26 **Abstract**

27

28 Objective: To quantify the influence of baseline pain levels on weight change at one-year  
29 follow-up in patients attending a National Health Service specialist weight management  
30 programme.

31

32 Methods: We compared one-year follow-up weight (body mass) change between patient sub-  
33 groups of none-to-mild, moderate, and severe pain at baseline. A mean sub-group difference  
34 in weight change of  $\geq 5$ kg was considered clinically relevant.

35

36 Results: Of the 141 complete cases, n=43 (30.5%) reported none-to-mild pain, n=44 (31.2%)  
37 reported moderate pain, and n=54 (38.3%) reported severe pain. Covariate-adjusted mean  
38 weight loss (95%CI) was similar for those with none-to-mild (8.1kg (4.2 to 12.0kg)) and  
39 moderate pain (8.3kg (4.9 to 11.7kg)). The mean weight loss of 3.0kg (-0.4 to 6.4kg) for the  
40 severe pain group was 5.1kg (-0.6 to 10.7, p=0.08) lower than the none-to-mild pain group  
41 and 5.3kg (0.4 to 10.2kg, p=0.03) lower than the moderate pain group.

42

43 Conclusions: Patients with severe pain upon entry to a specialist weight management service  
44 in England achieve a smaller mean weight loss at one-year follow-up than those with none-  
45 to-moderate pain. The magnitude of the difference in mean weight loss was clinically  
46 relevant, highlighting the importance of addressing severe persistent pain in obese patients  
47 undertaking weight management programmes.

48

49

50

## 51 **Introduction**

52

53 Obesity is a major public health issue affecting one in four adults in England (1). As such,  
54 strategies to enhance the effectiveness of weight loss services are of national importance (2)  
55 and it is essential that the weight management services that are in place are appropriate and fit  
56 for purpose. Chronic pain affects 13% of people in the UK (3). There is a substantial body of  
57 evidence demonstrating a link between obesity and chronic pain (4-15). A dose response  
58 relationship exists, with the prevalence of pain increasing with progressively higher BMI  
59 (14). Whilst, the full extent of this relationship has yet to be explored, it is likely to be bi-  
60 directional and may be underpinned by a range of mechanical, physiological, psychosocial,  
61 and behavioural mechanisms (16,17).

62

63 Clinically, pain has been implicated as an important barrier to weight loss (18) and the  
64 management of obesity-related conditions such as diabetes (19). Chronic pain can have  
65 negative effects on an individual's diet via mechanisms such as hedonic (non-hunger related)  
66 eating (11). Additionally, pain can impede physical activity (20) and activities of daily living  
67 (21), thus hindering weight loss. Chronic pain may also adversely affect an individual's  
68 mood, which can have negative implications for weight loss via dysregulated stress systems  
69 or unhealthy lifestyles (11,22,23). However, few studies have directly investigated the impact  
70 of persistent pain on weight loss.

71

72 Wachholtz et al (21) found that 83% of patients on a 4-week intensive weight loss program in  
73 the USA reported pain. Patient sex, influenced the pain and obesity relationship, with joint  
74 pain identified as a predictor of weight loss in women but not men. In a recent secondary  
75 analysis of an RCT investigating a weight loss intervention for patients with co-existing pain

76 and overweight/obesity 80% reported moderate or severe pain (24). Those with severe pain  
77 reported significantly less weight loss (-0.1%) compared to those with moderate (-1.9%) or  
78 no pain (-2.1%) (24). These findings support the work of Wachholtz et al (21) and  
79 demonstrate that pain may be a considerable barrier to weight loss. However, the participants  
80 in this US study were veterans, 85% of whom were male. Thus, it is unclear if these findings  
81 would generalise to patients undergoing weight management interventions within the  
82 National Health Service (NHS) in England where up to 88% of patients are female (25) and  
83 women receive 75% of bariatric surgery (1). Thus there is a need to specifically investigate  
84 the potential effect of pain on weight loss in this context. The aim of this study was to  
85 investigate the effect of persistent pain on weight loss in individuals receiving NHS specialist  
86 weight management services.

