1 Intraspecific variation in an **Ediacaran** skeletal metazoan:
2 *Namacalathus* from **the Nama Group**, Namibia.

3
4 **ABSTRACT**

5 *Namacalathus hermanastes* is one of the oldest known skeletal metazoans, found in
6 carbonate settings of the terminal Ediacaran (~550-541 Million years (Ma) ago). The
7 palaeoecology of this widespread, goblet-shaped, benthic organism is poorly constrained yet
8 critical for understanding the dynamics of **the** earliest metazoan communities.

9 Analysis of in-situ assemblages from the Nama Group, Namibia (~548-541 Ma), shows
10 that *Namacalathus* exhibited size variation in response to differing water depths,
11 hydrodynamic conditions, and substrate types. In low energy, inner ramp environments,
12 *Namacalathus* attains the largest average sizes but grew in transient, loosely-aggregating,
13 monospecific aggregations attached to microbial mats. In **high energy** mid-ramp reefs,
14 *Namacalathus* spatially segregated into different palaeoecological **habitats with distinct size**
15 **distributions**. In outer ramp environments, individuals were small and formed patchy, dense,
16 monospecific aggregations attached to thin microbial mats. **Asexual** budding is common in
17 all settings.

18 We infer that variations in size distribution in *Namacalathus* reflect differences in habitat
19 heterogeneity and stability, including the **longevity** of mechanically stable substrates and oxic
20 conditions. In the Nama Group, long-lived skeletal metazoan communities developed within
21 topographically heterogeneous mid-ramp reefs which provided **diverse** mechanically stable
22 microbial substrates in persistently oxic waters, while inner and outer ramp communities
23 were often ephemeral, developing during fleeting episodes of either oxic and/or substrate
24 stability. We conclude that *Namacalathus*, which forms a component of these communities in
25 the Nama Group, was a generalist that adapted to various palaeoecological habitats within a

1
2
3 26 heterogeneous ecosystem landscape where favourable conditions persisted, and was also able
4
5 27 to opportunistically colonise transiently hospitable environments. These early skeletal
6
7 28 metazoans colonised previously **unoccupied substrates in thrombolitic reefs and other**
8
9 29 **microbial carbonate settings**, and while **they experienced** relatively **low levels of inter-**
10
11 30 **specific competition**, they were nonetheless adapted to the diverse environments and highly
12
13 31 dynamic redox conditions present in the terminal Ediacaran.

19 33 INTRODUCTION

20
21 34 Ediacaran (580–541 million years ago) strata yield diverse non-skeletal and skeletal
22
23 35 macrofossils which record the emergence of metazoans and complex ecosystems. Many of
24
25 36 these forms have unresolved phylogenetic relationships, reproductive modes, and ecologies,
26
27 37 even though an understanding of these is critical to **investigating** the origins of the modern
28
29 38 biosphere.

30
31
32 39 Ediacaran macroorganisms may have been capable of multiple reproductive modes,
33
34 40 implying the presence of correspondingly complex developmental systems (Mitchell *et al.*,
35
36 41 2015). The terminal Ediacaran (~550-541 Ma) skeletal taxa *Cloudina* and *Namacalathus*
37
38 42 reproduced clonally through budding (Hua *et al.*, 2005; **Cortijo *et al.*, 2010**; Zhuravlev *et al.*,
39
40 43 **2015a**), but their **broad geographic distribution** suggests that like many extant benthic
41
42 44 invertebrates, they also possessed a dispersive, planktonic larval stage (**Zhuravlev *et al.*,**
43
44 45 **2012, fig. 7**; **Cortijo *et al.*, 2015**). **Size** distributions, and bedding plane-scale spatial
45
46 46 distributions have further been used to distinguish reproductive styles. For example, the
47
48 47 unmineralised taxa *Funisia* and *Tribrachidium* cluster into groups of similar size, suggesting
49
50 48 episodic larval settlement (Droser & Gehling, 2008; Hall *et al.*, 2015), and *Fractofusus* shows
51
52 49 a **recurring** pattern of smaller individuals clustered around larger ones suggestive of clonal
53
54 50 reproduction via stolons (Mitchell *et al.*, 2015).
55
56
57
58
59
60

1
2
3 51 *Namacalathus* has a goblet-like morphology, consisting of a hollow stem which flares to
4
5 52 form a 'cup'. The cup generally has 6 or 7 lumens in the side walls imparting a polygonal
6
7 53 cross-section, and a larger opening at the top whose edges curl in towards a central cavity
8
9
10 54 (Grotzinger *et al.*, 2000; Watters & Grotzinger, 2001). On the basis of this distinctive but
11
12 55 simple morphology, *Namacalathus* has been assigned various affinities. It has been
13
14 56 interpreted as a possible cnidarian because of its goblet-shaped morphology and hexaradial
15
16 57 cross-section (Grotzinger *et al.*, 2000), a protozoan due to its small size and an apparent lack
17
18 58 of accretionary growth (Seilacher *et al.*, 2003), and a stem eumetazoan based on its
19
20 59 symmetrical, stalked morphology and sessile, benthic life habit (Wood, 2011). More recently,
21
22 60 a lophophorate affinity has been suggested, based on the presence of bilaterally symmetrical
23
24 61 budding and a distinctive skeletal ultrastructure of a tripartite microlamellar construction with
25
26 62 columnar deflections (Zhuravlev *et al.*, 2015a).

27
28
29 63 *Namacalathus* occurs associated with thrombolitic reefs in carbonate inner, mid- and
30
31 64 outer ramp settings in the Nama Group, Namibia (Grotzinger *et al.*, 2000; Wood, 2011), and
32
33 65 thrombolitic reefs in western Canada and Oman (Hofmann & Mountjoy, 2001; Amthor *et al.*,
34
35 66 2003). Some fossils putatively attributed to *Namacalathus* are reported from in a mixed
36
37 67 clastic-carbonate environment in West Siberia (Kontorovich *et al.*, 2008; Grazhdankin *et al.*,
38
39 68 2015) and in reefs associated with calcimicrobes in the Altay Sayan Foldbelt, South Siberia,
40
41 69 Russia (Terleev *et al.*, 2011). Siberian *Namacalathus* differs from all other fossils ascribed to
42
43 70 this genus in possessing a phosphatic skeleton, and pores which are much more numerous
44
45 71 than the lumens of *Namacalathus* and are distributed randomly across the cup, while in
46
47 72 *Namacalathus* they are fairly uniform in number and position on the cup facets (Grazhdankin
48
49 73 *et al.*, 2015, fig.4g, h, l). It is also an order of magnitude smaller than the smallest
50
51 74 *Namacalathus* from the type locality in Namibia, and from other localities globally (0.2 mm
52
53 75 against 2 mm), and so its assignment to this genus is questionable.

