Abstract

Recent treatments of the issue of a zero floor on nominal interest rates have been subject to some important methodological limitations. These include the assumption of perfect foresight or the introduction of the zero lower bound as an initial condition or a constraint on the variance of the interest rate, rather than an occasionally binding non-negativity constraint. This paper addresses these issues offering a global solution to a standard dynamic stochastic sticky price model with an explicit occasionally binding non-negativity constraint on the nominal interest rate. It turns out that the dynamics and sometimes the unconditional means of the nominal rate, inflation and the output gap are strongly affected by uncertainty in the presence of the zero lower bound. Commitment to the optimal rule reduces unconditional welfare losses to around one-tenth of those achievable under discretionary policy, while constant price level targeting delivers losses which are only 60% larger than under the optimal rule. Even though the unconditional performance of simple instrument rules is almost unaffected by the presence of the zero lower bound, conditional on a strong deflationary shock simple instrument rules perform substantially worse than the optimal policy.

1 Introduction

An economy is said to be in a "liquidity trap" when the monetary authority cannot achieve a lower nominal interest rate in order to stimulate output. Such a situation can arise when the nominal interest rate has reached its zero lower bound (ZLB), below which nobody would be willing to lend, if money can be stored at no cost for a nominally riskless zero rate of return.

The possibility of a liquidity trap was first suggested by Keynes (1936) with reference to the Great Depression of the 1930s. At that time he compared the effectiveness of monetary policy in such a situation with trying to "push on a string". After WWII and especially during the high inflation period of the 1970s interest in the topic receded, and the liquidity trap was relegated to a hypothetical textbook example. As Krugman (1998) noticed, of the few modern papers that dealt with it most concluded that "the liquidity trap can't happen, it didn't happen, and it won't happen again".

With the benefit of hindsight, however, it did happen, and to no less than Japan. Figure 1 illustrates this, showing the evolution of output, inflation, and the short-term nominal interest rate following the collapse of the Japanese real estate bubble of the late 1980s. The figure exhibits a persistent downward trend in all three variables, and in particular the emergence of deflation since 1998 coupled with a zero nominal interest rate since 1999.

Motivated by the recent experience of Japan, the aim of the present paper is to contribute a quantitative analysis of the ZLB issue in a standard sticky price model under alternative monetary policy regimes. On the one hand, the paper characterizes optimal monetary policy in the case of discretion and commitment.¹ And on the other hand, it studies the performance of several simple monetary policy rules, modified to comply with the zero floor, relative to the optimal policy. The analysis is carried out within a stochastic general equilibrium model with monopolistic competition and Calvo (1983) staggered price setting, under a standard calibration to the postwar US economy.

The main findings are as follows: the optimal discretionary policy with zero

¹The part of the paper on optimal policy is similar to Adam and Billi (2006) and Adam and Billi (2007) and the main findings here are largely consistent with these authors. The added value is to quantify and compare the performance of optimal policy to that of a number of suboptimal rules in the same stochastic sticky price setup.

floor involves a deflationary bias, which may be significant for certain parameter values and which implies that any quantitative analyses of discretionary biases of monetary policy that ignore the zero lower bound may be misleading. In addition, optimal discretionary policy implies much more aggressive cutting of the interest rate when the risk of deflation is high, compared to the corresponding policy without zero floor. Such a policy helps mitigate the depressing effect of private sector expectations on current output and prices when the probability of falling into a liquidity trap is high.²

In contrast, optimal commitment policy involves less preemptive lowering of the interest rate in anticipation of a liquidity trap, but it entails a promise for sustained monetary policy easing following an exit from a trap. This type of commitment enables the central bank to achieve higher expected inflation and lower real rates in periods when the zero floor on nominal rates is binding.³ As a result, under the baseline calibration, the expected welfare loss under commitment is only around one-tenth of the loss under optimal discretionary policy. This implies that the cost of discretion may be much higher than normally considered when abstracting from the zero lower bound issue.

The average welfare losses under simple instrument rules are 8 to 20 times bigger than under the optimal rule. However, the bulk of these losses stem from the intrinsic suboptimality of simple instrument rules, and not from the zero floor *per se*. This is related to the fact that under these rules the zero floor is hit very rarely - less than 1% of the time - compared to optimal policy, which visits the liquidity trap one-third of the time. On the other hand, conditional on a large deflationary shock, the relative performance of simple instrument rules deteriorates substantially vis-a-vis the optimal policy.

Issues of deflation and the liquidity trap have received considerable attention recently, especially after the experience of Japan.⁴ In an influential article

²An early version of this paper comparing the performance of optimal discretionary policy with three simple Taylor rules was circulated in 2004; optimal commitment policy and more simple rules were added in a version circulated in 2005. Optimal discretionary policy was studied independently by Adam and Billi (2004b), and optimal commitment policy was studied by Adam and Billi (2004a).

³This basic intuition was suggested already by Krugman (1998) based on a simpler model.

⁴A partial list of relevant studies includes Krugman (1998), Wolman (1998), McCallum (2000), Reifschneider and Williams (2000), Klaeffling and Lopez-Perez (2003), Eggertsson and Woodford (2003), Coenen, Orphanides and Wieland (2004), Kato and Nishiyama (2005), Jung, Teranishi and Watanabe (2005), Adam and Billi (2006), Adam and Billi (2007).

Krugman (1998) argued that the liquidity trap boils down to a credibility problem in which private agents expect any monetary expansion to be reverted once the economy has recovered. As a solution he suggested that the central bank should commit to a policy of high future inflation over an extended horizon.

More recently, Jung, Teranishi and Watanabe (2005) have explored the effect of the zero lower bound in a standard sticky price model with Calvo price setting under the assumption of perfect foresight. Consistent with Krugman (1998), they conclude that optimal commitment policy entails a promise of a zero nominal interest for some time after the economy has recovered. Eggertsson and Woodford (2003) study optimal policy with zero lower bound in a similar model in which the natural rate of interest is allowed to take two different values. In particular, it is assumed to become negative initially and then to jump to its "normal" positive level with a fixed probability in each period. These authors also conclude that the central bank should create inflationary expectations for the future. Importantly, they derive a moving price level targeting rule that delivers the optimal policy in this model.

One shortcoming of much of the modern literature on monetary policy rules is that it largely ignores the ZLB issue or at best uses rough approximations to address the problem. For instance Rotemberg and Woodford (1997) introduce nominal rate targeting as an additional central bank objective, which ensures that the resulting path of the nominal rate does not violate the zero lower bound too often. In a similar vein, Schmitt-Grohe and Uribe (2004) exclude from their analysis instrument rules that result in a nominal rate the average of which is less than twice its standard deviation. In both cases therefore one might argue that for sufficiently large shocks that happen with a probability as high as 5%, the derived monetary policy rules are inconsistent with the zero lower bound.

