Abstract

Measuring changes in tumor volume using anatomical imaging weeks to months post radiation therapy (RT) is currently the clinical standard for indicating treatment response to RT. For patients whose tumors do not respond successfully to treatment, this approach is suboptimal as timely modification of the treatment approach may lead to better clinical outcomes. We propose to use tumor microvasculature as a biomarker for early assessment of tumor response to RT. Acoustic angiography is a novel contrast ultrasound imaging technique that enables high-resolution microvascular imaging and has been shown to detect changes in microvascular structure due to cancer growth. Data suggest that acoustic angiography can detect longitudinal changes in the tumor microvascular environment that correlate with RT response.

Methods: Three cohorts of Fisher 344 rats were implanted with rat fibrosarcoma tumors and were treated with a single fraction of RT at three dose levels (15 Gy, 20 Gy, and 25 Gy) at a dose rate of 300 MU/min. A simple treatment condition was chosen for testing the feasibility of our imaging technique. All tumors were longitudinally imaged immediately prior to and after treatment and then every 3 days after treatment for a total of 30 days. Both acoustic angiography (using in-house produced microbubble contrast agents) and standard b-mode imaging was performed at each imaging time point using a pre-clinical Vevo770 scanner and a custom modified dual-frequency transducer.

Results: Results show that all treated tumors in each dose group initially responded to treatment between days 3-15 as indicated by decreased tumor growth accompanied with decreased vascular density. Untreated tumors continued to increase in both volume and vascular density until they reached the maximum allowable size of 2 cm in diameter. Tumors that displayed complete control (no tumor recurrence) continued to decrease in size and vascular density, while tumors that progressed after the initial response presented an increase in tumor volume and volumetric vascular density. The increase in tumor volumetric vascular density in recurring tumors can be detected 10.25 ± 1.5 days, 6 ± 0 days, and 4 ± 1.4 days earlier than the measurable increase in tumor volume in the 15, 20, and 25 Gy dose groups, respectively. A dose-dependent growth rate for tumor recurrence was also observed.

Conclusions: In this feasibility study we have demonstrated the ability of acoustic angiography to detect longitudinal changes in vascular density, which was shown to be a potential biomarker for tumor response to RT.

Key words: microbubble, acoustic angiography, dual-frequency, radiation therapy, ultrasound.

Introduction

Radiation therapy (RT) is one of the most common cancer treatment modalities and is used to treat 30-70% of all cancer patients in North America alone, by itself or in combination with surgery or chemotherapy [1]. RT is used either with curative intent for complete tumor eradication or local control, or with palliative intent to reduce tumor growth and symptom control. Unfortunately, patients often have varied tumor responses to RT due to differences in tumor type and other genetic and epigenetic factors [2]. Furthermore, the biological mechanisms of RT effects are still not well understood enough for clinicians to account for this variability [3]. For many types of cancers, the current clinical standard for assessing response to RT is RECIST (Response Evaluation Criteria in Solid Tumors), in which changes in tumor size are measured with MR and CT diagnostic imaging [4]. Unfortunately for patients receiving RT, the extent of tumor control (complete reduction in tumor size, tumor shrinkage, or cessation of tumor progression) is often not measurable until months after treatment [5]. Since a timely switch to an alternative treatment approach may lead to a better prognosis in cases where RT is not effective, it is important to determine response to therapy as early as possible [6]. The ability to measure early physiological biomarkers that indicate treatment failure prior to long term changes in tumor size would represent a significant advancement in early treatment response detection.

Hanahan et al proposed six "hallmarks of cancer" consisting of molecular characteristics of the tumor microenvironment that contribute to the development and proliferation of tumors, one of which is aberrant angiogenesis. Tumor neovascularization is signified by excessive sprouting of tortuous vessels within or near the tumor area, therefore increasing vessel density and in some cases, perfusion [7]. The tumor microvascular environment also plays an important role in the efficacy of RT. Endothelial apoptosis of tumor microvasculature is known to be a homeostatic factor in the regulation of tumor growth and is strongly correlated with tumor control when treated with radiation, therefore suggesting that DNA damage and consequential cell death due to exposure to ionizing radiation may not be the only significant factor determining the effect of RT [8]. Additionally, microvascular remodeling and angiogenesis after RT has been observed in animal models within two days of treatment using intravital optical microscopy, which demonstrates the highly dynamic nature of the tumor microvasculature [9]. While the biological basis of vascular remodeling is not entirely understood, patterns in the microvascular

response to treatment may be a tell-tale sign of the fate of the treated tumor that can be discerned remarkably soon after therapy. Currently, there are very few clinical technologies available that have the sensitivity to measure microvascular structure. In this study, we propose a contrast ultrasound imaging technique to image and characterize tumor microvasculature in terms of volumetric vascular growth. We hypothesize that changes in tumor microvasculature caused by RT occur sooner than changes in tumor volume, and therefore can potentially be used as a biomarker for predicting tumor control.

Contrast enhanced ultrasound (CEUS) is a low-cost, non-ionizing, and safe imaging modality that can visualize and measure vascularity and perfusion in tissue with high contrast sensitivity compared to CT and MR [10]. The microbubble contrast agents used for CEUS are composed of a gas core and a stabilizing shell. Typically, the core consists of an inert gas such as a perfluorocarbon or sulfur hexafluoride, and common shell materials include PEGylated phospholipids or albumin. The gas is exhaled out through the lungs and the shell components are filtered and excreted through the liver and spleen via the reticuloendothelial system and phagocytic mechanisms [11]. Microbubbles are non-toxic unlike MR and CT gadolinium based and iodinated contrast agents, which are contraindicated in various patient populations due to their nephrotoxicity [12]. Commercial microbubbles are polydisperse and typically range from 1-5 μm in diameter, constraining them within the vasculature [13].