1
2
3 76 To date, published studies on *Namacalathus* are mostly restricted to its morphology and
4
5 77 biostratigraphic significance while its reproduction, relationship to substrate, environmental
6
7 78 preferences, and other ecological traits have received comparatively little attention. Size
8
9
10 79 distribution data may help constrain some of these uncertainties as *Namacalathus* shows
11
12 80 notable size variation between localities both locally and globally. In the Nama Group,
13
14 81 Namibia, cup diameters range from 2 to 35 mm (Grotzinger *et al.*, 2000; Wood, 2011).
15
16 82 Maximum cup diameters of 30 mm are reported from Oman (Amthor *et al.*, 2003), and 17
17
18 83 mm from Canada (Hofmann & Mountjoy, 2001), giving a global size range from 2 - 35 mm,
19
20 84 excluding Siberian forms. In assemblages from the Byng Formation of western Canada, size
21
22 85 differences have been used to infer variation between environmental settings, with larger
23
24 86 individuals (modal value ~12 mm) occurring in pockets between stromatolite columns and
25
26 87 smaller individuals (modal size ~6 mm) in channel fills (Hofmann & Mountjoy, 2001).
27
28 88 Grotzinger *et al.* (2000) observed that *Namacalathus* was more abundant on thrombolites
29
30 89 than on other substrates, and suggested that *Namacalathus* preferred the firm, elevated
31
32 90 substrates provided by thrombolites in the Nama Group of Namibia. Wood (2011) noted that
33
34 91 such habitats also appeared to support the largest individuals.

35
36
37
38 92 Metazoans, particularly skeletal ones, are strongly influenced by oxygen levels in their
39
40 93 environments. The size and abundance of metazoans in modern benthic communities declines
41
42 94 with bottom-water oxygen levels, as does biodiversity (e.g. Rhoads & Morse, 1971). Oxygen
43
44 95 levels also have an impact on benthic community structure, with communities under sub-oxic
45
46 96 conditions showing reduced pelagic-benthic coupling and suppressed community succession
47
48 97 (Nilsson & Rosenberg, 2000; Broman *et al.*, 2015). At reduced oxygen levels, communities
49
50 98 also consist of smaller, shorter-lived species with opportunistic life histories and few
51
52 99 predators (Diaz & Rosenberg, 1995; Sperling *et al.*, 2013; 2015), and only very few metazoan
53
54
55
56 100 taxa may live under permanently anoxic conditions (Danovaro *et al.*, 2010). In addition to
57
58
59
60

1
2
3 101 oxygen level, redox stability plays a role: some metazoans tolerate temporary, but not
4
5 102 permanent, anoxia (Bernhard *et al.*, 2000; Müller *et al.*, 2012). Consequently, both pO_2 and
6
7 103 redox stability are likely to have been important controls on the structure of early metazoan
8
9 104 communities (Johnston *et al.*, 2012; Wood *et al.*, 2015).

10
11 The terminal Ediacaran Nama Group, Namibia, was deposited under highly dynamic
12
13 redox conditions, where shallow, inner ramp settings experienced transient oxygenation
14
15 (Wood *et al.*, 2015). These environments supported short-lived and monospecific skeletal
16
17 metazoan communities of either *Cloudina* or *Namacalathus*. By contrast, microbial
18
19 (thrombolite) reefs, found in deeper inner- and mid-ramp settings, support more diverse
20
21 communities of organisms which constructed reefs and aggregations, may have had distinct
22
23 environmental preferences, and could attain large sizes (Wood *et al.*, 2002; Wood & Curtis,
24
25 2015). These long-lived reef communities, as well as Ediacaran soft-bodied biotas, are found
26
27 particularly within transgressive systems, where oxygenation was persistent. A mid-ramp
28
29 position may have enabled physical ventilation mechanisms for water column oxygenation to
30
31 operate during flooding and transgressive sea-level rise. In the Nama Group it appears that
32
33 the stability of oxygenated conditions may have controlled both the distribution and ecology
34
35 of Ediacaran skeletal metazoan communities (Wood *et al.*, 2015).

36
37 Here we explore *Namacalathus* size data and substrate relationships in the Nama Group,
38
39 Namibia, in order to better constrain its environmental preferences and relationship to its
40
41 substrate. Among other skeletal metazoans, *Namacalathus* colonized carbonate habitats
42
43 where microbial mats were abundant, in the diverse environments presented by the late
44
45 Ediacaran Nama Group. This raises the question of whether the earliest skeletal metazoans
46
47 were generalists able to colonise a range of environments, or specialists requiring a narrow
48
49 range of environmental conditions. We place size data within the context of hydrodynamic
50
51 setting, substrate type and relative redox stability to explore local environmental controls on
52
53
54
55
56
57
58
59
60

1
2
3 126 early metazoan life habits and ecosystems. Such an analysis contributes to the ongoing
4
5 127 discussion of the role of environmental conditions and substrate types in controlling the
6
7 128 evolution and palaeoecology of Ediacaran metazoans.
8
9

10 129

11 130 **GEOLOGICAL SETTING**

12
13
14 131 The Nama Group (~550 – 541 Ma) is a terminal Ediacaran succession comprising a
15
16 132 foreland basin infill of marine shelf and fluvial deposits (Saylor *et al.*, 1995). Fossiliferous
17
18 133 successions consist of mixed clastics and carbonates ranging from supratidal to outer ramp
19
20 134 settings with varying hydrodynamic conditions (Germs, 1995; Jensen *et al.*, 2000; Geyer,
21
22 135 2005; Grotzinger & Miller, 2008).
23
24

25 136 The Nama Group was deposited across the Zaris and Witputs sub-basins (Fig. 1), which
26
27 137 have been correlated using a combination of sequence stratigraphy and chemostratigraphy
28
29 138 (Figs. 2 and 3) (Saylor *et al.*, 1995; 1998). Carbon isotope measurements indicate that the
30
31 139 lower Nama Group was deposited during the final stages of the Shuram-Wonoka carbon
32
33 140 isotope excursion (Kaufman *et al.*, 1991; Wood *et al.*, 2015).
34
35

