14 **Short title:** Feline hepatology following isoflavone exposure

### 15 **Summary**

16 Dietary isoflavones have been hypothesised to play a role in hepatic veno-occlusive disease  
17 in captive exotic felids, although empirical evidence is lacking. This study aimed to  
18 investigate the effect of long-term (>1 year) dietary genistein and daidzein exposure on the  
19 hepatic biochemistry and histology of domestic cats. Individual cats were assessed for hepatic  
20 enzyme and bile acid production before and after the removal of isoflavones from their diet in  
21 the treatment group (n=4), and at the same times in unexposed control animals (n=7). No

22 significant differences were detectable in hepatic biochemistry between treatment and control  
23 groups, and all serum values were within the normal reference ranges for domestic cats.  
24 Additionally, treatment animals demonstrated slightly greater areas of fibrosis surrounding  
25 hepatic venules than control animals, but this difference was not statistically significant. On  
26 the basis of the results presented, dietary isoflavones, at the current dose and duration of  
27 exposure do not appear to modulate hepatic enzyme production or histological parameters.

28 **Keywords:** cats, feline, soya, isoflavone, liver

## 29 **Introduction**

30 Dietary isoflavones, such as genistein and daidzein, have previously been shown to elicit a  
31 diverse array of physiological effects including endocrinological, morphological and  
32 histological changes in a variety of tissues or organs in species such as rodents, pigs and  
33 humans (Barnes *et al* 2000; Ford *et al* 2006; McClain *et al* 2006). Isoflavones are structurally  
34 similar to oestradiol and can bind to oestrogen receptors and function as natural selective  
35 oestrogen receptor modulators, although a diverse array of non-hormonal effects and tissue-  
36 or species-specific effects have also been observed in both rodents and humans (Hollander  
37 1997; Barnes *et al* 2000; Pike 2006).

38 The liver is also a target of oestrogen activity (Diel *et al.* 2002), and isoflavones have been  
39 shown to exert a variety of effects on hepatic activities. Both genistein and daidzein have  
40 been associated with hypertrophic effects in the liver (Banz *et al.*, 2004; McClain *et al.*,  
41 2006b). However, studies with soy protein isolate (containing isoflavones) have produced  
42 divergent results, with no effect in female rats and reduced liver weights in male rats (Peluso  
43 *et al.*, 2000; Huang *et al.*, 2005; Tachibana *et al.*, 2005). Likewise, mild hepatotoxicity was  
44 only demonstrated following exposure to high isoflavone doses (500mg/kg BW) with these

45 changes reversible, suggesting that normal dietary exposure (estimated to be < 10 mg/kg BW  
46 for domestic cats and captive cheetahs; Bell *et al.*, 2006 and 2010) is unlikely to pose a risk to  
47 hepatic health (McClain *et al.*, 2006b). Moreover, other studies have demonstrated a  
48 protective role for isoflavones against various hepatic insults (Lee *et al.* 1995; Kang *et al.*  
49 2001; Liu *et al.* 2002; Kuzu *et al.* 2007; Wong *et al.* 2007).

50 However, dietary isoflavones have been implicated in the onset or progression of veno-  
51 occlusive disease (VOD; hepatic fibrosis) in captive cheetahs (Setchell *et al.*, 1987ab;  
52 Gosselin *et al.*, 1988). This disease is responsible for significant levels of mortality in the  
53 global captive cheetah population (Munson *et al.*, 2005), but the cause(s) are not yet clearly  
54 defined. Hepatic architecture is modulated during VOD and histological changes include  
55 hepatic congestion, haemorrhage, hepatocyte and hepatic stellate cell vacuolation, foci of  
56 extra-medullary haematopoiesis (EMH; a marker for hypoxia, infection and/or precocious  
57 immune response) (Törő *et al.* 2007), and increased neutrophil and macrophage cell numbers.  
58 However, no controlled study has been conducted to determine the ability of isoflavones to  
59 modulate hepatic parameters in any felid species. Therefore, the aim of this study was to  
60 determine the potential of long term consumption of genistein and daidzein to elicit  
61 detectable effects on hepatic histology or biochemical parameters (as an indication of  
62 hepatocyte health and biliary secretion) in a felid species, the domestic cat.