87

88

## 89 **Methods**

90

### 91 **Participants**

92

93 This is an analysis of an NHS clinical dataset of patients who attended a specialist weight  
94 management service in the North East of England from February 2013 to November 2014. To  
95 be referred to the specialist weight management service patients were required to meet the  
96 following admissions criteria of having a BMI of  $\geq 40$  or a BMI  $\geq 35$  with a significant co-  
97 morbidity such as diabetes or hypertension. Furthermore, patients were required to be  
98 registered with a local GP; aged  $\geq 16$  years; with an ability to take charge of their dietary  
99 intake; assessed as “ready to change”; and have had previous attempts at weight loss either in

100 primary care including community weight management programmes, exercise programmes or  
101 anti-obesity medication for a minimum of 6 months. Their GP needed to have completed a  
102 recent metabolic and endocrine assessment and could show that the patient's underlying  
103 endocrine diagnosis was stable and any secondary causes of obesity excluded. Patients were  
104 excluded from referral to the specialist weight management service if they did not meet the  
105 admission criteria above, or if they had a suspected or diagnosed malignancy, were pregnant,  
106 or requiring post-bariatric care (unless previously known to the service). From the pre-  
107 existing patient database, to be included in this study, participants needed to have provided  
108 baseline and one-year outcome data. Response: Ethical approval for this study was obtained  
109 from The School of Health and Social Care Research Ethics and Governance Committee at  
110 Teesside University (Reference number 074/14) and the Wales 7 National Research Ethics  
111 Committee (Reference number 14/WA/1050). The IRB waived the need for individual participant  
112 consent for medical records to be used in this study, and data was accessed anonymously.

113

114

## 115 **Intervention**

116

117 The specialist weight management service provides a multidisciplinary, biopsychosocial  
118 approach for morbidly obese patients.

119

120 Patient treatment programmes consist of three main phases. The timing of these phases varied  
121 from patient to patient. In phase 1, patients initially receive a multidisciplinary team (MDT)  
122 assessment including consultation with a Dietician, Physiotherapist, Psychologist, Metabolic  
123 Physician/Endocrinologist, GP with a specialist interest in obesity management, and an  
124 individual care plan is generated. The individual care plan includes: an exercise and physical

125 activity plan; outcomes expected for the individual; target weight; behavioural goals;  
126 modification of eating patterns; goals relating to lifestyle factors; changes in behaviour  
127 relating to triggers and barriers; food and activity diaries; tools and educational materials. In  
128 phase 2, patients move into group services and treatment according to their specific needs and  
129 care plan. During this phase a weekly drop-in and telephone support service is provided.  
130 Interactions with these elements of the service are recorded and shared with the patient's Care  
131 Manager. In phase 3, patients are discharged from the service with details of the patient's  
132 outcomes and an ongoing care plan sent to their GP; signposting to support groups;  
133 community weight management services and exercise groups for further weight loss and/or  
134 weight maintenance support.

135

136

## 137 **Outcome measures**

138

139 Whilst outcome measures within the specialist weight management service are collected at  
140 regular intervals this study includes only the baseline and one-year post baseline data. The  
141 primary outcome measure was weight (body mass) loss, which was measured using a  
142 weighing scales (SECA 645 hand rail scale). Height was also recorded using a Leicester  
143 Height Measure (Mark 2) so that BMI could be calculated.

144

145 Pain was measured using the Short-form 36 (SF36) bodily pain subscale (26,27). The scale  
146 includes two questions 1) *how much bodily pain have you had during the past four weeks?*  
147 *and 2) during the past four weeks, how much did pain interfere with your normal work*  
148 *(including work both outside the home and housework)?* The first question is rated on a 6-  
149 point Likert scale ranging from *none* to *very severe*, whilst the second question is rated on a

150 5-point Likert scale ranging from *not at all* to *extremely*. The raw score is then converted as a  
151 simple algebraic sum into a 0-100% scale value with higher scores representing higher pain  
152 levels (27). The SF36 bodily pain scale is widely used and has demonstrated good levels of  
153 validity and reliability as a measure of pain (27-29).

154

155 The following additional participant characteristics were collected: sex, age, socioeconomic  
156 status and depression levels. Socioeconomic status was assessed using the Lower layer Super  
157 Output Area (LSOA) which is derived from the patient's postcode. The LSOA was used to  
158 assign each patient an index of multiple deprivation, which was categorised into deciles with  
159 1 being least affluent and 10 being most affluent. Depression levels were measured using the  
160 depression subscale of the Hospital Anxiety and Depression scale (HADs) (30).