36 141 Zircons from ash beds in the Nama Group have provided radiometric dates (Fig. 2). The
37
38 142 earliest, dated to 547.32 ± 0.65 Ma, is in the Hoogland Member of the Kuibis Subgroup
39
40 143 (Grotzinger *et al.*, 1995; revised by Schmitz, 2012), and provides a minimum age for the base
41
42 144 of the Nama Group. The age of the underlying base of the Nama Group is less certain, but is
43
44 145 estimated at around 550 – 553 Ma based on assumed sedimentation rates (Ries *et al.*, 2009).
45
46 146 An intermediate date of 542.68 ± 1.245 Ma was obtained from an ash bed in the lower
47
48 147 Spitskopf Member of the Urusis Formation of the Schwarzrand Subgroup (Grotzinger *et al.*
49
50 148 1995; Schmitz, 2012). The youngest Ediacaran ash bed in the Nama Group, 130 m below the
51
52 149 youngest *Cloudina* and unmineralised Ediacaran fossils, but above the stratigraphically
53
54 150 highest *Namacalathus* assemblage in this study gave U-Pb dates of 540.61 ± 0.67 Ma in the
55
56
57
58
59
60

1
2
3 151 upper Spitskopf Member (Grotzinger *et al.*, 1995 as 543.3 ± 1 Ma; date recalculated by
4
5 152 Schmitz, 2012). A fourth ash bed in the lower Nomtsas Formation, above the unconformity
6
7 153 that includes the Precambrian-Cambrian boundary, gave an estimated date of 538.18 ± 1.24
8
9 154 Ma, giving a minimum age for the Precambrian-Cambrian boundary in the Nama Group
10
11 155 (Grotzinger *et al.*, 1995; Schmitz, 2012). The localities in this study therefore span ≥ 6 Myr
12
13 156 from the Lower Omkyk Member (> 547 Ma) to the Spitskopf Member (~ 541 Ma).
14
15
16
17

157

158 *Environmental and redox settings of localities*

159 *Namacalathus* assemblages were studied at five localities which represent three
160 environments: Low energy inner ramp, high energy mid-ramp thrombolitic reefs, and low
161 energy outer ramp (Table 1, Figs. 2 and 3, for locality coordinates, see Table SM 1). Below,
162 we briefly document the sedimentology, and outline the redox dynamics of each setting.
163 Redox conditions for each of these localities has been inferred by Wood *et al.* (2015) based
164 on a multiproxy approach using iron speciation (Fe_{HR}/Fe_T), total iron (Fe_T), and Fe/Al ratios,
165 summarised in Table 1; for an explanation of the proxies see Table SM 2.

166 The use of geochemical proxies to explain biological patterns requires reconciliation of
167 markedly different time scales of integration. Biological time scales, such as the time
168 between successive generations are often short compared with the geological timescales over
169 which sediment accumulates and geochemical signatures develop (Wood *et al.*, 2015). In
170 addition, iron speciation may not be sufficiently sensitive to detect whether pO_2 was above or
171 below the crucial thresholds for metazoan life (Sperling *et al.*, 2013). With care, however,
172 geochemical proxies may be used to make inferences on local-scale palaeoenvironmental
173 dynamics (Hall *et al.*, 2013; Wood *et al.*, 2015; Sperling *et al.*, 2015; Jin *et al.*, 2016).

174 The low energy inner ramp setting in the Omkyk Member is dominated by dolomitised
175 micritic, laminated lithologies, with thinly bedded (~ 10 -100 mm thickness) mudstones,

1
2
3 176 wackestones and packstones, which accumulated mainly during sea level highstands. Thin,
4
5 177 closely-spaced, undulating laminae suggest that thin microbial mats developed regularly,
6
7 178 binding fine grained sediment. Fe_{HR}/Fe_T , Fe_T and Fe/Al data show that such settings
8
9 179 experienced only intermittent oxic, and benthic metazoan communities developed during
10
11 180 these fleeting oxic episodes (Wood *et al.*, 2015). Some beds with clearly in-situ
12
13 181 *Namacalathus* assemblages nonetheless present an anoxic iron speciation signature, even
14
15 182 when microsampled (Wood *et al.*, 2015). From this it has been inferred that the transient
16
17 183 populations exploited brief periods of oxic in otherwise dominantly and more persistently
18
19 184 anoxic settings, which may have been caused by periodic upwelling of anoxic deep waters
20
21 185 (Wood *et al.*, 2015).

22
23
24
25 186 Mid-ramp thrombolitic reefs in the Omkyk Member are associated with packstones, cross-
26
27 187 bedded grainstones and breccias that developed during transgressive systems tracts in
28
29 188 relatively energetic waters. These microbial reef complexes range from a few metres to
30
31 189 kilometres in extent. Variable *Namacalathus* ecology has been documented from these reefs,
32
33 190 and includes attachment to thrombolite heads (Grotzinger *et al.*, 2000; Wood, 2011), growth
34
35 191 as monospecific sheet-like aggregations, intergrowth with *Cloudina riemkeae* thickets, and
36
37 192 growth within primary cavities (crypts) in thrombolitic reefs (Wood & Curtis, 2015). The
38
39 193 very low Fe_T of mid-ramp reef settings suggest that these were probably persistently oxic,
40
41 194 especially during transgressive systems tracts, when large microbial reefs with calcified
42
43 195 metazoan communities developed.

44
45
46
47 196 Swartpunt locality from the Spitskopf Member of the Schwartzrand Subgroup is
48
49 197 interpreted as an outer ramp setting. Although the succession shallows to inner ramp
50
51 198 environments, the sampled lower part of the succession is dominated by laterally continuous
52
53 199 to discontinuous thin- to medium bedded (50-150 mm) wackestones and packstones. Some
54
55 200 units show scoured bases and low relief channels. We infer deposition below fair weather
56
57
58
59
60

1
2
3 201 wave base, under weak current activity and occasional disturbance by storms. Thin,
4
5 202 undulating, irregularly spaced laminae suggest that thin microbial mats developed
6
7 203 intermittently, binding fine micritic or fine grain sediment. Very low Fe_T suggests that these
8
9 204 settings were probably deposited in oxic waters (Wood *et al.*, 2010)

10
11 205 Size data were sub-divided by locality and setting, and individuals from mid-ramp reefs
12
13 206 were further sub-divided into three palaeoecological habitats: those found adjacent to
14
15 207 thrombolite heads, those in low-relief sheets on open surfaces, and those found within reef
16
17 208 crypts. On the basis of these differing habitats, we infer that *Namacalathus* occupied
18
19 209 different specific areas within the overall metazoan-microbial ecosystem. In sum, we identify
20
21 210 five palaeoecological habitats: Low energy inner ramp, Mid-ramp reef: Thrombolite
22
23 211 association, Mid-ramp reef: Open surface sheet, Mid-ramp reef: Cryptic (occupying reef
24
25 212 crypts), and Outer ramp.