### 63 **Materials and Methods**

64 Eleven female short-haired domestic cats were utilised in this study. Premature removal of  
65 four cats from the treatment group (for reasons unrelated to this study) resulted in a low and  
66 uneven sample size. Cats were bred and maintained at the Centre for Feline Nutrition  
67 (Massey University, New Zealand). Kittens were mother-reared until six weeks of age,  
68 during which time they had access to the queen's diet (a commercial diet which met the

69 AAFCO (2004) standards for gestation and lactation). Previous analysis of this diet  
70 demonstrated it contained a very low (16 µg total isoflavone/g DM) isoflavone  
71 concentrations (Bell *et al* 2006), and exposed the queens to a total daily isoflavone dose of  
72 approximately 0.56 mg – 0.84 mg/kg BW. Intake of the maternal diet by kittens prior to  
73 weaning was thought to be minimal, but accurate assessment of the intake was not possible  
74 due to co-housing with the queen. However, pre-weaning exposure was identical between  
75 control and isoflavone-treated animals and intake predicted to be equivalent. At six weeks of  
76 age, cats were gradually weaned from the queens and separated into treatment and control  
77 groups. Cats were gradually introduced to the trial diets, and the day of sole consumption of  
78 the trial diet was recorded as the start of the trial for each individual cat. Cats were group-  
79 housed (maximum nine per pen) in multi-level outdoor pens (approx. 5 m x 2 m x 3 m),  
80 exposed to natural day/night cycles and provided with daily exercise opportunities and  
81 environmental enrichment. Control and treatment groups were housed in adjacent pens. Each  
82 cat was weighed weekly and body weight was recorded and tracked against the colony  
83 average. Cats had consumed the trial diets for an average of 394 ( $\pm$  25.73) days at the time of  
84 blood collection.

85 Cats assigned to the treatment group (n = 4 at study completion) had been exposed to the  
86 dietary isoflavones, genistein and daidzein, since weaning. Cats in the control group (n = 7)  
87 consumed the same base diet as the treatment group, without the addition of isoflavones.

88 The base diet for both control and treatment groups for the duration of the trial was a moist  
89 feline diet which met the requirements for growth in the domestic cat according to AAFCO  
90 (2009) testing. Previous analysis of this diet demonstrated it contained no detectable  
91 isoflavones (Bell *et al* 2006). The purified (99.9%) form of each isoflavone, genistein  
92 (150µg/g DM) and daidzein (150µg/g DM) (LC Laboratories, MA, USA) was added to the

93 base diet of the treatment group, to provide a calculated dose of 300 µg total isoflavone/g  
94 DM, which is representative of exposure through consumption of certain commercially  
95 prepared feline diets (Bell *et al* 2006). Due to the small quantities of powder to be added to  
96 large quantities of base diet it was necessary to use a freeze-dried inert carrier. The same  
97 concentration of freeze-dried carrier was added to the control diet without the addition of  
98 isoflavone powders.

99 Cats were provided water *ad libitum* during the trial, and offered enough food to provide each  
100 cat with appropriate energy intake for its age (i.e. 200 kcal/kg BW/d at 10 weeks, gradually  
101 reducing to 88 kcal/kg BW/d by 40 weeks; Legrand-Defretin and Munday 1993). Food intake  
102 per group was accurately weighed on a daily basis. Monthly assessments were made of  
103 individual food intake by separation of each cat into individual metabolism cages for 24 h,  
104 during which time food intake and urinary and faecal output were recorded.

105 Sub-samples of the control and treatment diets were assayed for isoflavone content  
106 intermittently throughout the trial, according to methodology described in Bell *et al* (2006).  
107 Ethical approval (MUAEC Protocol No. 06/06) for this trial was obtained from the Massey  
108 University Animal Ethics Committee (2006).

109 The average age at the time of initial blood collection was 428 ( $\pm$  25.75) days. Cats were  
110 fasted overnight, prior to an initial (2 ml) blood sample being collected by venipuncture of  
111 the jugular vein. The cats were then offered a meal of basal diet, and a second (1 ml) blood  
112 sample withdrawn by venipuncture, 2 h after ingestion of this meal. Blood was transferred  
113 into vacutainers and centrifuged to collect serum. Following collection of initial blood  
114 samples, the diet of the treatment group was replaced with the control diet (devoid of  
115 isoflavones), while the cats in the control group continued to be maintained on the control

116 diet. Forty days following this dietary change, a second pair of blood samples were collected  
117 and analysed, as described above.