161

162

## 163 **Statistical analysis**

164

165 Individuals were categorised into none-to-mild, moderate, and severe pain sub-groups  
166 according to their baseline pain scores. The cut-off points used in this analysis were <50%  
167 mild pain, 50-69.99% moderate pain, and 70-100% severe pain (31). A general linear model  
168 was used with weight loss (kg) as the dependent variable and pain subgroup as the  
169 independent variable (fixed effect). This model was covariate-adjusted for any differences in  
170 baseline weight, age, sex, socioeconomic status, and depression levels between sub-groups.  
171 Covariate-adjusted subgroup mean differences in weight loss and associated 95% confidence  
172 intervals (95%CI) were estimated for our primary comparisons.

173

174 A sub-group difference in mean weight change was considered clinically relevant if it was  
 175  $\geq 5$ kg. This was based upon the American Heart Association guidelines which state that  
 176 reductions in weight of 2.5-5.5kg achieved through lifestyle interventions can reduce the risk  
 177 of developing type 2 diabetes in overweight and obese individuals by 30-60%, while a  
 178 reduction of 5-8kg can improve triglyceride levels and blood lipid profile (32).

179

180

## 181 **Results**

182

183 Data were obtained for 167 participants who provided baseline and one-year follow-up data.

184 Of these, 26 had missing data and were thus excluded from the analysis. The descriptive

185 characteristics for those with complete data and those with missing data are shown in Table 1.

186 There was no substantial difference for outcome or exposure variables between those with

187 complete and incomplete data.

188

189 **Table 1: Key characteristics for complete case and missing data groups.**

	Complete n=141	Missing n=26
Age (yrs)	52.2 (11.9)	52.5 (14.6)
Sex		
Men	30%	31%
Women	70%	69%
Socioeconomic status (1-10)	3 (1-6)	2 (1-4.5)
Depression (0-21)	8.0 (4.4)	8.8 (4.2)
Height (m)	1.65 (0.09)	1.65 (0.11)
Weight (kg)	127.2 (23.0)	130.7 (25.1)
Weight change (kg)	6.2 (11.5)	7.5 (7.5)
Weight change (%)	-4.9	-5.7
$\geq 5$ kg weight loss achieved	52%	52%
BMI (kg.m <sup>-2</sup> )	46.3 (7.2)	47.6 (8.4)
Pain (0-100%)	60.3 (26.9)	66.7 (24.3)

190 *Data are mean (SD) unless stated*

191 *Median and IQR is presented for socioeconomic status*  
192 *In the missing group column n=26 for all variables except: socioeconomic status n=14,*  
193 *depression n=23, weight change kg and % n=21, 5kg and 5% weight loss achieved n=21,*  
194 *pain n=16.*  
195

196 Of the 141 complete cases, over the one-year period 52% of patients lost  $\geq 5$ kg, which is a  
197 greater proportion than that expected due to typical within-subjects variation in weight (33).  
198 The adjusted mean weight loss for the pooled sample was 6.5kg (95% CI 4.6 to 8.4kg)  
199 equivalent to a loss of 5.1% of initial weight. The average pain levels at baseline were 60.3%  
200 (SD 26.9%). When broken down into the pain subgroups, n=43 (30.5%) reported none-to-  
201 mild pain (of which n=6 reported no pain), n=44 (31.2%) reported moderate pain, and n=54  
202 (38.3%) reported severe pain.

203

204 Covariate-adjusted mean weight loss (95%CI) was similar for those with none-to-mild pain  
205 (8.1kg (4.2 to 12.0kg)) and moderate pain (8.3kg (4.9 to 11.7kg)), but was lower for the  
206 severe pain group (3.0kg (-0.4 to 6.4kg)) (Figure 1). There was evidence of an effect of  
207 baseline pain levels on weight loss after adjusting for all other covariates (p=0.08). The mean  
208 difference (95%CI) in weight loss between the none-to-mild pain and the moderate pain  
209 groups was 0.2kg (-4.9 to 5.3, p=0.94). The mean difference in weight loss for the severe  
210 pain group was 5.1kg (-0.6 to 10.7, p=0.08) lower than the none-to-mild pain group and  
211 5.3kg (0.4 to 10.2, p=0.03) lower than the moderate pain group. The raw data used for the  
212 analysis can be found in supporting information (S1\_appendix).

213 **Fig 1:** One-year weight loss separated by pain classification group

214

215

## 216 **Discussion**

217

218 This is the first study to directly investigate the effect of persistent pain on weight loss in  
219 patients undergoing specialist weight management within the NHS. More than 95% of the  
220 patients reported persistent pain at baseline with more than a third of patients reporting severe  
221 pain. Our findings indicate that patients with severe pain at baseline lost less weight at one-  
222 year follow-up when compared to those with none-to-mild pain or moderate pain. There was  
223 no difference between the none-to-mild pain and moderate pain groups.