26
27
28
29
30 213

31 214 METHODS

32
33 215 *Namacalathus* fossils were identified as in life position on the basis of intact skeletons
34
35 216 with an upwards growth perpendicular to bedding planes. Some show skeletal deformation
36
37 217 due to close-packed growth, or show the base of the stem anchored in sediment or attached to
38
39 218 microbial mats. Measurements were taken from scans of rock samples, and from field
40
41 219 photographs, and the cup diameter of in-situ *Namacalathus* individuals was recorded (see
42
43 220 Table SM 7).

44
45
46
47 221 Because of the three-dimensional preservation of *Namacalathus* in the Nama Group,
48
49 222 exposed or cut rock surfaces present a variety of different sections through the skeleton due
50
51 223 to variations in the orientation of individuals relative to exposed rock surfaces. Consequently,
52
53 224 a complete set of measurements is impossible on most *Namacalathus* individuals. However,
54
55 225 cup diameter is commonly measurable, so has been used as a size indicator. Field
56
57
58
59
60

1
2
3 226 photographs and scans of rock specimens were imported into ImageJ for **data collection**, and
4
5 227 measurements were made from all clearly visible individuals in each image; specimens where
6
7 228 cup diameter could not be measured or identification as *Namacalathus* was not certain were
8
9 229 excluded.

11 230 Different sections through the skeleton **were categorised into ‘vertical’, ‘horizontal’ and**
13
14 231 **‘oblique’ as the type of section measured can alter the apparent size. ‘Vertical’, ‘horizontal’**
15
16 232 **and ‘oblique’ sections are defined as follows: ‘vertical’ sections represent a slice parallel to**
17
18 233 **the growth axis of the fossil which includes both the apical opening in the cup and the hole at**
19
20 234 **the base of the stem. ‘Horizontal’ sections through the cup are perpendicular to the growth**
21
22 235 **axis and preserve the outer wall of the cup together with the 5-7 lateral lumens. ‘Oblique’**
23
24 236 **sections are any other section through the apical cup. An oblique section through a goblet**
25
26 237 **shape is likely to show a smaller cup diameter** than a vertical or horizontal section.

28
29 238 Vertical and horizontal sections are most useful as they permit a consistent comparison of
30
31 239 measurements between individuals. However, oblique sections are also useful as they provide
32
33 240 a minimum size constraint, so they have been included in this analysis. **Maximum measured**
34
35 241 **cup diameter at each site may also usefully reflect** size differences between **palaeoecological**
36
37 242 **habitats**, although is not amenable to statistical testing. When describing *Namacalathus*
38
39 243 assemblages, we therefore use the median for statistical purposes (for a justification of this,
40
41 244 see the Shapiro-Wilk normality test in Results section), but also quote the maximum cup
42
43 245 diameter.

44
45 246 Where vertical sections were available, both cup diameter and cup height measurements
46
47 247 were taken (see Table SM 8), to determine whether *Namacalathus* individuals in different
48
49 248 settings shared a growth trajectory. Since vertical sections, which are required for cup height
50
51 249 measurements, are much rarer than oblique ones, **this dataset is much smaller than the cup**
52
53 250 **diameter dataset and consequently has not been subjected to the same statistical analyses. In**

1
2
3 251 total, 398 sections were measured, of which 97 were vertical; there are five vertical sections
4
5 252 for which cup height was not measured due to breakage at the apical part of the cup. For all
6
7 253 statistical tests, p-values lower than 0.05 were taken as significant. Statistical tests were
8
9
10 254 performed in PAST, version 3.02 (Hammer, 2014), and in R.

11
12 255 To determine whether the cup diameter data were normally distributed, and inform further
13
14 256 statistical tests, a Shapiro-Wilk test was applied to the data from each of the five
15
16 257 palaeoecological habitats, and to the dataset as a whole. The Shapiro-Wilk test was selected
17
18 258 due to its statistical power, and was first applied to the raw data, then to the log-transformed
19
20
21 259 dataset. In the Shapiro-Wilk test, the null hypothesis (H_0) is that the data were taken from an
22
23 260 assemblage with a normal distribution.

24
25 261 The Kolmogorov-Smirnov test was used to compare the overall cup diameter distribution
26
27 262 across all data with the distributions in each of the five palaeoecological habitats (Table SM
28
29 263 5). The Kolmogorov-Smirnov test is a pairwise non-parametric test which detects differences
30
31 264 in both the shape and position of a distribution, and was selected because it makes no
32
33 265 assumptions about the distribution of the data, and its application in this way avoids multiple
34
35 266 comparisons problems which can lead to Type 1 errors. In the Kolmogorov-Smirnov test, the
36
37 267 null hypothesis (H_0) is that the two samples under comparison come from assemblages with
38
39 268 the same distribution.

40
41
42
43 269 To compare the median cup diameter values from each dataset, a Kruskal-Wallis test was
44
45 270 performed. The Kruskal-Wallis test is a multiple samples test whose null hypothesis (H_0) is
46
47 271 that there is no statistically significant difference between the medians of the samples. The
48
49 272 test was selected because it does not require an assumption that the data are normally
50
51 273 distributed.