On the other hand, of the few papers that do introduce an explicit non-negativity constraint on nominal interest rates, most simplify the stochastics of the model, for example by assuming perfect foresight (Jung, Teranishi and Watanabe 2005), or a two-state low/high economy (Eggertsson and Woodford (2003); Wolman (1998)). Even then, the zero lower bound is effectively imposed as an initial ("low") condition and not as an occasionally binding constraint.⁵

⁵Namely, the zero floor binds for the first several periods but once the economy transits to the "high" state, the ZLB never binds thereafter.

While this assumption may provide a reasonable first-pass at a quantitative analysis, it may be misleading to the extent that it ignores the occasionally binding nature of the zero interest rate floor.

Other studies (e.g. Coenen, Orphanides and Wieland (2004)) lay out a stochastic model but knowingly apply inappropriate solution techniques which rely on the assumption of certainty equivalence. It is well known that this assumption is violated in the presence of a non-linear constraint such as the zero floor but nevertheless these researchers have imposed it for reasons of tractability (admittedly they work with a larger model than the one studied here). Yet forcing certainty equivalence in this case amounts to assuming that agents ignore the risk of the economy falling into a liquidity trap when making their optimal decisions.

The present study contributes to the above literature by solving numerically a stochastic general equilibrium model with monopolistic competition and sticky prices with an explicit occasionally binding zero lower bound, using an appropriate global solution technique that does not rely on certainty equivalence. It extends the analysis of Jung, Teranishi and Watanabe (2005) to the stochastic case with an AR(1) process for the natural rate of interest.

After a brief outline of the basic framework adopted in the analysis (section 2), the paper characterizes and contrasts the optimal discretionary and optimal commitment policies (sections 3 and 4). It then analyzes the performance of a range of simple instrument and targeting rules (sections 5 and 6) consistent with the zero floor.⁶ Sections 4 to 6 include a comparison of the conditional performance of all rules in a simulated liquidity trap, while section 7 presents their average performance, including a ranking according to unconditional expected welfare. Section 8 studies the sensitivity of the findings to various parameters of the model, as well as the implications of endogenous inflation persistence for the ZLB issue and the last section concludes.

⁶These rules include truncated Taylor-type rules reacting to contemporaneous, expected future, or past, inflation, output gap, or price level; with or without "interest rate smoothing"; truncated first-difference rules; price level targeting; and strict inflation targeting rules.

2 Baseline Model

While in principle the zero lower bound phenomenon can be studied in a model with flexible prices, it is with sticky prices that the liquidity trap becomes a real problem. The basic framework adopted in this study is a stochastic general equilibrium model with monopolistic competition and staggered price setting *a la* Calvo (1983) as in Gali (2003) and Woodford (2003). In its simplest log-linearized⁷ version the model consists of three building blocks, describing the behavior of households, firms and the monetary authority.

The first block, known as the "IS curve", summarizes the household's optimal consumption decision,

$$x_t = E_t x_{t+1} - \sigma (i_t - E_t \pi_{t+1} - r_t^n) \quad (1)$$

It relates the "output gap" x_t (i.e. the deviation of output from its flexible price equilibrium) positively to the expected future output gap and negatively to the gap between the ex-ante real interest rate, $i_t - E_t \pi_{t+1}$, and the "natural" (i.e. flexible price equilibrium) real rate, r_t^n (which is observed by all agents at time t). Consumption smoothing accounts for the positive dependence of current on expected future output demand, while intertemporal substitution implies the negative effect of the ex-ante real interest rate. The interest rate elasticity of output, σ , corresponds to the inverse of the coefficient of relative risk aversion in the consumers' utility function.

The second building block of the model is a "Phillips curve"-type equation, which derives from the optimal price setting decision of monopolistically competitive firms under the assumption of staggered price setting *a la* Calvo (1983),

$$\pi_t = \beta E_t \pi_{t+1} + \kappa x_t \quad (2)$$

where β is the time discount factor and κ , "the slope" of the Phillips curve, is related inversely to the degree of price stickiness⁸. Since firms are unable

⁷It is important to note that, like in the studies cited in the introduction, the objective here is a modest one, in that the only source of non-linearity in the model stems from the ZLB. Solving the fully non-linear sticky price model with Calvo (1983) contracts can be a worthwhile enterprise, however it increases the dimensionality of the computational problem by the number of states and co-states that one should keep track of (e.g. the measure of price dispersion and in the case of optimal policy the Lagrange multipliers associated with all forward-looking constraints).

⁸In the underlying sticky price model the slope κ is given by $[\theta(1 + \varphi\varepsilon)]^{-1} (1 - \theta) (1 -$

to adjust prices optimally every period, whenever they have the opportunity to do so, they choose to price goods as a markup over a weighted average of current and expected future marginal costs. Under appropriate assumptions on technology and preferences, marginal costs are proportional to the output gap, resulting in the above Phillips curve. Here this relation is assumed to hold exactly, ignoring the so-called “cost-push” shock, which sometimes is appended to generate a short-term trade-off between inflation and output stabilization.

The final building block models the behavior of the monetary authority. The model assumes a "cashless limit" economy in which the instrument controlled by the central bank is the nominal interest rate. One possibility is to assume a benevolent monetary policy maker seeking to maximize the welfare of households. In that case, as shown in Woodford (2003), the problem can be cast in terms of a central bank that aims to minimize (under discretion or commitment) the expected discounted sum of losses from output gaps and inflation, subject to the optimal behavior of households (1) and firms (2), and the zero nominal rate floor:

$$\text{Min}_{i_t, \pi_t, x_t} E_0 \sum_{t=0}^{\infty} \beta^t (\pi_t^2 + \lambda x_t^2) \quad (3)$$

$$\text{s.t. (1), (2)}$$

$$i_t \geq 0 \quad (4)$$

where λ is the relative weight of the output gap in the central bank’s loss function.

An alternative way of modeling monetary policy is to assume that the central bank follows some sort of simple decision rule that relates the policy instrument, implicitly or explicitly, to other variables in the model. An example of such a rule, consistent with the zero floor, is a truncated Taylor rule,

$$i_t = \max [0, r^* + \pi^* + \phi_\pi (\pi_t - \pi^*) + \phi_x x_t] \quad (5)$$

where r^* is an equilibrium real rate, π^* is an inflation target, and ϕ_π and ϕ_x are response coefficients for inflation and the output gap.