118 Serum from the pre-prandial blood sample was analysed for alkaline phosphate (ALP),  
119 aspartate aminotransferase (AST), alanine aminotransferase (ALT), gamma glutamyl  
120 transferase (GGT) and bile acids (Gribbles Pathology Ltd., Palmerston North, NZ). Serum  
121 from the post-prandial blood sample was analysed for bile acid concentration only (Gribbles  
122 Pathology Ltd., Palmerston North, NZ). Serum was analysed within 48 h of collection.

123 A liver biopsy was obtained from cats that had been exposed to dietary isoflavones for  
124 approximately 394 days, when these animals underwent routine gonadectomy. Briefly,  
125 general anaesthesia was induced with Zoletil 100 (tiletamine and zolazepam 500 mg/ml each;  
126 12 mg/kg BW, sub-cutaneously) (Virbac, Auckland, New Zealand) and maintained with  
127 halothane/oxygen delivered *via* an endotracheal tube. A midline incision was made in order  
128 to perform routine ovario-hysterectomy. Upon completion of this procedure, a distal liver  
129 lobe was located and a wedge biopsy (0.7 – 1 g) taken from its border. One or two catgut  
130 sutures were used to control haemorrhage of the liver parenchyma (Cole *et al.* 2002), before  
131 routine abdominal closure. All animals received Temgesic (324 µg/ml buprenorphine  
132 hydrochloride, 0.03 mg/kg BW, sub-cutaneously) (Reckitt Benckiser, Auckland, New  
133 Zealand) for pain relief after surgery, and Ketofen (ketobrofen, 1 mg/kg BW *per os*) for the  
134 next 48 h. Cats were maintained in individual metabolism cages for 14 days following  
135 surgery, after which time sutures were removed and cats were returned to normal housing.

136 Each liver biopsy was immediately weighed and transferred to 10% neutral-buffered formalin  
137 (NBF), before processing on a Leica® TP1050 Tissue Processor (Global Science and  
138 Technology, Auckland, NZ). The samples were dehydrated through a series of graded  
139 alcohols (70%, 95% and absolute ethanol, BD, Poole, UK) at ambient temperature, cleared in

140 xylene and impregnated with Paraplast<sup>®</sup> Tissue embedding Medium (Global Science and  
141 Technology, Auckland, NZ) under pressure at 60°C. The samples were then embedded using  
142 a Leica Histo Embedder (Global Science and Technology, Auckland, NZ) and 3 µm sections  
143 were cut using MicroTec<sup>®</sup> Rotary Microtome (Global Science and Technology, Auckland,  
144 NZ). The sections were floated onto a Thermo<sup>®</sup> Tissue Bath (Medica Pacifica, Auckland,  
145 NZ) at 43°C and mounted onto Superfrost, pre-cleaned slides. Half of the slides were then  
146 placed in a 60°C oven for 20 min then stained with haematoxylin and eosin (H&E) on a  
147 Leica<sup>®</sup> Autostainer XL (Global Science and Technology, Auckland, NZ).

148 The remaining slides were placed in a 60°C oven for 20 min then dewaxed on a Leica<sup>®</sup>  
149 Autostainer XL (Global Science and Technology, Auckland, NZ) before staining using the  
150 Masson's Trichrome method. Following hydration in water, slides were left to mordant in  
151 Bouin's solution (Merck, Palmerston North, NZ), overnight at room temperature. Slides were  
152 then washed in tap water, stained in Celestine Blue (Merck, Palmerston North, NZ) for 10  
153 min, rinsed again before staining in Mayer's Haematoxylin (Merck, Palmerston North, NZ)  
154 for 10 min. Slides were rinsed again for 4 min and then stained in Beibrich Scarlet-Acid  
155 Fuchsin (Merck, Palmerston North, NZ) for 2 min before further rinsing. Sections were  
156 covered in 5% Phosphotungstic Acid (Merck, Palmerston North, NZ) for 15 min and then  
157 rinsed prior to staining with Light Green Solution (Merck, Palmerston North, NZ). After  
158 further rinsing, sections were blotted dry with filter paper and placed in 1% Glacial Acetic  
159 Acid (BD, Poole, UK). Sections were then blotted dry again before dehydrating in 95%  
160 ethanol, absolute ethanol, and finally clearing in xylene before mounting.