52
53
54 274 Although the results of the Kruskal-Wallis test do not identify the sources of statistically
55
56 275 significant differences in the median between samples, this can sometimes be ascertained by
57
58
59
60

1
2
3 276 visually comparing the data distributions of the samples. However, Mann-Whitney tests were
4
5 277 also carried out on all possible pairs of palaeoecological habitats to ascertain where
6
7 278 statistically significant differences in the median lay, as data from some palaeoecological
8
9 279 habitats gave visually similar distributions. In the Mann-Whitney test, the null hypothesis
10
11 280 (H_0) is that there is no significant difference between the medians of two samples. A
12
13 281 Bonferroni correction was applied to remedy the potential problem of multiple comparisons
14
15 282 leading to Type 2 errors (i.e. falsely identifying significant differences). A linear regression
16
17 283 was used to determine if the cup diameter and cup height of all vertical sections correlated,
18
19 284 with the aim of determining if they had a shared growth trajectory. A Spearman's Rank
20
21 285 correlation coefficient (r_s) was also calculated to quantify the correlation, and was selected
22
23 286 because it makes no assumptions about data distribution. If $r_s = 1$ or -1 , there is a perfect
24
25 287 monotonic relationship between the two variables (in this case, cup height and cup diameter).
26
27
28
29
30

31 289 RESULTS

32 290 *Aggregation Style*

33
34
35 291 *Namacalathus* commonly occurs in densely aggregated assemblages which range from
36
37 292 decimetre to metre scale. In the inner ramp setting, some in-situ *Namacalathus* occur as
38
39 293 isolated individuals (Fig. 4A, C), but most are found in aggregations of up to 0.5 m diameter
40
41 294 (Fig. 4B).
42
43
44

45 295 In mid-ramp reefs, small (<0.5 m) aggregations are associated with thrombolite heads.
46
47 296 These close-packed aggregations contain individuals of up to 35 mm cup diameter, though a
48
49 297 range of individual sizes occurs (Fig. 5A, B, F). Some of these large individuals also have
50
51 298 external spines, though the sample contains too few individuals with this feature to
52
53 299 statistically analyse its occurrence (Fig. 5B). On open surfaces in mid-ramp reefs,
54
55 300 *Namacalathus* aggregates to form sheets of up to 5 m in diameter (Fig. 5D, G), and also
56
57
58
59
60

1
2
3 301 intergrows with extensive (> 20 m in diameter) thickets of *Cloudina riemkeae* (Fig. 5E, D,
4
5 302 Wood & Curtis, 2015). One open surface aggregation appeared to contain individuals whose
6
7 303 cups are slightly ellipsoidal, with a preferential orientation to their long axes, though the
8
9
10 304 sample is small (Figs. SM 1, 2); however, oblique sectioning of a uniformly oriented
11
12 305 assemblage of in-situ fossils cannot be discounted. The small available sample size for the
13
14 306 cryptic habitat does not permit an assessment of aggregation style (Fig. 5C).

15
16 307 In the low energy outer ramp, small lenticular aggregations (<0.3 m diameter) occur (Fig.
17
18 308 6A, C, D). These aggregations develop very little topographic relief, and may occupy scours
19
20 309 produced by periodic storms.
21
22

23 310

24 311 *Cup Diameter*

25
26
27 312 In total, 398 individuals were measured, and of these 97 were represented by a vertical
28
29 313 section through the skeleton, 12 by horizontal sections, and 289 by oblique sections. Cup
30
31 314 diameter data are given in Table SM 7.

32
33
34 315 The Shapiro-Wilk test returned a p-value of 9.156E-16 when applied to the whole cup
35
36 316 diameter dataset, and 0.003318 when applied to the log-transformed dataset, implying that
37
38 317 the data do not show a normal or log-normal distribution overall. Histograms of the cup
39
40 318 diameter data were also plotted to give a visual indication of the data distribution (Fig. 7).
41
42 319 These show a highly non-normal distribution, with most individuals tending towards the
43
44 320 smaller end of the size scale. This distribution persists whether the whole cup diameter
45
46 321 dataset is plotted, or just data from vertical and horizontal sections, which we might expect to
47
48 322 reflect true cup diameter more accurately.
49
50

51
52 323 The results of the Shapiro-Wilk test on cup diameter datasets from each of the five
53
54 324 palaeoecological habitats are given in the Supplemental Material (Table SM 3). All returned
55
56 325 p-values below 0.05, so we reject the null hypothesis that the cup diameter data are normally
57
58
59
60

1
2
3 326 distributed. In the case of the outer ramp locality, the p-value returned was 0.049, very close
4
5 327 to the critical value but still below it.
6

7
8 328 The Shapiro-Wilk test was repeated on the log-transformed cup diameter data for each
9
10 329 palaeoecological habitat, returning p-values over 0.05 (Table SM 4  we cannot reject the
11
12 330 null hypothesis that the log-transformed data from each palaeoecological habitat are normally
13
14 331 distributed.
15

16
17 332 Since the untransformed cup diameter data are not normally distributed, the median
18
19 333 was used for comparison of central tendency between habitats (Fig. 8A). Inner ramp
20
21 334 individuals have the largest median cup diameter (8.0 mm) and also show a larger range of
22
23 335 cup diameters than the outer ramp. The outer ramp showed the smallest median cup diameter
24
25 336 (4.4 mm), and the smallest range. In mid-ramp reefs, individuals from the three distinct
26
27 337 habitats have different cup diameter ranges. Individuals associated with thrombolite heads
28
29 338 have a median cup diameter of 7.7 mm. Those growing on open surfaces or intergrown with
30
31 339 *Cloudina riemkeae* had a median cup diameter of 6.9 mm, and individuals in reef crypts have
32
33 340 a median cup diameter of 5.8 mm.
34
35

36
37 341 Non-parametric tests were applied to the untransformed cup diameter data to assess the
38
39 342 statistical significance of differences between size distributions. Kolmogorov-Smirnov tests
40
41 343 were applied to *Namacalathus* cup diameter datasets from each palaeoecological habitat, to
42
43 344 compare them with the overall cup diameter distribution for all data. Results are tabulated in
44
45 345 Supplementary Materials (Table SM 5). For all palaeoecological habitats except for the mid-
46
47 346 ramp reef open surface, the Kolmogorov-Smirnov test returned a p-value lower than 0.05, so
48
49 347 we may reject the null hypothesis that cup diameter distributions within the other
50
51 348 palaeoecological habitats match the overall distribution of the data.
52
53

54
55 349 The Kruskal-Wallis test returned a p-value of 2.9E-19, so we reject the null hypothesis
56
57 350 that there is no significant difference in the median cup diameter of samples from each of the
58
59
60

1
2
3 351 five palaeoecological habitats. Bonferroni corrected p-values resulting from the Mann-
4
5 352 Whitney tests on all pairs of samples are given in Table SM 6, and vary from $p = 1.43E-15$
6
7 353 (for the comparison of the outer ramp with low energy inner ramp palaeoecological habitats)
8
9
10 354 to $p = 1$ (for the comparison of the low energy inner ramp and mid-ramp reef thrombolite
11
12 355 associated samples).