Advanced CEUS techniques can yield quantitative diagnostic information, including relative tissue enhancement, tissue perfusion, expression of endothelial biomarkers, and vascular structure [14-17]. CEUS perfusion imaging and molecular imaging (used for measuring tissue perfusion and endothelial molecular expression, respectively) have been investigated extensively in both pre-clinical and clinical settings for measuring vascular response to therapy and both short and long-term effects on tumor control [16,18,19]. Angiogenic-based cancer therapeutics (i.e. sunitinib, bevacizumab, sorafenib, Dll4-notch inhibitors) and RT alter the expression of angiogenic factors, thus interfering with microvascular growth or inflicting injury to the endothelium resulting in severe local hypoxia and tumor growth delay [20-23]. Molecular imaging has been shown to detect changes in angiogenic and inflammation endothelial biomarkers, such as vascular endothelial growth factor and P-selectin, that may predict response to therapy [16,24,25]. Perfusion imaging techniques, such as

power Doppler and destruction reperfusion, have also demonstrated that tumor blood flow changes caused by RT by itself or in combination with adjuvant chemotherapy can be detected within days after treatment [18,26–29].

Acoustic angiography (AA) is a super-harmonic CEUS imaging technique that enables *high-resolution* microvascular imaging. This technique requires a confocal dual-frequency transducer design with a low frequency element to transmit and a high frequency element to receive at several harmonics higher than the transmit frequency [30]. The large bandwidth separation of the transmit and receive frequencies enables the detection of broadband microbubble signals while rejecting linear tissue signal. Reconstructing a stack of 2D images using this dual-frequency technique results in a high-resolution (100–200 μm) and high contrast-to-tissue ratio (30–40 dB) 3D image volume of the underlying microvasculature (Figure 1).

These images can be subsequently segmented and analyzed to quantify vascular features such as vascular density, vessel tortuosity, and vessel diameter and can also be used to better assess the tumor boundary since abnormal microvasculature extends beyond the physical tumor space. Vessel morphology and density cannot be directly quantified with other clinically existing CEUS technologies due to the resolution limitations and relatively low signal-to-noise ratio. We have previously shown that quantitative acoustic angiography can detect and quantify abnormal vascular density and vessel

tortuosity in areas of cancer growth compared to healthy tissue [31,32]. Our objective in this study is to demonstrate the sensitivity of acoustic angiography to detect and quantify changes in tumor vascular density in response to RT as an indicator for long-term treatment success or failure. We propose to begin this investigation under a simple high-dose single fraction treatment condition to demonstrate feasibility and potential benefit of our technique.

Materials and Methods

Rat and Tumor Models

All animal surgical and imaging procedures were reviewed and approved by the University of North Carolina at Chapel Hill Animal Care and Use Committee prior to conducting this study. Rat fibrosarcoma (FSA) tumor tissue graciously provided by the Dewhirst lab at Duke University was subcutaneously implanted in the right flank of 30 female Fischer 344 rats as previously described [33]. The rat FSA model was originally induced and isolated from Fischer 344 rats injected with the carcinogen, methylcholanthrene [34]. Rat FSA is characterized as a local, non-metastasizing tumor that is highly vascular and oxygen dependent [34, 35]. Because of its high vascularity, it is an appropriate tumor model for acoustic angiography imaging after RT, since we are specifically interested in the tumor vascular response to therapy. Because rat FSA is oxygen dependent, avascular regions typically undergo tissue necrosis [35].

Figure 1. A) B-mode image in the coronal view of a tumor located in the right flank of a rat indicated with yellow arrows. B) A coronal maximum intensity projection of 3D intensity data from a stack of 2D acoustic angiography images in the same imaging area. Using acoustic angiography we can visualize the tumor tissue and microvasculature with exceptional tissue rejection.

Radiation Therapy and Monitoring

Once the tumors reached their target treatment size of 5-10 mm in diameter in the longest dimension of the sagittal plane, the tumors were given a single dose of radiation. The rats were split into four different dose cohorts and received either 0 Gy (treatment control, $n=9$), 15 Gy ($n=8$), 20 Gy ($n=5$), or 25 Gy ($n=8$) of radiation. The dose levels were determined during a longitudinal pilot RT study (unpublished) that was conducted at 0, 5, and 20 Gy. We found that 5 Gy had no tumor control, and 20 Gy had roughly 50% local control (tumor shrinkage and eventual disappearance) and 50% local failure (initial tumor shrinkage followed by a delayed tumor regrowth). We selected a dose level of 15-25 Gy as it allowed us to investigate the dose dependent correlation between TV change and VVD change for both local control and local failure groups with similar statistics.