161 Liver sections were examined by a veterinary histo-pathologist (W. Roe) who provided a  
162 detailed report of the sections from each cat. The histo-pathologist was blinded to the  
163 treatment groups. Parameters reported were haemosiderin accumulation, intra-hepatocyte

164 vacuolation, hepatocyte degeneration, necrosis or regeneration. The presence/absence and  
165 extent of histological parameters were then tabulated and averaged according to treatment  
166 group.

167 The extent of fibrous tissue development around three hepatic blood venules (see Figure 1)  
168 was measured using ImageJ software (version 1.38. Rasband 2007; Research Services  
169 Branch, National Institute of Mental Health, MD, USA) and expressed as the percentage of  
170 the total area of each blood venule.

171

172 Figure 1. Liver section from a domestic cat in the current study. Central vein surrounded by  
173 subendothelial fibrosis (stained green/blue). Massons Trichrome stain

174 Changes in the serum concentrations of enzymes over time were calculated for each cat, and  
175 groups were tested for significant differences in any temporal changes. Differences in  
176 biochemical parameters at the first sampling time (prior to removal of isoflavones from the  
177 treatment group's diet), were also tested between groups. Residual data was tested for  
178 normality using the Anderson-Darling test. Differences between groups were tested for  
179 significance using the Mann-Whitney test as data was found to be not normally distributed.

180 Differences between the incidence of congestion, vacuolation, extra-medullary  
181 haematopoiesis (EMH) and inflammatory cells in treatment and control groups were tested  
182 using Fisher's exact test. The median is reported instead of the mean (Glantz, 2005). All  
183 statistical analyses were performed with Minitab software (version 15, Minitab Inc., PA,  
184 USA).

## 185 **Results and Discussion**

186 No significant differences ( $P > 0.05$ ) were detected in any biochemical parameters (ALP,  
187 AST, ALT, GGT, fasted or fed bile acids) within the first sampling phase, prior to isoflavone  
188 removal from the diet of the treatment cats (Table 1). Overall, changes in hepatic  
189 biochemistry parameters were generally similar between control and treatment cats.  
190 However, the results of a power analysis suggests that subtle differences were undetectable in  
191 the study, and that only large differences would be considered significant with the available  
192 sample size (a minimum difference of 59.6% with a power of 95%, or a minimum difference  
193 of 46.1% at 80% power).

194 Changes in these parameters, as well as bile acid response to a meal within each cat (before  
195 and after dietary change) did not differ between groups, or within the treatment group (i.e.  
196 during isoflavone exposure compared to following removal of isoflavones from the diet;  $P >$   
197  $0.05$ ) (Table 2). All parameters were within normal reference ranges for domestic cats, at all  
198 time points.

199 The consistent increase in ALT and GGT production between first and second sampling,  
200 observed in both control and treatment groups (Table 2), may reflect altered metabolism or  
201 hepatic activity as a consequence of removal of the reproductive tract.

202

203 Table 1. Median (lower quartile, upper quartile) hepatic biochemistry parameters following a  
 204 394 day ( $\pm 25.73$ ) period of dietary isoflavone exposure in the treatment group

	ALP (U/L)	AST (U/L)	ALT (U/L)	GGT (U/L)	Pre- prandial bile acids ( $\mu\text{mol/L}$ )	Post- prandial bile acids ( $\mu\text{mol/L}$ )	Bile acid response to a meal (U/L)
Control	29 (25, 31)	23 (18, 27)	43 (36, 52)	1.0 (0, 2.0)	0.5 (0.3, 0.5)	1.5 (1, 2.2)	0.9 (0.6, 1.7)
Treatment	56 (33, 82)	25 (18, 35)	45 (33, 56)	0.5 (0, 1.3)	0.4 (0.3, 0.6)	2.3 (2.0, 2.8)	1.7 (1.4, 2.3)

205 The increases observed in plasma ALT and GGT may have occurred from hepatocellular  
 206 injury, hormonal action, or as a consequence of muscle injury (Roth-Johnson 2004; Webster  
 207 2005), all of which are possible mechanisms in these cases. Gonadectomy would have been  
 208 associated with a reduction in circulating oestrogen, whilst the muscle trauma resulting from  
 209 abdominal opening during gonadectomy may have elicited the increased ALT and GGT  
 210 production. However, the lack of significance between changes in the control and treatment  
 211 groups ALT and GGT levels suggests that the hepatic production of these enzymes was not  
 212 modulated in response to dietary isoflavones, either during exposure or following a 40-day  
 213 recovery period.