$\beta\theta)(\sigma^{-1} + \varphi)$, where θ is the fraction of firms that keep prices unchanged in each period, φ is the (inverse) wage elasticity of labor supply, and ε is the elasticity of substitution among differentiated goods.

To close the model one needs to specify the behavior of the natural real rate. In the fuller model the latter is a composite of a variety of real shocks, including preferences, government spending, and technology. Following Woodford (2003) here I assume that the natural real rate follows an exogenous mean-reverting process,

$$\widehat{r}_t^n = \rho \widehat{r}_{t-1}^n + \epsilon_t, \quad (6)$$

where $\widehat{r}_t^n \equiv r_t^n - r^*$, is the deviation of the natural real rate from its mean, r^* ; ϵ_t are i.i.d. $N(0, \sigma_\epsilon^2)$ real shocks, and $0 \leq \rho < 1$ is a persistence parameter.

The equilibrium conditions of the model therefore include the constraints (1), (2), and either a set of first-order optimality conditions (in the case of optimal policy), or a simple rule like (5). In either case the resulting system of equations cannot be solved with standard solution methods relying on local approximation because of the non-negativity constraint on the nominal rate. Hence I solve them with a global solution technique known as "collocation". The rational expectations equilibrium with occasionally binding constraint is solved by way of parametrizing expectations (Christiano and Fischer 2000), and is implemented with the MATLAB routines developed by Miranda and Fackler (2001). Appendix A outlines the simulation algorithm, while the following sections report the results.

2.1 Baseline Calibration

The model's parameters are chosen to be consistent with the "standard" Woodford (2003) calibration to the US economy, which in turn is based on Rotemberg and Woodford (1997) (Table 1). Thus, the slope of the Phillips curve (0.024), the weight of the output gap in the central bank loss function (0.003), the time discount factor (0.993), the mean (3% pa) and standard deviation (3.72%) of the natural real rate are all taken directly from Woodford (2003). The persistence (0.65) of the natural real rate is assumed to be between the one used by Woodford (2003) (0.35) and that estimated by Adam and Billi (2006) (0.8) using a more recent sample period.⁹ The real interest rate elasticity of aggregate demand (0.25)¹⁰ is lower than the elasticity assumed by Woodford (2003) (0.5),

⁹These parameters for the shock process imply that the natural real interest rate is negative about 15% of the time on an annual basis. This is slightly more often than with the standard Woodford calibration (10%).

¹⁰which corresponds to a constant relative risk aversion of 4 in the underlying model.

Structural parameters		
Discount factor	β	0.993
Real interest rate elasticity of output	σ	0.25
Slope of the Phillips curve	κ	0.024
Weight of the output gap in loss function	λ	0.003
Natural real rate parameters		
Mean (% per annum)	r^*	3%
Standard deviation (annual)	$\sigma(r^n)$	3.72%
Persistence (quarterly)	ρ	0.65
Simple instrument rule coefficients		
Inflation target (% per annum)	π^*	0%
Coefficient on inflation	ϕ_π	1.5
Coefficient on output gap	ϕ_x	0.5
Interest rate smoothing coefficient	ϕ_i	0

Table 1: Baseline calibration (quarterly unless otherwise stated)

but as these authors point out, if anything a lower degree of interest sensitivity of aggregate expenditure biases the results towards a more modest output contraction as a result of a binding zero floor.¹¹ In the simulations with simple rules, the baseline target inflation rate (0%) is consistent with the implicit zero target for inflation in the central bank's loss function. The baseline reaction coefficients on inflation (1.5), the output gap (0.5), and the lagged nominal interest rate (0) are standard in the literature on Taylor (1993)-type rules. Section 8 studies the sensitivity of the results to various parameter changes.

3 Optimal Discretionary Policy with Zero Floor

Abstracting from the zero floor, the solution to the discretionary optimization problem is well known¹². Under discretion, the central bank cannot manipulate the beliefs of the private sector and it takes expectations as given. The private sector is aware that the central bank is free to re-optimize its plan in each period and, therefore, in a rational expectations equilibrium, the central bank should have no incentives to change its plans in an unexpected way. It can be shown that in this case the discretionary policy problem reduces to a sequence of static

¹¹With the Woodford (2003) value of this parameter (6.25), the model predicts unrealistically large output shortfalls when the zero floor binds - e.g. an output gap around -30% for values of the natural real rate around -3%.

¹²In this section attention is restricted to Markov-perfect equilibria only.

optimization problems in which the central bank minimizes current period losses by choosing the current inflation, output gap and nominal rate (Clarida, Gali and Gertler 1999).

Since in the baseline model there are no endogenous state variables, the Markovian policy functions depend only on the exogenous natural real rate, r_t^n . The solution without zero bound then is straightforward: inflation and the output gap are fully stabilized at their (zero) targets in every period and state of the world, while the nominal interest rate moves one-for-one with the natural real rate. This is depicted by the dotted lines in Figure 2. With this policy the central bank is able to achieve the globally minimal welfare loss of zero at all times.

With the zero floor, the problem of discretionary optimization can also be cast as a sequence of static problems. The Lagrangian is

$$L_t = \frac{1}{2} (\pi_t^2 + \lambda x_t^2) + \phi_{1t} [x_t - f_{1t} + \sigma (i_t - f_{2t})] + \phi_{2t} [\pi_t - \kappa x_t - \beta f_{2t}] + \phi_{3t} i_t \quad (7)$$

where ϕ_{1t} is the Lagrange multiplier associated with the IS curve (1), ϕ_{2t} with the Phillips curve (2), and ϕ_{3t} with the zero constraint (4). The functions $f_{1t} = E_t(x_{t+1})$, and $f_{2t} = E_t(\pi_{t+1})$ are the private sector expectations which the central bank takes as given. Noticing that $\phi_{3t} = \sigma\phi_{1t}$, the Kuhn-Tucker conditions for this problem can be written as:

$$\pi_t + \phi_{2t} = 0 \quad (8)$$

$$\lambda x_t + \phi_{1t} - \kappa\phi_{2t} = 0 \quad (9)$$

$$i_t\phi_{1t} = 0 \quad (10)$$

$$i_t \geq 0 \quad (11)$$

$$\phi_{1t} \geq 0 \quad (12)$$

Substituting (8) and (9) into (10), and combining the result with (1), (2), and (4), a Markov perfect rational expectations equilibrium in the case of discre-

tionary optimization should satisfy:

$$x_t - E_t x_{t+1} + \sigma (i_t - E_t \pi_{t+1} - r_t^n) = 0 \quad (13)$$

$$\pi_t - \kappa x_t - \beta E_t \pi_{t+1} = 0 \quad (14)$$

$$i_t (\lambda x_t + \kappa \pi_t) = 0 \quad (15)$$

$$i_t \geq 0 \quad (16)$$

$$\lambda x_t + \kappa \pi_t \leq 0 \quad (17)$$

Notice that (15) implies that the typical "targeting rule" involving inflation and the output gap is satisfied whenever the zero floor on the nominal interest rate is not binding,

$$\lambda x_t + \kappa \pi_t = 0, \quad (18)$$

$$\text{if } i_t > 0 \quad (19)$$

However, when the zero floor is binding, from (13) the dynamics are governed by

$$x_t + \sigma p_t - \sigma r_t^n = E_t x_{t+1} + \sigma E_t p_{t+1} \quad (20)$$

$$\text{if } i_t = 0 \quad (21)$$

where p_t is the (log) price level. Notice that it is no longer possible to set inflation and the output gap to zero at all times, for such a policy would require a negative nominal rate when the natural real rate falls below zero. Moreover, (20) implies that if the natural real rate falls so that the zero floor becomes binding, then since next period's output gap and price level are independent of today's actions, for expectations to be rational, the sum of the current output gap and price level must fall. The latter is true for any process for the natural real rate which allows it to take negative values.

An interesting special case, which replicates the findings of Jung, Teranishi and Watanabe (2005), is the case of perfect foresight. By perfect foresight it is meant here that the natural real rate jumps initially to some (possibly negative) value, after which it follows a deterministic path (consistent with an AR(1) process) back to its steady-state. In this case the policy functions are represented by the solid lines in Figure 2. As anticipated in the previous paragraph, at negative values of the natural real rate both the output gap and

inflation are below target. On the other hand, at positive levels of the natural real rate, prices and output can be stabilized fully in the case of discretionary optimization with perfect foresight. The reason for this is simple - in the absence of an endogenous state variable the discretionary optimization problem is static and once the natural real rate is above zero deterministic reversion to steady-state ensures that it will never be negative. This means that it can always be tracked one-for-one by the nominal rate (as in the case without zero floor), which is sufficient to fully stabilize prices and output.

One of the contributions of this paper is to extend the analysis in Jung, Teranishi and Watanabe (2005) to the more general case in which the natural real rate follows a stochastic AR(1) process. Figure 3 plots the optimal discretionary policies in the stochastic environment. Clearly optimal discretionary policy differs in several important ways both from the optimal policy unconstrained by the zero floor and from the constrained perfect-foresight solution. First of all, given the zero floor, it is in general no longer optimal to set either inflation or the output gap to zero in any period. In fact, in the solution with zero floor, inflation falls short of target at *any* level of the natural real rate. This gives rise to a "deflationary bias" of optimal discretionary policy, in other words an *average* rate of inflation below the target. Sensitivity analysis shows that for some plausible parameter values the deflationary bias becomes quantitatively significant¹³. This implies that any quantitative analysis of discretionary biases in monetary models that does not take into account the zero lower bound can be misleading.

Secondly, as in the case of perfect foresight, at negative levels of the natural real rate, both inflation and the output gap fall short of their respective targets. However, the deviations from target are larger in the stochastic case - up to 1.5 percentage points for the output gap, and up to 15 basis points for inflation at a natural real rate of -3% under the baseline calibration.

Third, above a positive threshold for the natural real rate, the optimal output gap becomes positive, peaking around +0.5%.

Finally, at positive levels of the natural real rate the optimal nominal interest rate policy with zero floor is both *more expansionary* (i.e. prescribing a lower

¹³E.g. half a percentage point with $\rho = 0.8$ and $r^* = 2\%$.

nominal rate), and *more aggressive* (i.e. steeper) compared to the optimal policy without zero floor¹⁴. As a result, the nominal rate hits the zero floor at levels of the natural real rate as high as 1.8% (and is constant at zero for lower levels of the natural real rate).

These results hinge on two factors: (1) the non-linearity induced by the zero floor; and (2) the stochastic nature of the natural real rate. The combined effect is an asymmetry in the ability of the central bank to respond to positive versus negative shocks when the natural real rate is close to zero. Namely, while the central bank can fully offset any positive shocks to the natural real rate because nothing prevents it from raising the nominal rate by as much as is necessary, it cannot fully offset large enough negative shocks. The most it can do in this case is to reduce the nominal rate down to zero, which is still higher than the rate consistent with zero output gap and inflation. Taking private sector expectations as given, the latter implies a higher than desired *real* interest rate, which depresses output and prices through the IS and Phillips curves.

At the same time, when the natural real rate is close to zero, private sector expectations reflect the asymmetry in the central bank's problem: a positive shock in the following period is expected to be neutralized, while an equally probable negative one is expected to take the economy into a liquidity trap. This gives rise to a "deflation bias" in expectations, which in a forward-looking economy has an immediate impact on the current evolution of output and prices. Absent an endogenous state, the current evolution of the economy is all that matters today, and so it is rational for the central bank to partially offset the depressing effect of expectations about the future on today's outcome by more aggressive lowering of the nominal rate when the risk of deflation is high. In this way, by engineering a positive output gap at low levels of the natural real rate, the central bank is able to "lean against" deflation in equilibrium.

At sufficiently high levels of the natural real rate, the probability for the zero floor to become binding converges to zero. In that case optimal discretionary policy approached the unconstrained one, namely zero output gap and inflation and a nominal rate equal to the natural real rate. However, around the deterministic steady-state the differences between the two policies - with and without

¹⁴... or compared to the optimal discretionary policy with zero floor and perfect foresight.

zero floor - remain significant.

Since in the baseline model the discretionary optimization problem is equivalent to a sequence of static problems, optimal policy is independent of history. This means that it is only the current risk of falling into a liquidity trap that matters for current policy, regardless of whether the economy is approaching a liquidity trap or has just exited one. This is in sharp contrast with the optimal policy under commitment, which involves a particular type of history dependence as will become clear in the following section.

4 Optimal Commitment Policy with Zero Floor

In the absence of the zero lower bound the equilibrium outcome under optimal discretion is globally optimal and therefore it is observationally equivalent to the outcome under optimal commitment policy. The central bank manages to stabilize fully inflation and the output gap while adjusting the nominal rate one-for-one with the natural real rate.

However, this observational equivalence no longer holds in the presence of a zero interest rate floor. While full stabilization under either regime is not possible, important gains can be obtained from the ability to commit to future policy. In particular, by committing to deliver inflation in the future, the central bank can affect private sector's expectations about inflation, and thus the real rate, even when the nominal interest rate is constrained by the zero floor. This channel of monetary policy is simply unavailable to a discretionary policy maker.