The rats were anesthetized using vaporized isoflurane and oriented in the left lateral recumbent position on a heating pad throughout the duration of the treatment with front and rear paws stabilized on the heating pad with medical tape. Positioning was performed using a rotatable rat positioning table (VisualSonics, Toronto Canada) so that the tumor was completely irradiated while minimizing exposure to the abdominal region (Figure 2). The rats were treated with a Primus II clinical linear accelerator (Siemens Healthcare, Malvern, PA) with a dose prescription of 6 MV photons, 2 cm x 2 cm collimated radiation field size at 100 cm source-to-skin-distance (SSD), and 1 cm of water-equivalent build-up material. All rats were monitored daily for the first 2 weeks following treatment, and then every third day thereafter. Additionally, the animals were all fed identical diets consisting of regular protein pellets and both calorie-rich and hydrating gels to mitigate excessive weight-loss and water-loss due to dehydration in the case of intestinal distress caused by radiation enteritis.

Figure 2. Setup used for irradiation and ultrasound imaging. A) (Front view) For irradiation, the rat was positioned on a heating pad mounted to a 3-axis rotatable base. The heating pad was rotated to an angle such that the irradiation beam was centered on the tumor while minimizing exposure to the abdominopelvic region. The 1 cm water-equivalent bolus was then placed on top of the tumor region. B) (Top view) The rat was secured to the heating pad using medical tape. A 2 cm x 2 cm irradiation field size was used. C) (Front view) For imaging, the rat was positioned on the same heating pad, oriented parallel to the floor such that the tumor was facing up. A custom designed water bath was used to separate the transducer from the gel while still being continuously coupled to the tumor, so that the mechanical translation of the transducer would not displace the gel causing decoupling and introducing air bubbles. D) (Side view) The transducer was mechanically translated in the elevational dimension for 2 cm for each scan.

Imaging Procedure

Rats were imaged immediately prior to radiation for baseline measurements. After the radiation treatment, imaging was performed daily for 3 consecutive days and then every 3 days for approximately 30 days or until the tumors reached the maximum size of 2 cm in the longest diameter.

During each imaging session, the rats were anesthetized using vaporized isoflurane and positioned on a heating pad as described above. A tail vein IV catheter was inserted for constant microbubble contrast infusion during acoustic angiography imaging. Microbubble contrast agents were prepared in-house using sterile techniques, as previously described [33]. The contrast was diluted with 0.9% sterile saline in a 1:1 ratio. The contrast agent was administered as a small bolus of 50 μL immediately followed by a constant rate of infusion of 40 $\mu\text{L}/\text{min}$ using a pre-clinical infusion pump. Contrast was infused for 30 s before imaging was initiated to allow contrast flow to achieve a steady state and then was continued for the duration of the imaging scan. A total contrast volume of approximately 180 μL was injected for one acoustic angiography scan. The tumor region of the rat was shaved and depilated and ultrasound gel was applied onto the tumor region for ultrasound coupling. A custom imaging bath was used for all imaging to minimize gel decoupling during mechanical translation of the transducer (Figure 2). All imaging was performed on a Vevo 770 pre-clinical ultrasound scanner (VisualSonics, Toronto, ON, Canada) with a custom prototype dual-frequency transducer modified from a VisualSonics RMV707 probe, as previously described [36]. This transducer utilized a 4 MHz transmitter and a 30 MHz receiver, and was mechanically swept to acquire 2D images, and then translated in the elevational axis to acquire 3D data. A b-mode (anatomical) image volume was acquired over a 2 cm region, followed by an acoustic angiography scan over the same region. The elevational step size for each image was 100 μm . Two-frame averaging with a frame rate of 3 frames/s was used for all acoustic angiography imaging to improve the signal-to-noise ratio for producing optimal images.

Image Analysis

The b-mode images were used to calculate tumor volume (TV). The caliper feature on the Vevo 770 imaging software was used to measure the longest tumor diameter in each image axis to approximate the ellipsoidal volume of the tumor. The acoustic angiography images were post-processed using MATLAB (MathWorks, Natick, MA) to measure

volumetric vascular density (VVD). It is important to identify and remove large hypoechoic regions to not overestimate the total perfused tissue volume [37,38]. We assumed that large hypoechoic regions were due to necrosis and hypoxia, based on tumor ex vivo observations and prior literature that describes rat FSA as a highly oxygen dependent tumor [35]. These hypoechoic regions will be referred to as “necrotic” for simplicity, which encompasses necrotic and perinecrotic regions. For identifying necrotic regions, a de-noising 2D median filter was applied to each frame of the acoustic angiography image slices to smooth the image and then a threshold was used to create a binary mask that identified large dark regions. This binary mask was then applied to the corresponding frame of the original acoustic angiography image followed by subsequent thresholding to identify the vessels using the local Otsu threshold method [39]. VVD was calculated by dividing the number of pixels representing vessels by the number of pixels representing the tumor tissue sans necrosis (Figure 3).

Figure 3. Summary of the image analysis for calculating VVD. A single 2D slice of a 3D volume is shown in this figure. A) The original acoustic angiography region of interest (ROI). B) The original image, de-noised with a 2D median filter. C) The binary vessel image of the original ROI produced by applying an Otsu threshold. D) The hypoechoic mask made by applying a threshold on the de-noised image (B). E) The mask (D) applied to the binary vessel image (C). Arrows indicate resolvable vessels that have been converted into binary by thresholding.

Data Analysis

At the end of the study, treated rats were retrospectively categorized based on the treatment

outcome as either local failure (initial treatment response followed by tumor recurrence) or local control (full treatment response resulting in complete tumor disappearance). The 20 Gy study was terminated early at day 20 due to imaging schedule constraints. All local control tumors were monitored for the duration of the study (30 days) for tumor regrowth, followed by an additional 30 days.