13
14 356 According to the Mann-Whitney tests, the median cup diameter in the low energy inner
15
16 357 ramp palaeoecological habitat was significantly different to that of all other palaeoecological
17
18 358 habitats (p-values of $1.43E-15$ to 0.01665) except to that of the mid-ramp reef thrombolite
19
20 359 association, which returned a p-value of 1. Within the mid-ramp reef setting, there was no
21
22 360 significant difference between the median cup diameters of the open surface, thrombolite-
23
24 361 associated and cryptic palaeoecological habitats (p-values of 0.1195 to 0.4417), though the
25
26 362 open surface and cryptic palaeoecological habitats hosted *Namacalathus* with a significantly
27
28 363 different median cup diameter to the low energy inner ramp and outer ramp habitats (p-values
29
30 364 of $6.07E-14$ to 0.01665). Finally, the outer ramp *Namacalathus* assemblage had a
31
32 365 significantly different median cup diameter to the assemblages from all other
33
34 366 palaeoecological habitats (p-values of $1.43E-15$ to 0.005758).

35
36
37 367 Though not amenable to statistical analysis, maximum cup diameter may also be
38
39 368 informative due to the prevalence of oblique sections in our dataset. Inner ramp individuals
40
41 369 have a maximum cup diameter of 23.7 mm, while in the mid-ramp reef environment,
42
43 370 individuals in cryptic environments had a maximum cup diameter of 12 mm, those on open
44
45 371 surfaces 18.4 mm, and in thrombolite associations 35.1 mm. Outer ramp settings show the
46
47 372 smallest maximum cup diameter at 8.9 mm.

48
49 373 To check whether all individuals in the dataset shared a growth trajectory, cup height was
50
51 374 plotted against cup diameter for 92 vertical sections from the entire dataset, regardless of
52
53 375 habitat. Spearman's Rank correlation coefficient (r_s) returned a value of 0.84506 , suggesting
54
55
56
57
58
59
60

1
2
3 376 a correlation between the two. A major axis linear regression model was fitted to the data and
4
5 377 visual inspection shows that that cup height appears to be proportional to cup diameter **across**
6
7 378 **all data** (See Fig. 8B).
8
9

10 379

11 380 ***Relationship to substrate***

12
13
14 381 In the inner and outer ramp settings, *Namacalathus* **is** anchored to or within thin microbial
15
16 382 laminae by the base of the stem, occupying small **primary** depressions in the surface of the
17
18 383 microbial laminae (Figs. 4C and 6B, D). By contrast, mid-ramp settings provided
19
20 384 thrombolitic substrates. While direct contact between **the bases of** stems and thrombolite
21
22 385 surfaces was not observed in the mid-ramp reefs, early cements encase the **erect**
23
24 386 *Namacalathus* individuals, suggesting that they are in life position. Forms in reef crypts are
25
26 387 also attached to thrombolitic substrates (Fig. 5C). The attachment of the sheet-like
27
28 388 aggregations is not clear, but these may be attached to *Cloudina riemkeae* thickets intergrown
29
30 389 with thrombolite (Wood & Curtis, 2015).
31
32
33

34 390

35 391 ***Budding distribution***

36
37 392 **Regular bilateral** budding in *Namacalathus* was reported **in the outer ramp** (Figs. 6D and
38
39 393 **E) and inner ramp** (Fig. 4B) (Zhuravlev *et al.* 2015a). In contrast, smaller individuals are
40
41 394 **sometimes apparently randomly attached to the inner or outer cup surfaces of larger**
42
43 395 **individuals in mid-ramp thrombolites** (Fig. 5A). This may reflect attachment to the **pre-**
44
45 396 **existing abandoned skeletons of other individuals.**
46
47
48

49 397 In the inner ramp, budding is common (Fig. 4B) and smaller individuals also frequently
50
51 398 occur within larger forms. In the mid-ramp setting the skeletal continuity between individuals
52
53 399 observed in open surface assemblages is suggestive of budding. In the thrombolite-associated
54
55 400 setting, one or more small individuals are observed inside the cup of **larger** individuals,
56
57
58
59
60

1
2
3 401 apparently attached (Fig. 5A). Individuals in reef crypts exhibited no budding, though the
4
5 402 sample size here is small.

6
7 403 In the outer ramp, *Namacalathus* forms small, dense aggregations with individuals
8
9 404 commonly displaying budding. Here, two possible generations of buds are noted on some
10
11 405 individuals (Fig. 6D, E)

12
13 406

14 15 16 407 **DISCUSSION**

17
18 408 *Namacalathus* occupied diverse carbonate settings in terms of water depth, hydrodynamic
19
20 409 energy, and variable microbial substrate types (Fig. 9), and *Namacalathus* from different
21
22 410 palaeoecological habitats show distinct size distributions (Fig. 8B). However, cup diameter
23
24 411 and cup height data correlate across all settings, suggesting that all *Namacalathus* individuals
25
26 412 shared the same growth trajectory (Fig. 8B). This implies that they belong to one taxon
27
28 413 showing considerable intraspecific size variation, rather than *Namacalathus* in different
29
30 414 settings representing different species with distinct environmental preferences. Since size in
31
32 415 metazoans is influenced by a variety of factors, many of which are not amenable to
33
34 416 explanation using the environmental factors discussed identified here, we will not attempt to
35
36 417 assign particular environmental causes to the differences in median cup diameter between
37
38 418 palaeoecological habitats. Quantifying size and comparing size distributions can, however,
39
40 419 yield information on the adaptations of metazoans to their environments.