Using the same Lagrange method as before, but this time taking into account the dependence of expectations on policy choices, it is straightforward to obtain

the equilibrium conditions that govern the optimal commitment solution:

$$x_t - E_t x_{t+1} + \sigma (i_t - E_t \pi_{t+1} - r_t^n) = 0 \quad (22)$$

$$\pi_t - \kappa x_t - \beta E_t \pi_{t+1} = 0 \quad (23)$$

$$\pi_t - \phi_{1t-1} \sigma / \beta + \phi_{2t} - \phi_{2t-1} = 0 \quad (24)$$

$$\lambda x_t + \phi_{1t} - \phi_{1t-1} / \beta - \kappa \phi_{2t} = 0 \quad (25)$$

$$i_t \phi_{1t} = 0 \quad (26)$$

$$i_t \geq 0 \quad (27)$$

$$\phi_{1t} \geq 0 \quad (28)$$

From conditions (24) and (25) it is clear that the Lagrange multipliers inherited from the past period will have an effect on current policy. They in turn will depend on the history of endogenous variables and in particular on whether the zero floor was binding in the past. In this sense the Lagrange multipliers summarize the effect of commitment, which in contrast to optimal discretionary policy, involves a particular type of history dependence.

Figures 4 to 6 plot the optimal policies in the case of commitment. The figures illustrate specifically the dependence of policy on ϕ_{1t-1} , the Lagrange multiplier associated with the zero floor, while holding ϕ_{2t-1} fixed. When the nominal interest rate is constrained by the zero floor ϕ_1 becomes positive, implying that the central bank commits to a lower nominal rate, higher inflation and higher output gap in the following period, conditional on the value of the natural real rate.

Since the commitment is assumed to be credible, it enables the central bank to achieve higher expected inflation and a lower real rate in periods when the nominal rate is constrained by the zero floor. The lower real rate reinforces expectations for higher future output and thus further stimulates current output demand through the IS curve. This, together with higher expected inflation stimulates current prices through the expectational Phillips curve. Commitment therefore provides an additional channel of monetary policy, which works through expectations and through the ex-ante real rate, and which is unavailable to a discretionary monetary policy maker.

A standard way to illustrate the differences between optimal discretionary and commitment policies is to compare the dynamic evolution of endogenous

variables under each regime in response to a single shock to the exogenous natural real rate. Figures 7 and 8 plot the impulse-responses for a small and a large negative shock to the natural real rate respectively. Notice that in the case of a small shock to the natural real rate from its steady-state of 3% down to 2%, inflation and the output gap under optimal commitment policy (lines with circles) remain almost fully stabilized. In contrast, under discretionary optimization (lines with squares), inflation stays slightly below target and the output gap remains about half a percentage point above target, consistent with equation (18), as the economy converges back to its steady-state. The nominal interest rate under discretion is about 1% lower than the one under commitment throughout the simulation, yet it remains strictly positive at all times.

The picture changes substantially in the case of a large negative shock to the natural interest rate to -3%. Notably, under both commitment and discretion, the nominal interest rate hits the zero lower bound, and remains there until two quarters after the natural interest rate has returned to positive.¹⁵ Under discretionary optimization, both inflation and the output gap fall on impact, consistent with equation (20), after which they converge towards their steady-state. The initial shortfall is significant, especially for the output gap, amounting to about 1.5%. In contrast, under the optimal commitment rule the initial output loss and deflation are much milder, owing to the ability of the central bank to commit to a positive output gap and inflation once the natural real rate has returned to positive.

An alternative way to compare optimal discretionary and commitment policies in the stochastic environment is to juxtapose the dynamic paths that they prescribe for endogenous variables under a chosen evolution for the stochastic natural real rate¹⁶. The experiment is shown in figure 9, which plots a simulated "liquidity trap" under the two regimes. The line with triangles in the bottom panel is the assumed evolution of the natural real rate. It slips down from +3 percent (its deterministic steady-state) to -3 percent over a period of 15 quarters, then remains at -3 percent for 10 quarters, before recovering grad-

¹⁵That the zero interest rate policy should terminate in the same quarter under commitment and under discretion is a coincidence in this experiment. The relative duration of a zero interest rate policy under commitment versus discretion depends on the parameters of the shock process as well as the particular realization of the shock.

¹⁶In the model agents observe only the current state, i.e. the future evolution of the natural real rate is unknown to them in this experiment.

ually (consistent with the assumed AR(1) process) to +3 percent in another 15 quarters.

The first and the second panels of figure 9 show the responses of inflation and the output gap under each of the two regimes. Not surprisingly, under the optimal commitment regime both inflation and the output gap are closer to target than under the optimal discretionary policy. In particular, under optimal discretion inflation is always below the target as it falls to -0.15% shadowing the drop in the natural real rate. Compared to that, under optimal commitment prices are almost fully stabilized, and in fact they even slightly increase while the natural real rate is negative. In turn, under optimal discretion the output gap is initially around +0.4% but then it declines sharply to -1.6% with the decline in the natural real rate. In contrast, under optimal commitment, output is initially at its potential level and the largest negative output gap is only half the size of the one under optimal discretion.

Supporting these paths of inflation and the output gap are corresponding paths for the nominal interest rate. Under discretionary optimization the nominal rate starts at around 2% and declines at an increasing rate until it hits zero two quarters before the natural real rate has turned negative. It is then kept at zero while the natural real rate is negative, and only two quarters after the latter has returned to positive territory does the nominal interest rate start rising again. Nominal rate increases following the liquidity trap mirror the decreases while approaching the trap, so that the tightening is more aggressive in the beginning and then gradually diminishes as the nominal rate approaches its steady-state.

In contrast, the nominal rate under optimal commitment begins closer to 3%, then declines to zero one quarter before the natural real rate turns negative. After that, it is kept at its zero floor until three quarters after the recovery of the natural real rate to positive levels, that is one quarter longer compared to optimal discretionary policy. Interestingly, once the central bank starts increasing the nominal rate, it raises it very quickly - the nominal rate climbs nearly 3 percentage points in just two quarters. This is equivalent to six consecutive monthly increases by 50 basis points each. The reason is that once the central bank has validated the inflationary expectations (which help mitigate deflation

during the liquidity trap), there is no more incentive to keep inflation above target when the natural interest rate has returned back to normal.