TV and VVD growth curves for all individual rats were normalized by their respective baseline (pre-treatment) values. Initial TV growth curves (before tumor regression) and tumor recurrence rates were characterized by calculating their doubling times (D_t) using the following equation, where D_t is the doubling time, T_0 is the time of initial measurement, V_0 is the initial volume, and V_f is the final volume: $D_t = (T - T_0) \times (\log(2)/\log(V_f)) - \log(V_0)$.

Similarly, TV regression was characterized by calculating the tumor halving times (H_t) using the following equation: $H_t = (T - T_0) \times (\log(1/2)/\log(V_f)) - \log(V_0)$ [40].

Different phases of the VVD curves (initial response, regression, and recurrence phases) were characterized using linear regression.

TV_x and VVD_x represent the beginning of the recurrence phase for tumor volume and volumetric vascular density measurements, respectively, for an individual tumor. Statistical differences in growth curves and TV_x and VVD_x values were evaluated using the Mann-Whitney U-test, and differences observed between dose groups were evaluated with the Kruskal-Wallis test, followed by the Tukey Post-Hoc multiple comparison test ($\alpha = 0.05$). All statistical analysis was performed in MATLAB.

Results

The treatment response statistics and sample sizes for each dose group are summarized in Table 1. Local failure, local control and untreated tumors in each dose group present distinctly different VVD and TV growth curves (Figure 4).

Table 1. Treatment Response Statistics by Dose Group Summary statistics of the treatment outcomes for each dose group. Local tumor failure refers to tumors that initially responded but regrew and progressed, and local tumor control refers to tumors that completely disappeared after treatment.

	15 Gy	20 Gy	25 Gy
Local Tumor Failure	5 (63%)	3 (60%)	3 (38%)
Local Tumor Control	3 (38%)	2 (40%)	5 (63%)
Total Treated Tumors:	8	5	8

Initial Response

Untreated tumors underwent normal, uninterrupted exponential volume growth with a mean doubling time of 1.9 ± 0.5 days (median: 1.9 days; range: 1.4 days; IQR: 0.6 days). All treated tumors presented delayed tumor volume growth after the treatment (day 0) until day 3, at a growth rate significantly less ($p=0.009$) than the untreated tumors with a mean tumor doubling time of 3.8 ± 2.6 days (median: 3.2 days; range: 11.7 days; IQR: 2.0 days). There was a non-significant decrease in the average tumor doubling time for treated tumors as RT dose increased. VVD of all treated tumors increased by an average of $18 \pm 13\%$, significantly greater ($p=0.023$) than in untreated tumors, which increased by $4 \pm 6\%$. There were no significant VVD or TV differences between local failure and local control tumors within each dose group (Table 2).

Table 2. Tumor Volume and Volumetric Vascular Density Growth Curve Statistics Statistical analysis of tumor volume and volumetric vascular density growth curves for each dose group. Significant differences were observed in TV doubling time and VDD increase, immediately post-treatment. Treated tumors experienced delayed tumor growth (increased TV doubling time) immediately after treatment while VVD in treated tumors increased at a significantly higher rate than untreated tumors. There were no other statistically significant growth curve trends between treated and untreated, and local control and local failure tumors.

	Untreated	All Treated	15 Gy		20 Gy		25 Gy	
			Local Control	Local Failure	Local Control	Local Failure	Local Control	Local Failure
Tumor Volume Doubling time - Initial Response (days)	1.9 ± 0.5	3.8 ± 2.6 ($p=0.009$)	5.6 ± 3.4 5.5 ± 1.2	5.7 ± 4.7	3.4 ± 0.5 3.6 ± 0.7	3.3 ± 0.3	2.4 ± 1.4 2.3 ± 1.3	2.4 ± 1.9
Volumetric Vascular Density increase - Initial Response (%)	4.3 ± 6.1	18.1 ± 12.7 ($p=0.023$)	21.0 ± 15.8 22.3 ± 21.3	20.5 ± 14.0	26.5 ± 10.2 23.8 ± 15.3	28.3 ± 8.9	10.0 ± 5.1 8.6 ± 5.9	12.4 ± 2.9
Tumor Volume Halving time - Regression (days)	~	3.0 ± 1.0	3.2 ± 0.7 2.5 ± 0.3	3.8 ± 0.5	2.8 ± 0.3 3.0 ± 0.6	2.7 ± 0.1	2.9 ± 1.4 2.1 ± 0.3	1.3 ± 1.6