224

225 The findings of our study are broadly in keeping with Masheb et al. (24) who found that  
226 people with severe pain lost significantly less weight -0.3kg (-1.8 to 1.2kg) than those with no  
227 pain -2.1kg (-2.7 to -1.4kg) or moderate pain -2.2kg (-3.5 to -0.09kg) and similar levels of  
228 weight loss between those with no pain and moderate pain (24). The magnitude of the weight  
229 loss in our study was greater than that seen in Masheb et al. (24) who reported a group weight  
230 loss of 1.71% with 21.9% achieving weight loss of  $\geq 5\%$  in comparison to our study where  
231 there was a weight loss of 5.1% and 48% of patients achieved a weight loss of  $\geq 5\%$ . The  
232 difference in magnitude may be related to baseline obesity levels which were higher in the  
233 current study compared to that of Masheb et al. (24) (BMI = 46 vs. 36kg.m<sup>-2</sup>). Other reasons  
234 may be to do with differences in study methodology. Masheb et al. (24) was a reanalysis of  
235 an RCT investigating the effects of a weight loss intervention compared to a control in  
236 veterans, predominantly middle-aged males (85%), while our data was from patients  
237 receiving their usual care, predominantly females (70%). The differences may also have been  
238 cultural/geographical between the US and the UK. The magnitude of the weight loss in our  
239 study is comparable to that seen in conservative weight loss programmes in other parts of the  
240 UK (-4.8kg and -4.6%) (25).

241

242 The clinical implication of our findings is that severe pain levels may be a considerable  
243 barrier to weight loss in those referred to specialist weight management services in the NHS  
244 by a magnitude of 5kg. Given the high prevalence levels of persistent pain in obese  
245 populations, especially in those with more severe obesity (14), the reach and significance of  
246 pain as a barrier to weight loss may be considerable. As such, these findings support previous  
247 calls for better integration between weight management and pain management services  
248 (12,18). Additional support may be warranted for patients with severe pain. Given that pain  
249 and its associated functional impairments are at least partly modifiable, targeting pain as part  
250 of a weight management strategy could potentially enhance weight loss outcomes for those  
251 with co-existing obesity and severe pain. There are a small but growing number of trials  
252 investigating the effectiveness of combined pain and weight management interventions in  
253 obese patients (34,35). Our findings emphasise the merit of this work and suggest that such  
254 interventions may be best targeted at those with more severe pain.

255

256 This study has a number of limitations. This is a retrospective observational study, thus no  
257 claims of cause and effect can be made. While pain was measured using a valid and reliable  
258 questionnaire, pain characteristics such as location, duration and type of pain were not  
259 recorded. Thus, their potential role in weight loss was not explored. Whilst a number of  
260 important co-variables were adjusted for within the statistical model, some potentially important  
261 co-variables such as diet were not included. During the time period in which this data was  
262 collected, 837 patients were discharged from the specialist weight management service. Thus,  
263 data was only available for 19% of the patients at this clinic. As such, this sample may not be  
264 representative of patients attending NHS weight management services, reducing the  
265 generalisability of our findings. Additionally, the sample is small, which increases the risk of  
266 a type II error. However, the strength of this work is the use of a well-validated measure of

267 pain and clinically established published cut-off values for none-to-mild, moderate and severe  
268 pain. Data on the location of the pain would have been useful contextual information but  
269 previous work suggests that it may be of limited relevance (24).

270

271

## 272 **Conclusion**

273

274 In conclusion, patients with severe pain at the point of entry to an NHS specialist weight  
275 management service appear to lose less weight at one-year follow-up compared to those with  
276 none-to-mild or moderate pain. The magnitude of the difference is likely to be clinically  
277 relevant and highlights the potential gains in weight loss that might be achieved by  
278 addressing concomitant persistent pain in weight management services. There was no  
279 difference in weight loss between those who reported none-to-mild pain and moderate pain.  
280 These findings broadly support earlier findings in a sample of, predominantly male, US  
281 veterans (24), thus suggesting they are applicable to the NHS, which comprises of a high  
282 proportion of female patients. Future studies need to be conducted to more firmly establish  
283 the generalisability of these findings into the wider NHS setting, including applicability in  
284 non-specialised community weight management setting, which include patients with less  
285 severe forms of obesity. Future work investigating the feasibility of incorporating some form  
286 of pain management into the weight management setting is also warranted.