Under discretion, the paths of inflation, output and the nominal rate are symmetric with respect to the midpoint of the simulation period because optimal discretionary policy is independent of history. Therefore, inflation and the output gap inherit the dynamics of the natural real rate, the only state variable on which they depend. This is in contrast with the asymmetric paths of the endogenous variables under commitment, reflecting the optimal history dependence of policy under this regime. In particular, the fact that under commitment the central bank can promise higher output gap and inflation in the wake of a liquidity trap is precisely what allows it to engage in less preemptive easing of policy in anticipation of the trap, and at the same time deliver a superior inflation and output gap performance compared to the optimal policy under discretion.

5 Targeting Rules with Zero Floor

In the absence of the zero floor, targeting rules take the form

$$\alpha_\pi E_t \pi_{t+j} + \alpha_x E_t x_{t+k} + \alpha_i E_t i_{t+l} = \tau,$$

where α_π , α_x , α_i are weights assigned to the different objectives, j , k and l are forecasting horizons, and τ is the target. These are sometimes called *flexible* inflation targeting rules to distinguish them from *strict* inflation targeting of the form $E_t \pi_{t+j} = \tau$. When j , k or $l > 0$, the rules are called inflation *forecast* targeting to distinguish them from targeting contemporaneous variables.

As demonstrated by (20) in section 3, in general such rules are not consistent with equilibrium in the presence of the zero floor for they would require negative nominal interest rates at times. A natural way to modify targeting rules so that they comply with the zero floor is to write them as a complementarity condition,

$$i_t (\alpha_\pi E_t \pi_{t+j} + \alpha_x E_t x_{t+k} + \alpha_i E_t i_{t+l} - \tau) = 0 \quad (29)$$

$$i_t \geq 0 \quad (30)$$

which requires that either the target τ is met, or else the nominal interest rate should be bounded below by zero. In this sense, a rule like (29)-(30) can be labelled "flexible inflation targeting with a zero interest rate floor".

In fact, section 3 showed that the optimal policy under discretion takes this form with $\alpha_i = 0$, $\alpha_\pi = \kappa$, $\alpha_x = \lambda$, $j = k = 0$, and $\tau = 0$, namely

$$i_t \left(x_t + \frac{\kappa}{\lambda} \pi_t \right) = 0 \quad (31)$$

$$i_t \geq 0 \quad (32)$$

In the absence of the zero floor it is well known that optimal commitment policy can be formulated as optimal *speed limit* targeting,

$$\Delta x_t + \frac{\kappa}{\lambda} \pi_t = 0,$$

where $\Delta x_t = \Delta y_t - \Delta y_t^{flex}$ is the growth rate of output relative to the growth rate of flexible price output (the *speed limit*). In contrast to discretionary optimization however, the optimal commitment rule with zero floor cannot be written in the form (29)-(30). This is so because with zero floor the optimal target involves a particular type of history dependence as shown by Eggertsson and Woodford (2003)¹⁷. In particular, manipulating the first order conditions of the optimal commitment problem, one can arrive at the following speed limit targeting rule with zero floor:

$$i_t \left[\Delta x_t + \frac{\kappa}{\lambda} \pi_t - \frac{1}{\lambda} \left(\frac{\kappa\sigma + \beta}{\beta} \phi_{1t-1} - \phi_{1t} + \frac{1}{\beta} \Delta \phi_{1t-1} \right) \right] = 0 \quad (33)$$

$$i_t \geq 0. \quad (34)$$

Since $\kappa\sigma$ is small and β is close to one, and for plausible values of ϕ_{1t} consistent with the assumed stochastic process for the natural real rate¹⁸, the above rule is approximately the same as

$$i_t \left[\Delta y_t + \frac{\kappa}{\lambda} \pi_t - \tau_t \right] = 0 \quad (35)$$

$$i_t \geq 0. \quad (36)$$

where $\tau_t \approx \Delta y_t^{flex} + \lambda^{-1} \Delta^2 \phi_{1t}$ is a history-dependent target (speed limit). In normal circumstances when $\phi_{1t} = \phi_{1t-1} = \phi_{1t-2} = 0$, the target is equal to the growth rate of flexible price output, as in the problem without zero bound; however if the economy falls into a liquidity trap, the speed limit is adjusted in

¹⁷These authors derive the optimal commitment policy in the form of a moving *price level* targeting rule. Alternatively, it can be formulated as a moving *speed limit* targeting rule as demonstrated here.

¹⁸ ϕ_{1t} is two orders of magnitude smaller than the natural real rate.

each period by the speed of change of the penalty (the Lagrange multiplier) associated with the non-negativity constraint. The faster the economy is plunging into the trap therefore, the higher is the speed limit target which the central bank promises to achieve contingent on the interest rate's return to positive territory.

While the above rule is optimal in this framework it is perhaps not very practical. Its dependence on the unobservable Lagrange multipliers makes it very hard if not impossible to implement or communicate to the public. Moreover, as pointed out by Eggertsson and Woodford (2003), credibility might suffer if all that the private sector observes is a central bank which persistently undershoots its target yet keeps raising it for the following period. To overcome some of these drawbacks Eggertsson and Woodford (2003) propose a simpler constant price level targeting rule, of the form

$$\begin{aligned} i_t \left[x_t + \frac{\kappa}{\lambda} p_t \right] &= 0 \\ i_t &\geq 0 \end{aligned} \tag{37}$$

where p_t is the log price level.¹⁹

The idea is that committing to a price level target implies that any undershooting of the target resulting from the zero floor is going to be undone in the future by positive inflation. This raises private sector expectations and eases deflationary pressures when the economy is in a liquidity trap. Figure 10 demonstrates the performance of this simpler rule in a simulated liquidity trap. Notice that while the evolution of the nominal rate and the output gap is similar to that under the optimal discretionary rule, the path of inflation is much closer to the target. Since the weight of inflation in the central bank's loss function is much larger than that of the output gap, the fact that inflation is better stabilized accounts for the superior performance of this rule in terms of welfare.

¹⁹Notice that the weight on the price level is optimal within the class of constant price level targeting rules. In particular, it is related to $\kappa/\lambda = \varepsilon$, the degree of monopolistic competition among intermediate goods producers.

6 Simple Instrument Rules with Zero Floor

The practical difficulties with communicating and implementing optimal rules like (33) or even (37) have led many researchers to focus on simple instrument rules of the type proposed by Taylor (1993). These rules have the advantage of postulating a relatively straightforward relationship between the nominal interest rate and a limited set of variables in the economy. While the advantage of these rules lies in their simplicity, at the same time - absent the zero floor - some of them have been shown to perform close enough to the optimal rules in terms of the underlying policy objectives (Gali 2003). Hence, it has been argued that some of the better simple instrument rules may serve as a useful benchmark for policy, while facilitating communication and transparency.