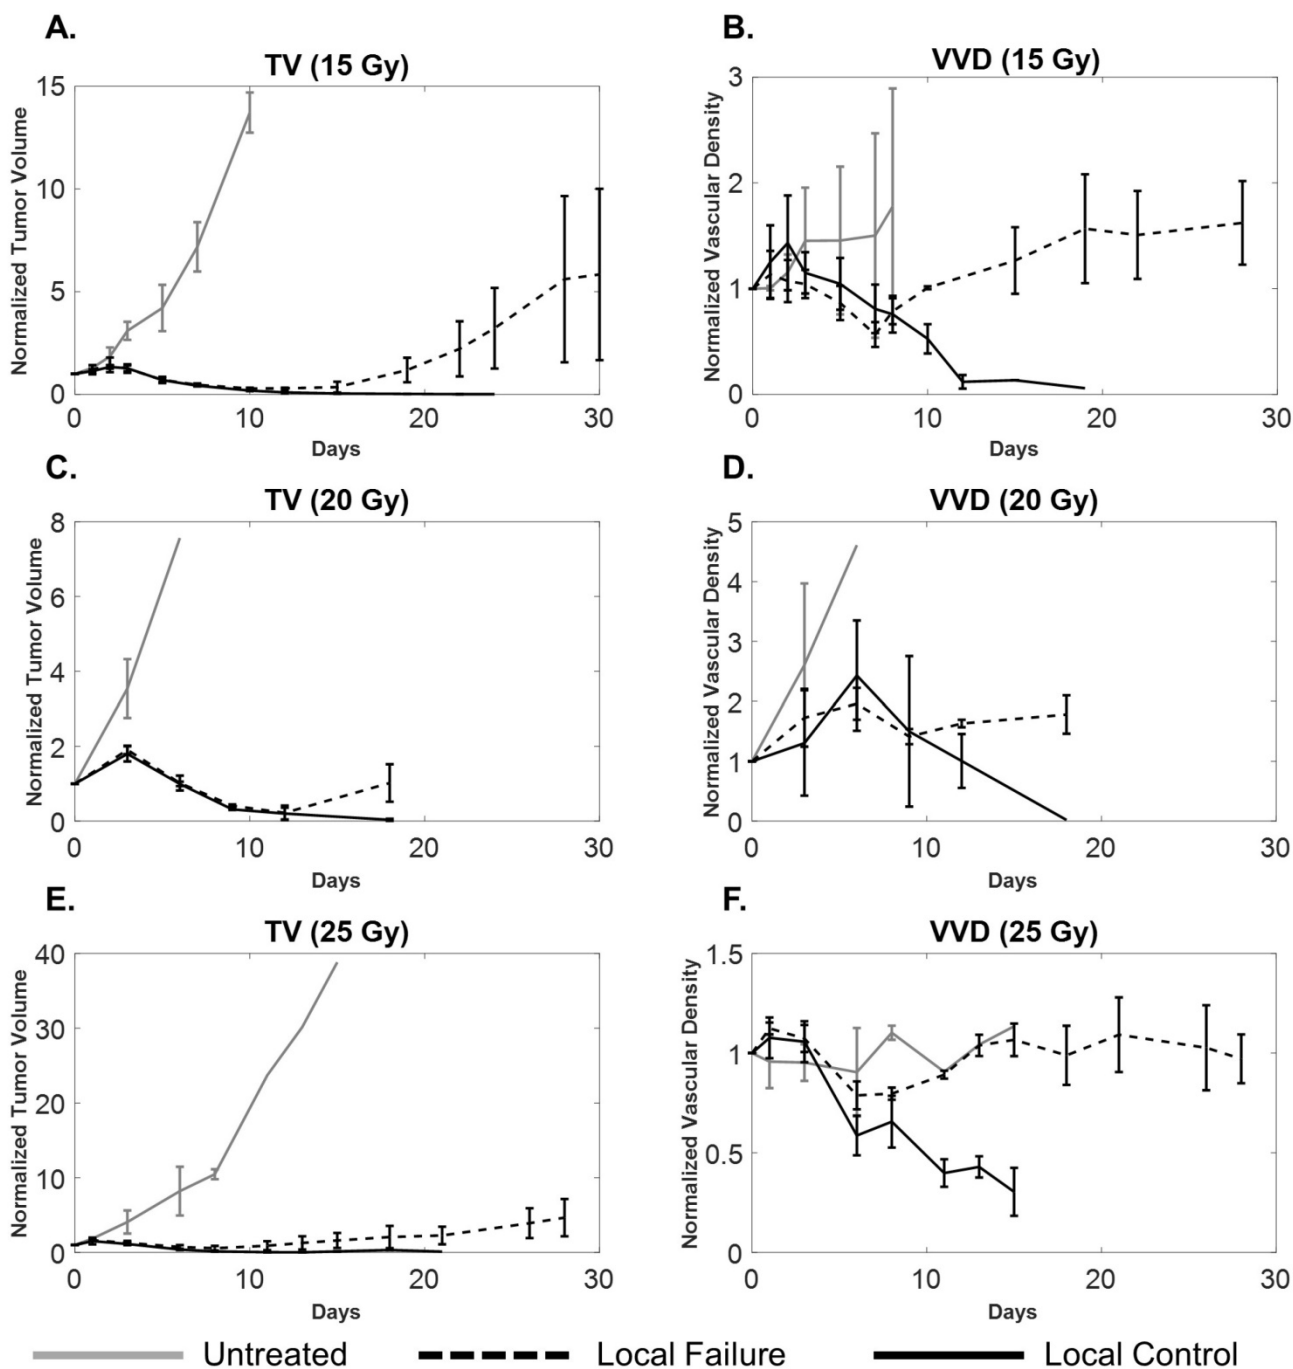

Figure 4. A comparison of tumor volume (A, C, E) and tumor microvascular density (B, D, F) growth curves for local control (solid black), local failure (dotted black), and untreated tumors (solid gray) for each dose group. Sample sizes for local control, local failure, and untreated groups were 3, 4, and 2 for the 15 Gy group, 2, 3, and 5 for the 20 Gy group, and 5, 3, and 2 for the 25 Gy cohorts, respectively. Error bars represent standard deviation. Local failure tumors undergo a transient decrease in vascular density that correlates with tumor regression and eventually increases, correlating with tumor recurrence. For local control tumors, both TV and VVD decrease. The large error bars in TV and VVD curves are expected due to variability in tumor growth as well as heterogeneity of vascular supply.