41
42
43 420 *Namacalathus* attains the largest median cup diameter and a large size range (3.6 – 23.7
44
45 421 mm) within aggregations in the low energy inner ramp environment, though does not attain
46
47 422 the maximum sizes found in mid-ramp reef thrombolite-associated individuals (35.1 mm).
48
49 423 Statistically, there is no significant difference between the median cup diameters of
50
51 424 *Namacalathus* assemblages in the low energy inner ramp and the mid-ramp reef. In the inner
52
53 425 ramp settings, thin microbial mats were preferentially colonised, and despite geochemical
54
55
56
57
58
59
60

1
2
3 426 evidence for only transient oxygenation on geological timescales, there is evidence of
4
5 427 budding which implies that multiple generations developed on the same sites.
6

7 428 In the mid-ramp reef setting, *Namacalathus* occupied at least three palaeoecological
8
9 429 habitats, though these assemblages show no statistically significant differences in cup
10
11 430 diameter. *Namacalathus* assemblages from each habitat do however show substantial
12
13 431 differences in maximum cup diameter and differing size distributions, as well as occupying
14
15 432 differing substrates. Individuals in depressions between microbialite mounds attained the
16
17 433 largest maximum sizes (Grotzinger *et al.* 2000; Hofmann & Mountjoy, 2001; Wood, 2011),
18
19 434 while individual sizes show a large range and the attachment of smaller individuals to larger
20
21 435 ones suggests that multiple generations were present. The low-relief open surface
22
23 436 assemblages do not show a cup diameter distribution that differs significantly from the cup
24
25 437 diameter distribution across the whole dataset, but the cup diameter distribution of the
26
27 438 assemblage in reef crypts does differ significantly from the overall distribution, likely
28
29 439 because of their smaller cup diameters and smaller size range (Fig. 8A). We suggest that
30
31 440 persistently oxic conditions and the range of varied, mechanically stable substrates in such
32
33 441 topographically complex habitats may have allowed occupancy of a wider range of substrates
34
35 442 over longer timescales.
36
37
38
39

40 443 By contrast, the inner and outer ramp environments lack any differentiation into different
41
42 444 habitats, which may in part reflect the lack of topographic heterogeneity offered in these
43
44 445 settings compared with mid-ramp reefs. The outer ramp *Namacalathus* individuals are
45
46 446 generally much smaller than those in the inner or mid-ramp, though the presence of budding
47
48 447 or multiple generations suggests that the outer ramp hosted assemblages of mature,
49
50 448 reproducing individuals. Nonetheless, *Namacalathus* in transiently hospitable inner and outer
51
52 449 ramp settings may still have experienced early mortality or shown high growth rates. This
53
54 450 may be compared to modern populations which show an adaptive response to stressful
55
56
57
58
59
60

1
2
3 451 conditions resulting in early growth cessation and reproductive onset combined with early
4
5 452 and high adult mortality (Perry & Dominy, 2009; Whiteman *et al.*, 2012). Regardless, it
6
7 453 appears that *Namacalathus* was adapted for life in transiently hospitable environments.
8

9
10 454 In modern ecosystems, species that first colonise newly available heterogeneous
11
12 455 landscapes in the absence of strong intra-specific competition, e.g., fishes in postglacial lakes,
13
14 456 often establish co-existing sympatric morphotypes (Rundle *et al.*, 2000; Klemetsen, 2010).
15
16 457 These can show remarkably different sizes, mouth parts, and behaviour within single lakes
17
18 458 even in the absence of reproductive isolation because such morphs are adapted to different
19
20 459 resource niches (Klemetsen, 2010). While there are few studies on low-competition benthic
21
22 460 metazoan communities, high rates of sympatric speciation are observed among benthic
23
24 461 caenogastropods of the East African Great Lakes due to phenotypic plasticity which in turn
25
26 462 reflect a rising opportunity for ecophenotypes to occupy different substrates (Salzburger *et*
27
28 463 *al.*, 2014). It is possible that carbonate settings in the late Ediacaran presented a similar
29
30 464 landscape of low competition with a limited number of metazoan species forming low
31
32 465 diversity communities. This may have promoted the intraspecific size variation of
33
34 466 *Namacalathus* noted here, allowing differentiation into morphs of different sizes due to
35
36 467 adaptation to various substrates, relative redox stability or variable hydrodynamic conditions.
37
38 468 This is particularly evident in the difference in median cup diameter between the outer ramp
39
40 469 *Namacalathus* and those in the rest of the dataset.
41
42
43
44

45 470 Size differentiation may indicate intraspecific niche partitioning, particularly in mid-ramp
46
47 471 reefs, whereby natural selection drives members of a species into different sub-groupings
48
49 472 according to different patterns of resource use or niches. Alternatively, the differences in size
50
51 473 distribution may represent intraspecific ecophenotypic variation - a phenomenon well-
52
53 474 documented in sessile benthic metazoans (e.g. Alexander, 1975; Scrutton, 1996; Gittenberger
54
55 475 & Hoeksema, 2006; Zieritz & Aldridge, 2009).
56
57
58
59
60

1
2
3 476 *Namacalathus* appears to have been an environmental generalist, occupying a range of
4
5 477 different settings from inner ramp lagoons to more distal ramp environments, and both open
6
7 478 surface and cryptic habitats in mid-ramp reefs. It was capable of high intraspecific size
8
9 479 variation, and may have differentiated into size morphs. Variable redox conditions and
10
11 480 otherwise transiently available habitats appear not to have been a barrier to growth and
12
13 481 reproduction despite *Namacalathus*' presumed reliance on oxygen for maintenance of
14
15 482 metabolism. A tendency towards opportunistically colonising areas during transient periods
16
17 483 of oxia would have served *Namacalathus* well in the Nama Group in the late Ediacaran, and
18
19 484 it is possible that this was a widespread ecological strategy among Ediacaran skeletal
20
21 485 metazoans.
22

23
24
25 486 This highly generalist behaviour  hereby *Namacalathus* occupied different
26
27 487 microenvironments via intraspecific variation and possibly the development of different size
28
29 488 morphs adapted to local conditions contrasts with the next phase of sessile calcified metazoan
30
31 489 development, represented by the lower Cambrian Stage 2 (~535 – 525 Ma) archaeocyathan
32
33 490 reefs of the Siberian Platform. Here, different microenvironments were occupied by
34
35 491 specialised representatives of different species and genera (Zhuravlev & Wood, 1995;
36
37 492 Debrenne & Zhuravlev, 1996; Zhuravlev, 2001; Zhuravlev *et al.*, 2015b). As such, we may
38
39 493 infer an escalation in levels of inter-specific competition in sessile skeletal metazoans from
40
41 494 ~548 to 535 Ma.

47

48 CONCLUSIONS

49
50 497 *Namacalathus* occupied a variety of palaeoenvironments in the Nama Basin, and exhibited
51
52 498 intraspecific size variation between settings. The largest individuals lived in association with
53
54 499 mid-ramp reef thrombolites, while the smallest lived in cryptic habitats in mid-ramp reefs,
55
56 500 and in more distal ramp environments. In mid-ramp reefs, *Namacalathus* occupied a range of
57
58
59
60

1
2
3 501 habitats, and formed large, persistent aggregations in association with other early skeletal
4
5 502 metazoans. This is likely to be due to the mechanical stability of substrates and persistence of
6
7 503 oxic waters in this **habitat**.