In most of the existing literature, however, simple instrument rules are specified as linear functions of the endogenous variables. This is in general inconsistent with the existence of a zero floor because for large enough negative shocks (e.g. to prices), linear rules would imply a negative value for the nominal interest rate. For instance, a simple instrument rule reacting only to past period's inflation,

$$i_t = r^* + \pi^* + \phi_\pi (\pi_{t-1} - \pi^*) \quad (38)$$

where r^* is the equilibrium real rate, π^* is the target inflation rate, and ϕ_π is an inflation response coefficient, can clearly imply negative values for the nominal rate.

In the context of liquidity trap analysis a natural way to modify simple instrument rules is to truncate them at zero with the $\max(\cdot)$ operator. For example, the truncated counterpart of the above Taylor rule can be written as:

$$i_t = \max [0, r^* + \pi^* + \phi_\pi (\pi_{t-1} - \pi^*)]$$

In what follows I consider several types of truncated instrument rules, including:

1. Truncated Taylor Rules (TTR) that react to past, contemporaneous or expected future values of the output gap and inflation,

$$i_t^{TTR} = \max [0, r^* + \pi^* + \phi_\pi (E_t \pi_{t+j} - \pi^*) + \phi_x (E_t x_{t+j})], \quad j = -1, 0, 1$$

2. TTR rules with partial adjustment or "interest rate smoothing" (TTRS),

$$i_t^{TTRS} = \max \{0, \phi_i i_{t-1} + (1 - \phi_i) i_t^{TTR}\}$$

3. TTR rules that react to the price *level* instead of inflation (TTRP),

$$i_t^{TTRP} = \max [0, r^* + \phi_\pi (p_t - p^*) + \phi_x x_t]$$

where p_t is the log price level and p^* is a constant price level target; and

4. Truncated "first-difference" rules (TFDR) that specify the *change* in the interest rate as a function of the output gap and inflation,

$$i_t^{TFDR} = \max [0, i_{t-1} + \phi_\pi (\pi_t - \pi^*) + \phi_x x_t].$$

The last formulation ensures that if the nominal interest rate ever hits zero it will be held there as long as inflation and the output gap are negative, thus extending the potential duration of a zero interest rate policy relative to a truncated Taylor rule.

I illustrate the performance of each family of rules by simulating a liquidity trap and plotting the implied paths of endogenous variables under each regime. The more rigorous evaluation of welfare is reserved for the following section.

Given the model's simplicity the focus here is not on finding the optimal values of the parameters within each class of rules but rather on evaluating the performance of alternative monetary policy regimes. To do that I use values of the parameters commonly estimated and widely used in simulations in the literature. I make sure that the parameters satisfy a sufficient condition for local uniqueness of equilibrium. Namely, the parameters are required to observe the so-called Taylor principle according to which the nominal interest rate must be adjusted more than one-to-one with changes in the rate of inflation, implying $\phi_\pi > 1$. I further restrict $\phi_x \geq 0$ and $0 \leq \phi_i \leq 0.8$.

Figure 11 plots the dynamic paths of inflation, the output gap and the nominal interest rate which result under regimes TTR and TTRP, conditional on the same path for the natural real rate as before. Both the truncated Taylor rule (TTR, lines with squares) and the truncated rule responding to the price level (TTRP, lines with circles) react contemporaneously with coefficients $\phi_\pi = 1.5$ and $\phi_x = 0.5$, and $\pi^* = 0$.

Several features of these plots are worth noticing. First of all, and not surprisingly, under the truncated Taylor rule, inflation, the output gap, and the nominal rate inherit the behavior of the natural real rate. Perhaps less expected though, while both inflation and especially the output gap deviate further from their targets compared to the optimal rules in figure 9, the nominal interest rate stays always above one percent, even when the natural real rate falls as low as -3 percent! This suggests that - contrary to popular belief - an equilibrium real rate of 3% may provide a sufficient buffer from the zero floor even with a truncated Taylor rule targeting zero inflation.

Secondly, figure 11 demonstrates that in principle the central bank can do even better than TTR by reacting to the price level rather than to the rate of inflation. The reason for this is clear - by committing to react to the price level the central bank promises to undo any past disinflation by higher inflation in the future. As a result when the economy is hit by a negative real rate shock current inflation falls by less because expected future inflation increases.

Figure 12 plots the dynamic paths of endogenous variables under regimes TTRS and TFDR, again with $\phi_\pi = 1.5$, $\phi_x = 0.5$ and $\pi^* = 0$. TTRS (lines with circles) is a partial adjustment version of TTR, with smoothing coefficient $\phi_i = 0.8$. TFDR (line with squares) is a truncated first-difference rule which implies more persistent deviations of the nominal interest rate from its steady-state level.

The figure suggests that interest rate smoothing (TTRS) may improve somewhat on the truncated Taylor rule (TTR), and may do a bit worse than the rule reacting to the price level (TTRP). However, it implies the least instrument volatility. On the other hand, the truncated first-difference rule (TFDR) seems to be doing the best job at stabilization in a liquidity trap among the examined four simple instrument rules. However, under this rule the nominal interest rate deviates most from its steady-state, hitting zero for five quarters. Interestingly, the paths for inflation and the output gap under this rule resemble, at least qualitatively, those under the optimal commitment policy. This suggests that introducing a substantial degree of interest rate inertia may be approximating the optimal history dependence of policy implemented by the optimal commitment rule.

It is important to keep in mind that the above simulations are conditional on one particular path for the natural real rate. It is of course possible that a rule which appears to perform well while the economy is in a liquidity trap, turns out to perform badly "on average". In the following section I undertake the ranking of alternative rules according to an unconditional expected welfare criterion, which takes into account the stochastic nature of the economy, time discounting, as well as the relative cost of inflation vis-a-vis output gap fluctuations.