Tumor Regression

By day 5, all treated tumors experienced tumor regression where both tumor volume and vascular density decreased. There was no statistical difference in the regression rates of either TV or VVD between local control and local failure tumors in the 15, 20, and 25 Gy treatment groups. For local control tumors, the

tumors continued to shrink and completely disappeared between days 15 and 20, accompanied with decreasing VVD (Table 2).

Tumor Recurrence

All local failure tumors rebounded and recurred between days 10 and 20 as indicated by their TV growth curves. VVD began to increase between days 7

and 11 and was also associated with tumor recurrence. Tumor recurrence occurred (non-significantly) earlier as dose increased as indicated by decreasing average TV_x ; VVD recurrence (average VVD_x) was not statistically different between dose groups. When comparing TV and VVD curves

for each individual tumor, the increase in VVD was observed earlier than the increase in TV (Figure 5). Figure 6 visually illustrates TV and VVD changes where VVD begins to increase while TV is still in the regression phase.

Figure 5. Example of vascular density (left) and tumor volume (right) growth curves from a 15 Gy local failure. All measurements were normalized to baseline values. In this particular local failure, vascular density begins to increase as early as day 8, while tumor volume regrowth occurs later. The increase in the growth curve for both metrics demarcates the recurrence phase for local failure tumors, which is illustrated by the shaded region. The tumor volume and vascular density growth curves of local failure tumors in each dose group behaved similarly.

Figure 6. A visual comparison of vascular density and tumor volume changes during the tumor regrowth phase of the same 15 Gy local failure tumor plotted in Figure 4. Vascular density (right) noticeably increases from day 7 to day 19, while tumor volume (left) size continues to decrease until day 19. The tumor boundary in the b-mode images is indicated by the solid yellow line. Note that microvascular data is shown as a maximum intensity projection but is actually a 3-D data set.

Increase in VVD for individual rats was observed 10.25 ± 1.5 days, 6 ± 0 days, and 4 ± 1.4 days earlier than increases in TV, in the 15 Gy*, 20 Gy*, and 25 Gy cohorts, respectively (Figure 7, * $p < 0.05$). The initial tumor volumes were 157.8 ± 5.9 mm³, 182.9 ± 68.1 mm³, 201.4 ± 77.4 mm³, for the 15, 20, and 25 G groups, respectively. Variation in initial tumor volumes between groups was due to tumor growth difficulties; specifically, at the time of treatment, tumors either did not develop or grew too large (>1 cm in diameter) to be continued in the study. There were non-statistically significant differences in TV and VVD measurements between local controls and local failures; specifically, local failures exhibited higher TVs and VVDs (Table 3).

Figure 7. Dose dependence of the early detection of treatment failure by tumor vascular density. Local failure identification using vascular density (black) occurred earlier than using tumor volume (gray). With increasing dose, the difference in the time of identification between vascular density and tumor volume decreased. ([*] significant at $p < 0.05$).

Table 3. Average Initial TV and VVD Values Average initial tumor volume and initial vascular density values for each dose group. Larger initial tumor volumes were associated with local failure. While not statistically significant, the average initial vascular density for local failure tumors was greater than local tumor control. This became less pronounced as dose increased.

Dose (Gy)	Average Initial TV (mm ³) (* $p < 0.05$)		Average Initial VVD (* $p < 0.05$)	
	Local Failure	Local Control	Local Failure	Local Control
15	171 ± 52	108 ± 40	$0.25 \pm .04$	0.16 ± 0.10
20	230 ± 67	137 ± 110	0.26 ± 0.01	0.20 ± 0.05
25	290 ± 77	$169 \pm 39^*$	0.27 ± 0.02	0.25 ± 0.04

No severe adverse health effects or significant weight loss were observed in any of the rats during the entirety of the study. The orientation of the rat during treatment minimized irradiation of the abdominopelvic region, resulting in less toxicity than in our previous studies where the rat was oriented perpendicular to the radiation beam. Mild radiation enteritis was experienced by fewer than 5 rats, which resulted in loose stool and an average of 5 g or 3% loss

of body weight. This was mitigated with supplementary high calorie food and hydrogel water (Methods section). All rats with recurring tumors were euthanized at the end of the study. Rats with successfully treated tumors have been kept indefinitely (>180 days) since the end of the study and have not shown any signs of tumor recurrence.

Discussion

We have previously demonstrated that acoustic angiography can visualize microvasculature with high-resolution, and various quantitative metrics are sensitive to certain abnormal microvascular structural properties (e.g. tortuosity, density) that allow us to discern cancerous tissue from normal tissue [31,32]. Based on previous research that has demonstrated that microvascular remodeling occurs within days after radiation exposure using optical imaging, we hypothesized that quantification of microvascular changes using acoustic angiography may indicate response to therapy sooner than using tumor volume alone, the current clinical standard for assessing response to treatment [9]. In this work, we have demonstrated that quantitative acoustic angiography is sensitive to changes in microvascular density induced by RT and its feasibility as a tool for predicting treatment response.

We believe the clinical implications of our data are significant. In this tumor model, we have demonstrated that by quantifying the dynamic microvascular response to RT, tumor recurrence can be detected earlier than using tumor volume measurements alone. In clinical practice, irradiated tumors often do not significantly change in size until 3-4 months after treatment and therefore post-treatment imaging is also not performed during this time [41]. For any cancer patient, early detection of cancer and early assessment of treatment response is critical for maximizing the chance of improving or maintaining quality of life. By decreasing the wait time between treatment and post-treatment evaluation, we may be able to increase the probability of successfully modifying an unsuccessful treatment strategy to one that is tailored to the patient. This is specifically important for RT, which by itself is often used with radical intent more than in a palliative setting.