8
9
10 504 We conclude that *Namacalathus* was **an environmental** generalist that **colonised both**
11
12 505 **persistently and transiently oxic habitats, and spatially differentiated into populations with**
13
14 506 **differing size distributions**. As such, *Namacalathus* was adapted to the various substrates and
15
16 507 sometimes highly dynamic redox environment that characterized the late Ediacaran Nama
17
18 508 Group. This contrasts with the situation in early Cambrian metazoan reefs, whereby
19
20 509 individual taxa were specialised for particular microenvironments, **and may reflect a trend**
21
22 510 **from generalist to specialist in the earliest sessile metazoans of shallow marine carbonate**
23
24 511 **settings**.

28 29 513 **ACKNOWLEDGEMENTS**

30
31
32 514 AP is grateful for funding from a University of Edinburgh, School of Geosciences
33
34 515 Scholarship and the International Centre for Carbonate Reservoirs. RW, RT, and AP
35
36 516 acknowledge support from NERC through the ‘Co-evolution of Life and the Planet’ scheme.
37
38 517 FB thanks the Laidlaw Hall Trust for fieldwork support. We thank the Geological Survey of
39
40 518 Namibia, and A. Horn of Omkyk, L. and G. Fourie of Zebra River, C. Husselman of
41
42 519 Driedoornvlagte, and L. G’Evereet of Swartpunt for access to their farms, and Mike Hall for
43
44 520 technical support. We also thank Duncan Murdock, Marc Laflamme and five anonymous
45
46 521 reviewers for their insightful and constructive comments.

3 721 & Curtis, 2015). E – *Namacalathus* intergrowing with *Cloudina riemkeae* to form metre-scale
4
5 722 reefs (Wood & Curtis, 2015). F – A thicket of thrombolite-associated *Namacalathus*. G –
6
7 723 Detail of *Namacalathus* in an open surface aggregation.
8

9
10 724

11 725 Figure 6. *Namacalathus* from an outer ramp setting. A - Aggregated individuals in the outer
12
13 726 ramp. B – Two small *Namacalathus* with geopetal infills showing that these examples
14
15 727 remained in-situ while micrite was deposited within them. A well-preserved stem is anchored
16
17 728 within microbial mat (arrow). C – Small, monospecific, lenticular aggregation enclosed in
18
19 729 microbially bound micrite in outer ramp setting. D – Enlargement of C showing
20
21 730 *Namacalathus* stems attached to other individuals or to the substrate (white arrows). E –
22
23 731 Enlargement of C showing *Namacalathus* individuals attached to each other by their stems,
24
25 732 possibly indicating budding (arrows).
26
27
28
29

30 733

31 734 Figure 7. Cup diameter distributions for the entire size dataset and for vertical and horizontal
32
33 735 sections only. Both show a near-lognormal distribution.
34
35
36

37 736

38
39 737 Figure 8. A - Box and whisker plots of cup diameter data for *Namacalathus* from three
40
41 738 settings, with the mid-ramp reef setting subdivided into three palaeoecological habitats.
42
43 739 “Thromb. Association” = Thrombolite association. Whiskers show the range of the data,
44
45 740 while upper and lower boundaries of the boxes show the first and third quartiles. Medians are
46
47 741 8.0 mm for inner ramp; 6.9mm for mid-ramp open surfaces, 7.7mm for *Namacalathus* in
48
49 742 thrombolite associations, 5.8 mm in cryptic environments; and 4.4 mm for outer ramp. B -
50
51 743 Cup height against cup diameter for all individuals in the three settings, with a major axis
52
53 744 linear model suggesting a linear relationship. $R^2 = 0.89867$. Data are given in Table SM 7.
54

59
60

1
2
3 745 Figure 9. Composite schematic transect placing *Namacalathus* palaeoecologies within a
4
5 746 palaeoenvironmental context. Scale bars represent 10mm. A – Inner ramp monospecific
6
7 747 aggregations of large *Namacalathus* on a microbially bound micritic substrate. These have
8
9 748 the largest median cup diameter of any palaeoenvironment in this study, but not the largest
10
11 749 maximum cup diameter. B-E, mid-ramp reef settings. B – Large *Namacalathus* in
12
13 750 association with thrombolites. C – Small *Namacalathus* pendant from primary crypt ceilings.
14
15
16 751 D - Thrombolite association of individuals of various cup diameters, with long stems.
17
18 752 Smaller individuals appear to be attached to the inner cup surfaces of the larger individuals. E
19
20
21 753 – *Namacalathus* intergrowing with *Cloudina riemkeae* to form metre-scale reefs on open
22
23 754 surfaces. F – Small aggregations of small *Namacalathus* on a microbially bound substrate in
24
25 755 outer ramp setting, with small individuals attached to, or budding from, pre-existing ones.

Locality	Stratigraphy	Dominant Lithology	Ramp Setting	Redox Data			Redox State
				Fe/Al	Fe _T (wt.%)	Fe _{HR} /Fe _T	
Omkyk Farm	Omkyk Member	Flaggy limestone and dolomitised wackstone and packstone	Inner Ramp	0.612-4.198	0.02-2.66	0.17-1.00	Predominantly anoxic, with fleeting oxia
Zebra River	Omkyk Member	Flaggy limestone and dolomitised wackstone and packstone, microbialite reefs	Inner Ramp	0.45-5.30	0.032-5.279	0.031-0.876	Predominantly anoxic, with fleeting oxia
Pinnacle Reefs	Feldschuhorn Member	Microbialite reefs	Mid-Ramp	No data	0.042-5.366	0.043-0.253	Probably persistently oxic
Driedoornvlagte	Upper Omkyk Member	Microbialite reefs	Mid-Ramp	No data	0.005-0.383	Not measurable as Fe _T < 0.5wt.%	Probably persistently oxic
Swartpunt	Spitzkopf Member	Lenses of wackstone and packstone	Outer Ramp	No data	0.057-5.544	0.062-0.605	Probable oxic conditions predominate at level of <i>Namacalathus</i> ; possible brief episodes of anoxia towards top of section (above <i>Namacalathus</i> occurrence).