214 This is in contrast to previous findings in cheetahs, in which removal of dietary isoflavones  
 215 elicited a reduction in ALT three months later (Setchell *et al.* 1987a). However, this earlier  
 216 study did not control for the variable nutrient composition of isoflavone-containing and

217 isoflavone-free diets and as such, the alteration in ALT cannot be apportioned solely to  
 218 isoflavones.

219

220 Table 2. Median (lower quartile, upper quartile) change in hepatic biochemistry parameters  
 221 after a 40 days period following the removal of isoflavones from the treatment group cats (no  
 222 dietary change in the control cats).

	ALP (U/L)	AST (U/L)	ALT (U/L)	GGT (U/L)	Pre- prandial bile acids ( $\mu\text{mol/L}$ )	Post Prandial Bile Acids ( $\mu\text{mol/L}$ )	Bile acid response to a meal (U/L)
Control	13 (10, 19)	-4.0 (-12, 0.5)	38 (30, 44)	2.0 (1.5, 2.5)	0.5 (0.2, 1.6)	-0.1 (-0.6, 1.2)	0.0 (-2.7, 0.7)
Treatment	-7.5 (-18, 2.5)	6.5 (-6.3, 16)	33 (19, 48)	4.5 (2.3, 12)	0.1 (-0.1, 0.1)	0.4 (0.1, 0.7)	0.5 (0.2, 0.8)

223

224 However, the current study utilised a shorter recovery period than Setchell *et al.* (1987a) and  
 225 gonadectomy occurred at the time that isoflavone exposure ceased, both of which may  
 226 explain the disparate results. Likewise, it is possible that the dose used in this study was  
 227 insufficient to elicit any change in these enzymes, since GGT was only slightly elevated in  
 228 rats when exposed to much higher genistein doses of 500 mg/kg BW (McClain *et al.* 2006b).  
 229 Additionally, the sensitivity of ALT for detection of hepatic disease is moderate at best  
 230 (Jacob *et al.* 2002), and only mild elevation of ALT or AST levels were noted in a domestic  
 231 cat diagnosed with hepatic VOD (Cave *et al.* 2002).

232 Rats exhibited a mild increase in plasma ALP after chronic exposure to 500 mg genistein/kg  
233 BW (McClain *et al.* 2006b). In the current study, no statistically significant difference in ALP  
234 concentrations were detected, although the treatment group's median ALP appeared to be  
235 higher than the control group's prior to removal of the isoflavones from their diet. Likewise,  
236 no significant changes in ALP were detected within individuals, but values suggest a  
237 reduction in ALP in treated animals following the removal of isoflavones from their diet,  
238 whilst control cats exhibited an increase in median ALP levels. Following a four week  
239 recovery period, rats exhibited significant recovery in the modulation of ALP (McClain *et al.*  
240 2006b), suggesting that isoflavones may have elicited a non-permanent increase in ALP  
241 production in cats in this study. However, this was not statistically determined due to the low  
242 sample size. In the cat, the combination of relatively low hepatic stores and the short half-life  
243 mean that plasma ALP is an insensitive marker of hepatic injury (Hoffmann *et al.* 1977).  
244 Thus, the absence of a significant change in serum ALP does not exclude modulation of  
245 hepatic injury.

246 The lack of difference between groups during the exposure phase, and the observed increase  
247 in ALT following cessation of isoflavone exposure indicates that hepatic injury was not  
248 associated with isoflavone consumption. Unchanged AST concentrations provided further  
249 evidence to support a lack of hepatic insult, since elevations of this enzyme, in combination  
250 with increased ALT levels are generally good indicators of hepatic dysfunction in the cat  
251 (Roth-Johnson 2004; Webster 2005). Rats exposed to significantly higher doses of genistein  
252 also failed to exhibit any change in AST concentration (McClain *et al.* 2006b).