The results in this study using a rat FSA model demonstrate that changes in volumetric vascular density is a biomarker that presents differently in local control and local failure tumors in response to RT, and that vascular density regrowth associated with tumor recurrence in local failure tumors occurs significantly sooner than tumor volume regrowth. In the tumors that present local control, VVD and TV

both decrease at similar rates until the tumor completely disappears.

We observe three phases after RT in both the VVD and TV curves, as described by Kozin *et al.*: 1) initial treatment response presented by a continued increase in TV and VVD, 2) tumor regression phase presented by decrease in TV and VVD, and in local failure tumors, 3) tumor recurrence phase [42]. In the initial treatment response phase, we observed an increase in VVD that occurred at a significantly greater rate than in untreated tumors, most likely due to short term inflammation and subsequent hypervascularization caused by the high-dose RT. This observation is supported by previous pre-clinical studies that observed hyperperfusion immediately after RT [26]. Days before TV recurrence (TV_x) is measurable in the local failure tumors, the tumors begin to undergo a rapid increase in vascular density that can be visualized on imaging and quantitatively measured. While we do not have data supporting why vascular density increases earlier than tumor volume, prior evidence suggests that the tumor endothelium experiences stress-induced expression of vascular endothelial growth factor (VEGF) and $\alpha_v\beta_3$ -integrins, therefore evading cell death and possibly promoting revascularization and tumor cell proliferation [43,44].

In this study, we observed that the average tumor volume in the local failure tumors was larger than the local control tumors, in all dose groups, although the size difference was not significant due to variance. The increased likelihood of failure in RT treatment of larger tumors is consistent with radiation biology theory [45,46]. As expected, the tumor volume threshold corresponding with local control increased as a function of radiation dose (Table 3). We also observed that average initial vascular density was greater in local failure tumors compared to local control tumors; however, the differences were not significant and require further investigation (Figure 7). Although a higher VVD at the time of treatment might be associated with an increase in tumor oxygenation and improved RT outcome, this hypothesis remains unanswered with conflicting results from previous studies [47]. Hypoxic tumors are known to be more radioresistant than normoxic tumors due to a number of reasons including the lower probability of reactive oxygen species being produced by ionizing radiation thus forming fewer DNA strand breaks, as well as the negative effect of hypoxia on the pathway for DNA damage repair resulting in a more radioresistant cell type [48]. While many previous studies have observed a positive correlation between vascular density and therapeutic response, others have reported that

vascular density has no effect, or an inverse correlation with treatment response [47,49]. We speculate that in this particular tumor model, endothelial cells within the larger tumors, which inherently have a higher VVD, may undergo a smaller fraction of lethal radiation damage than smaller tumors and can eventually repair, possibly encouraging tumor regrowth. Due to the variability in tumor growth rates and unforeseen treatment scheduling complications, our initial size distribution was not comparable in all dose groups and is a confounding factor in explaining the effect of initial vascular density on treatment outcome.

We observed earlier tumor recurrence with increasing dose; however, this requires further investigation. There are two possible explanations. First, as mentioned previously, the average initial (pre-treatment) TV was larger as dose increased, which may have resulted in a lower tumor cell kill fraction despite being treated with higher doses. Second, there is evidence that suggests that hypoxia induced by higher dose RT activates the unfolded protein response, protecting against hypoxia and resulting in the ability to more aggressively proliferate and metastasize [50]. However, further investigation is required to determine if FSA is affected by hypoxia-induced stress.

We chose to use a simple, single high-dose fraction treatment to demonstrate feasibility of our imaging technique. Our dosage scheme was determined based on pilot study results (unpublished) of a longitudinal RT study performed at 0, 5, and 20 Gy in the same rat and tumor model. In the 20 Gy treatment group, ~50% resulted in local control. We chose doses between 15 and 25 Gy to investigate the TV and VVD differences between local controls and local failures while also determining any dose dependent responses. Conventional dose fractionation, or the division of the total radiation dose into multiple smaller doses over 7-8 weeks, is clinically used to reduce healthy tissue toxicity by allowing cellular repair in between successive treatments [51]. At this point, the effect of a dose fractionated scenario on tumor VVD is unclear and is an important, clinically relevant question that still needs to be answered. Our high-dose treatment conditions are more relevant to stereotactic body radiotherapy (SBRT) or stereotactic radiosurgery (SRS), and hypo-fractionated radiation therapy, which precisely deliver high dose radiation to the target tissue with just a single or few treatments [52]. Hypofractionation and SBRT/SRS, while relatively new and controversial in the field of radiotherapy, are promising techniques that may reduce toxicity while improving tumor control [52-54]. The results from

this initial study motivate us to conduct further investigation under experimental conditions closer to more clinically relevant applications that incorporate conventional and hypo-fractionated RT.

As mentioned previously, tumor hypoxia and necrosis play an important role in tumor response to radiation [50, 55]. The microvascular changes observed in this study are specific to the Fischer 344 rat fibrosarcoma tumor model. Since this tumor strain has been shown to be highly oxygen dependent we made an assumption that areas of hypovascularity (hypoechoic regions) represented necrotic and perinecrotic regions [35]. The motivation for removing the hypoechoic regions was to prevent overestimation of the perfused tissue volume. However, histology was not performed to confirm the hypoechoic regions as necrotic/perinecrotic to validate our analysis. This can be performed in future studies using the TUNEL assay and hematoxylin and eosin staining [56].

