.85, 1.04)	0.24	0.94 (0.84, 1.04)	0.23
Baked and mashed potatoes	40.3 vs 6.7	1.03 (0.95, 1.11)	0.46	1.00 (0.92, 1.09)	0.96
Fries and chips	62.9 vs 11.4	1.10 (1.00, 1.21)	0.04	1.07 (0.96, 1.18)	0.21
Eggs	43.3 vs 7.1	1.07 (0.99, 1.16)	0.09	1.05 (0.97, 1.14)	0.22
Dairy products	268.1 vs 38.3	0.87 (0.80, 0.95)	0.00	0.88 (0.80, 0.97)	0.007
Fruit	103.6 vs 30.2	0.96 (0.89, 1.03)	0.24	1.00 (0.93, 1.08)	0.99
Fruit juice	356 vs 46.6	0.89 (0.82, 0.97)	0.006	0.91 (0.83, 0.99)	0.03
Sauces and dressings	46.8 vs 11.5	1.06 (0.97, 1.17)	0.21	1.03 (0.93, 1.15)	0.52
Oil and fat	15.8 vs 3.5	1.05 (0.98, 1.13)	0.19	1.03 (0.96, 1.12)	0.38
Non-Alcoholic Drinks	1543.8 vs 528.9	1.05 (0.98, 1.12)	0.16	1.05 (0.98, 1.12)	0.16
Alcoholic Drinks	136.9 vs 1.2	1.12 (0.99, 1.28)	0.08	1.10 (0.96, 1.26)	0.17

Model 1 adjusted for age at baseline, sex, smoking status, educational level, center, body mass index, and total kcal. Model 2 further adjusted for dietary variables that may contribute to cadmium intake (organ meat, processed meat, leafy vegetables, root vegetables, baked and mashed potatoes, fries and chips, dairy products and fruit juice). Food type (g/day) is modeled as log-transformed.

Table 3

Geometric Mean Ratios (95% confidence interval) of urine cadmium concentrations per interquartile range in daily food intake of processed meat, dairy products and fruit juice stratified by sex and smoking status (N=1725)

	Food type	p75 vs. p25 (g/day)	Model 1	p-value	Model 2	p-value
Female (n=1056)	Processed meat	38.1 vs 8.9	1.09 (0.97, 1.22)	0.13	1.07 (0.95, 1.20)	0.28
	Dairy products	243.9 vs 35.9	0.88 (0.79, 0.97)	0.01	0.88 (0.79, 0.99)	0.03
	Fruit juice	323.7 vs 43.2	0.88 (0.80, 0.98)	0.02	0.90 (0.81, 1.00)	0.05
Male (n=669)	Processed meat	66.4 vs 19.5	1.30 (1.06, 1.59)	0.01	1.31 (1.08, 1.60)	0.007
	Dairy products	332.1 vs 46.5	0.86 (0.71, 1.03)	0.10	0.87 (0.72, 1.05)	0.15
	Fruit juice	411.9 vs 50.7	0.88 (0.74, 1.04)	0.13	0.89 (0.73, 1.08)	0.25
Never (n=711)	Processed meat	41 vs 9.9	1.09 (0.94, 1.25)	0.25	1.07 (0.92, 1.25)	0.36
	Dairy products	268.2 vs 43.3	0.89 (0.79, 0.99)	0.04	0.87 (0.77, 0.99)	0.03
	Fruit juice	362.9 vs 47.8	0.90 (0.78, 1.05)	0.18	0.92 (0.79, 1.07)	0.26
Ever (n=1014)	Processed meat	55.2 vs 11.9	1.24 (1.05, 1.47)	0.01	1.23 (1.06, 1.44)	0.008
	Dairy products	267.8 vs 36.1	0.86 (0.75, 0.98)	0.02	0.87 (0.76, 1.00)	0.05
	Fruit juice	332.9 vs 46.3	0.87 (0.77, 0.99)	0.03	0.90 (0.79, 1.03)	0.11