253 Serum bile acid concentration is used in veterinary medicine to assess hepatic clearance from  
254 portal circulation and functional hepatic mass (Roth-Johnson 2004; Webster 2005). Fasted  
255 bile acid concentrations may offer greater specificity for detecting hepato-biliary disease than

256 ALP, ALT or GGT. However, bile acid levels are poorly correlated with histological  
257 findings, and may be elevated in cases of intestinal disease (Roth-Johnson 2004; Webster  
258 2005). Inter-individual differences in gall bladder emptying, gastric emptying rate, intestinal  
259 transit rate, ileal bile acid resorption and gut microflora are all known to affect entero-hepatic  
260 recirculation of bile acids (Webster 2005). Moreover pre- and post-prandial bile acid  
261 concentrations in a domestic cat known to be suffering from hepatic VOD were within the  
262 normal reference range for this species (Cave *et al.* 2002). Given the variability of this  
263 parameter and the small sample size in this study, it is unsurprising that no difference in bile  
264 acid production was detectable between the two groups. In light of the other parameters  
265 concurrently evaluated, our findings indicated no gross liver dysfunction or clinically  
266 significant effects following the consumption of dietary isoflavones under the conditions of  
267 this experiment.

268 Hepatic adaptation of enzyme production following chronic exposure to isoflavones may  
269 have occurred in this study, and between-group differences may have been more apparent  
270 following acute exposure. However, acute exposure was not measured in the current study  
271 since cats were exposed to dietary isoflavones at weaning which rendered it impossible to  
272 evaluate acute pre- and post-isoflavone exposure responses.

273 There were few histological abnormalities in any of the liver sections. A lack of haemosiderin  
274 accumulation indicated that any observed congestion and periportal haemorrhage was a  
275 recent occurrence. Intra-hepatocyte vacuolation was not significant, and any inter-individual  
276 variation in vacuolation was thought to represent divergent glycogen accumulation and  
277 reflective of differences in body condition and/or differences in fasting time.

278 No evidence of hepatocyte degeneration, necrosis or regeneration was observed. One  
279 treatment cat had low numbers of neutrophils around some periportal areas, but these were

280 considered unlikely to be significant. The mean area of fibrous tissue surrounding hepatic  
281 blood venules (Fig. 1b) in control cats represented 28.51% ( $\pm$  2.60%; range 14.78 – 40.05) of  
282 the venule area, and that of treatment cats was not significantly different ( $32.84 \pm 4.18\%$ ;  
283 range 20.72 – 51.16,  $P > 0.05$ ). A liver section from a domestic cat suffering from hepatic  
284 VOD was also measured from a published photomicrograph (Cave *et al.*, 2002) and found to  
285 exhibit fibrosis covering an area equivalent to 46.75% of the venule lumen area (Figure 2).

286

287 Figure 2. Liver section from a domestic cat with diagnosed hepatic veno-occlusive disease  
288 (VOD) (from Cave *et al.* 2002). Central vein surrounded by subendothelial fibrosis (stained  
289 dark green/blue). Masson Trichrome stain.

290 Over half (57% or 4 of 7) of the control cat sections, but all (100%: 4 of 4) of the treatment  
291 group cat sections demonstrated congestion, however this difference was not significant ( $P >$   
292 0.05). No significant difference in the incidence of vacuolation of hepatocytes and Ito cells  
293 was found between control cat sections (86%: 6 of 7) or treatment cat sections (50%: 2 of 4)  
294 ( $P > 0.05$ ). Extra-medullary haematopoiesis was detected in 14% (1 of 7) of control cat  
295 sections and 25% (1 of 4) of treatment cat sections, but no difference was detectable ( $P >$   
296 0.05). Neutrophils and/or macrophages were not observed in any control group sections (0 of  
297 7), but were seen in 50% (2 of 4) of treatment group sections. However, this difference also

298 failed to achieve statistical significance ( $P > 0.05$ ). A summary of the histological findings is  
299 provided in Table 3.

300 The lack of histological changes detected here is in agreement with the biochemistry results.  
301 Sinusoidal and haemorrhagic congestion with perivenular fibrosis are typical histological  
302 signs of VOD in both cheetahs (see Figure 3) and the domestic cat (see Figure 2) (Setchell *et*  
303 *al.* 1987a; Cave *et al.* 2002).