The diversity of human tumors is accompanied with a wide range of neovascularization patterns, including both avascular (hypoxic) and vascular development [7]. Further investigation using this technique in different types of human-derived tumor models is warranted since the microvascular response after exposure to radiation will likely vary among different tumor types. Regardless, we are encouraged from these results that quantitative microvascular measurements using acoustic angiography may significantly improve the current methods for treatment assessment.

The current dual-frequency prototype transducer suffers from resolution and imaging depth limitations. The resolution of acoustic angiography is between 100-200 μm , which places a limitation on the smallest size tumor that can be accurately analyzed for VVD. Tumors less than 1 mm in diameter may inaccurately measure VVD as high as 20-50% due to the resolution limitation. Additionally, due to the fixed focus of the dual-frequency transducer, our depth of field was limited to approximately 1.0 cm axially with a maximum depth penetration of ~ 2 cm. Tumors near 2 cm in diameter were clipped at the top and bottom in order to maintain the focus of the transducer in the center of the tumor. Acoustic angiography experiences substantial one-way frequency dependent attenuation due to the high frequency receive bandwidth, which limits the imaging penetration depth to superficial organs. Decreasing the transducer receiving frequency will improve the imaging penetration depth and depth of field, however the signal-to-noise ratio would be compromised due to the reduced separation between tissue signal and higher harmonic contrast signal.

Conversely, increasing the receiving frequency will improve resolution, but at the cost of decreasing contrast sensitivity, penetration depth, and depth of field. Despite these limitations, acoustic angiography has remarkably high resolution and contrast sensitivity relative to clinically available CEUS techniques. Further, development of a linear array dual-frequency transducer will enhance acoustic angiography with the increased depth of field and faster image acquisition required for clinical translation [57,58]. Nevertheless, due to the high-frequency receive bandwidth, acoustic angiography will always be limited to imaging targets within a few cm of the skin. Neck cancers, prostate, and breast cancers might be reasonable targets, however deeper cancers in organs such as the liver will not be accessible without an endoscopic imaging tool.

It is also worth noting that new super-resolution imaging techniques may provide an alternative solution to imaging angiogenic vasculature with an order of magnitude better resolution once the technology matures. However, super resolution imaging still requires tens of minutes to acquire a 3D volume of data due to data acquisition and processing limitations [59].

In our study, we retrospectively categorized the treated tumors as local control or failure based on the final treatment outcome. The development of a predictive tool indicating treatment outcome based on repeated vascular density (or other vessel morphological features) and tumor volume measurements will be highly relevant to the clinical translation of this diagnostic technique. There has been a recent surge of interest in developing models for predicting a patient's outcome to cancer therapy. The field of Radiomics, for example, has been established to use large sets of minable MR, CT and PET imaging data to extract quantitative features such as tumor sphericity, homogeneity, and volume. When combined with other patient medical data, it can be analyzed using advanced bioinformatics statistical techniques to determine correlations to tumor behavior and treatment response [60]. Similarly, with acoustic angiography image data, we can extract additional quantitative features that describe microvascular characteristics of certain tumors and their response to therapy. We plan to continue investigating changes in vessel morphology (using metrics to describe vessel tortuosity) and molecular expression in response to RT in future studies. Contrast-enhanced ultrasound imaging is a safe, inexpensive, and highly accessible imaging modality with many applications in all fields of oncology, and with on-going technical improvements, acoustic

angiography is a promising and clinically translatable imaging technology.

Conclusion

While the biological basis for the variation of tumor response to radiation is still not entirely understood, there is a growing body of evidence that suggests that the tumor microvascular environment plays a significant role in radiation treatment efficacy. Our objective in this study was to assess tumor response to radiation by quantifying changes in vascularity that may be associated with treatment outcome. Our results demonstrated that vascular changes, specifically increases in vascular density, are a potential biomarker for assessing long-term tumor response to RT. We believe that providing a more timely and reliable method for assessing treatment response may enable clinical treatment decisions to be made earlier than the current standard of care, therefore improving cancer patient outcomes.

Abbreviations

AA: acoustic angiography; VVD: volumetric vascular density; TV: tumor volume; RT: radiation therapy; FSA: fibrosarcoma; CEUS: contrast enhanced ultrasound; SRS: stereotactic radiosurgery; SBRT: stereotactic body radiotherapy.

Acknowledgments

The project described was supported by the National Institutes of Health through grant R01CA170665 and the National Center for Advancing Translational Sciences (NCATS), National Institutes of Health, through Grant Award Number UL1TR001111. The content is solely the responsibility of the authors and does not necessarily represent the official views of the funding agencies. The authors would like to acknowledge the UNC Department of Radiation oncology for providing access to the clinical linear accelerators for the animal treatments, as well as Dr. Stuart Foster, Mike Lee, Emmanuel Cherin, and Jay Son (Sunnybrook Research Institute) and Chris Chaggares and Desmond Hirson (Visualsonics) for their help with the development of our dual-frequency prototype transducers.

Competing Interests

Authors Paul A. Dayton and Ryan C. Gessner of this publication are co-inventors on the dual-frequency imaging approach described here and have equity ownership in Sonovol, Inc., a company that has licensed this patent. Other authors have declared that no competing interest exists.