Table 3. Summary of mean hepatic parameter scores in the liver biopsies of control (N = 7) and treatment cats (N = 4) at the time of ovario-hysterectomy

	Control Group	Treatment Group
Congestion	57%	100%
Vacuolation	86%	50%
Extra-medullary haematopoiesis	14%	25%
Neutrophils/macrophage infiltration	0%	50%
Fibrous area	28.9%	32.8%

304 N.B. Data is presented as the percentage of cats with positive observation scores for each  
305 parameter. The exception to this is fibrous area which is presented as the mean area of fibrous  
306 tissue surrounding hepatic blood venules as a percentage of the venule area.

307

308 However, no evidence of hepatic congestion, vacuolation, EMH or inflammatory cell  
309 infiltration was detected in the domestic cats following extended exposure to dietary  
310 isoflavones. Although a greater proportion of cats in the treatment group, compared to the  
311 control group, demonstrated hepatic congestion (100% *versus* 57%, respectively), this failed

312 to achieve statistical significance, and was most likely due to anaesthesia and surgical  
313 procedures, rather than any underlying hepatic disease.

314 Similarly, no evidence of hepatic fibrosis or pathology was detected in any cat, regardless of  
315 treatment group. The extent of hepatic fibrous tissue formation around blood venules did not  
316 differ between groups, which suggested that these compounds are unlikely to play an  
317 aetiological role in the VOD. However, hepatic fibrosis is a dynamic process, involving  
318 nonspecific mechanisms which respond to inflammation and/or hepatic injury (Center, 2004).  
319 Additionally, changes in liver architecture were primarily due to the deposition of  
320 extracellular matrix which operates to reduce perfusion and stimulate sinusoid capillarisation  
321 and collagenisation (Center 2004). The chronic nature of the appearance of these effects  
322 indicates that differences between treatment and control animals in the current study may not  
323 have become detectable until much later in life.

324  
325 Figure 3. Liver section from a cheetah with veno-occlusive disease (Courtesy Wellington  
326 Zoo, New Zealand) - central vein surrounded by subendothelial fibrosis (stained blue using  
327 Masson's Trichrome stain)

328 Furthermore, unlike cheetahs in which the disease is relatively common, hepatic VOD has  
329 only been reported in one domestic cat (Cave *et al.* 2002). It appears likely that the domestic  
330 cat and cheetah differ in their susceptibility to VOD or the biological action of isoflavones, or  
331 other environmental factors may be responsible for the incidence of VOD in captive cheetahs.  
332 Budd-Chiari-like syndrome is a rare condition which has only been reported in two domestic  
333 cats, and is typified by hepatic venous outflow obstruction (Cave *et al.* 2002), potentially  
334 related to VOD. Elevated levels of tumour necrosis factor-alpha (TNF- $\alpha$ ) and Interleukin-1 $\beta$   
335 are observed in association with this syndrome, although it is unclear as to whether they play  
336 an aetiological or responsive role (Cave *et al.* 2002). Interestingly, the ability of isoflavones  
337 to inhibit TNF- $\alpha$  (Kang *et al.* 2005), suggests that dietary isoflavone intake is more likely to  
338 reduce, rather than increase, the risk of hepatic fibrosis and VOD in domestic cats. Such a  
339 protective mechanism has been postulated in other studies (Kang *et al.* 2001; Liu *et al.* 2002).  
340 Although the current study was not designed to assess cellular proliferation or hepatic  
341 toxicity, the lack of difference between control and treatment animals indicates that neither  
342 beneficial nor detrimental effects were elicited in the liver following isoflavone exposure,  
343 under the conditions of this trial.

#### 344 **Conclusions**

345 The influence of dietary isoflavones, genistein and daidzein, on hepatic biochemistry and  
346 histology in the domestic cat was investigated here for the first time. The purified aglycones  
347 of genistein and daidzein, at the dose and duration of exposure utilised here, do not appear to  
348 modulate hepatic enzyme production or histological parameters in the domestic cat.  
349 Modulation of biochemical parameters was minor if present at all, and failed to achieve  
350 statistical significance or exceed normal reference ranges for clinically healthy cats.  
351 However, caution is warranted in extrapolating these findings to felids exposed to soy-

352 derived isoflavone glycosides or other phytoestrogen compounds. Although larger sample  
353 sizes are needed to confirm our findings, dietary isoflavones are not considered likely to exert  
354 hepatic changes with any clinical implications.