7 Welfare Ranking of Alternative Rules

A natural criterion for the evaluation of alternative monetary policy regimes is the central bank's loss function. Woodford (2003) shows that under appropriate assumptions the latter can be derived as a second order approximation to the utility of the representative consumer in the underlying sticky price model.²⁰ Rather than normalizing the weight of inflation to one, I normalize the loss function so that utility losses arising from deviations from the flexible price equilibrium can be interpreted as a fraction of steady-state consumption,

$$WL = \frac{\bar{U} - U}{U_c C} = \frac{1}{2} E_0 \sum_{t=0}^{\infty} \beta^t [\varepsilon (1 + \varphi \varepsilon) \zeta^{-1} \pi_t^2 + (\sigma^{-1} + \varphi) x_t^2] = \quad (39)$$

$$= \frac{1}{2} \varepsilon (1 + \varphi \varepsilon) \zeta^{-1} E_0 \sum_{t=0}^{\infty} \beta^t L_t \quad (40)$$

where $\zeta = \theta^{-1} (1 - \theta) (1 - \beta \theta)$; θ is the fraction of firms that keep prices unchanged in each period, φ is the (inverse) elasticity of labor supply, and ε is the elasticity of substitution among differentiated goods. Notice that $(\sigma^{-1} + \varphi) [\varepsilon (1 + \varphi \varepsilon)]^{-1} \zeta = \kappa / \varepsilon = \lambda$ implies the last equality in the above expression, where L_t is the central bank's period loss function, which is being minimized in (3).

I rank alternative rules on the basis of the *unconditional* expected welfare. To compute it, I simulate 2000 paths for the endogenous variables over 1000 quarters and then compute the average loss per period across all simulations.

²⁰ Arguably, Woodford's (2003) approximation to the utility of the representative consumer is accurate to second order only in the vicinity of the steady-state with zero inflation. To the extent that the shock inducing a zero interest rate pushes the economy far away from the steady-state, the approximation error could in principle be large. In that case, the welfare evaluation provided here can be interpreted as a relative ranking of alternative policies based on an *ad hoc* central bank loss criterion. Studying the welfare implication of different rules in the fully non-linear model lies outside the scope of this paper.

For the initial distribution of the state variables I run the simulation for 200 quarters prior to the evaluation of welfare. Table 2 ranks all rules according to their welfare score. It also reports the volatility of inflation, the output gap and the nominal interest rate under each rule, as well as the frequency of hitting the zero floor.

A thing to keep in mind in evaluating the welfare losses is that in the benchmark model with nominal price rigidity as the only distortion and a shock to the natural real rate as the only source of fluctuations, absolute welfare losses are quite small - typically less than one hundredth of a percent of steady-state consumption for any sensible monetary policy regime.²¹ Therefore, the focus here is on evaluating rules on the basis of their welfare performance relative to that under the optimal commitment rule with zero floor.

In particular, in terms of unconditional expected welfare, the optimal discretionary policy (ODP) delivers losses which are nearly eight times larger than the ones achievable under the optimal commitment policy (OCP). Recall that abstracting from the zero floor and in the absence of shocks other than to the natural real rate, the outcome under discretionary optimization is the same as under the optimal commitment rule. Hence, the cost of discretion is substantially understated in analyses which ignore the existence of the zero lower bound on nominal interest rates. Moreover, *conditional* on the economy's fall into a liquidity trap the cost of discretion is even higher.

Interestingly, the frequency of hitting the zero floor is quite high - around one third of the time under both optimal policies. This however depends crucially on the central bank's targeting zero inflation in the baseline model without indexation. If instead the central bank targets a rate of inflation of 2%, the frequency of hitting the zero floor decreases to around 12% of the time (which is still much higher than what is observed, say, in the US).

Table 2 further confirms Eggertsson and Woodford (2003) intuition about the desirable properties of an (optimal) constant price level targeting rule (PLT) - here losses are only 56% greater than those under the optimal commitment rule. It also involves hitting the zero floor around one third of the time.

In contrast, losses under the truncated first-difference rule (TFDR) are 7.5

²¹To be sure, output gaps in a liquidity trap are considerable; however the output gap is attributed negligible weight in the central bank loss function of the benchmark model.

	OCP	PLT	TFDR	ODP	TTRP	TTRS	TTR
$\text{std}(\pi) \times 10^2$	1.04	3.47	4.59	3.85	7.23	9.12	12.9
$\text{std}(x)$	0.45	0.69	1.04	0.71	1.61	1.91	1.90
$\text{std}(i)$	3.21	3.20	1.36	3.27	1.06	0.56	1.14
Loss $\times 10^5$	6.97	10.9	52.3	54.2	62.9	103	147
Loss/OCP	1	1.56	7.50	7.77	9.01	14.8	21.1
$\text{Pr}(i = 0) \%$	32.6	32.0	1.29	36.8	0.24	0.00	0.44

Table 2: Properties of Optimal and Simple Rules with Zero Floor

times as large as those under the optimal commitment rule. Interestingly, however, TFDR narrowly outperforms optimal discretionary policy. Even though the implied volatility of inflation and the output gap is slightly higher under this rule, it does a better job than ODP at keeping inflation and the output gap closer to target on average. This is possibly related to the highly inertial nature of this rule. An additional advantage - albeit one that is not reflected in the benchmark welfare criterion - is that instrument volatility is less than half of that under any of the optimal policies. This is why the zero floor is hit only around 1.3% of the time under this rule.

Similarly, losses under the truncated Taylor rule reacting to the price level (TTRP) are nine times larger than under OCP, but only slightly worse than optimal discretionary policy. Moreover, instrument volatility under this rule is smaller than under TFDR, which is why it involves hitting the zero floor even more rarely - only one quarter every 100 years on average.

Not surprisingly, the rule with the least instrument volatility among the studied simple rules - less than one-fifth of that under OCP - is the truncated Taylor rule with smoothing (TTRS). As a consequence, under this rule the nominal interest rate virtually never hits the zero lower bound. However, welfare losses are almost fifteen times larger than under OCP.

Finally, under the simplest truncated Taylor rule (TTR) without smoothing the zero lower bound is hit only two quarters every 100 years, while welfare losses are around 20 times larger than those under OCP. Nevertheless, even under this simplest rule losses are very small in absolute terms.

The fact that the zero lower bound is hit so rarely under the four simple instrument rules suggests that the zero constraint may not be playing a big role for unconditional expected welfare under these regimes. Indeed, computing their

welfare score without the zero floor (by removing the max operator), reveals that close to 99% of the welfare losses associated with the four simple instrument rules stem from their intrinsic suboptimality rather than from the zero floor per se. Put differently, if one reckons that the stabilization properties of a standard Taylor rule are satisfactory in an environment in which nominal rates can be negative, then adding the zero lower bound to it leaves unconditionally expected welfare virtually unaffected. Nevertheless, as was illustrated in the previous section, *conditional* on a negative evolution of the natural real rate, the losses associated with most of the studied simple instrument rules are substantially higher relative to the optimal policy.

8 Sensitivity Analysis

In this section I analyze the sensitivity of the main findings with respect to the parameters of the shock process, the strength of reaction and the timing of variables in truncated Taylor-type rules, and an extension of the model with endogenous inflation persistence.

8.1 Parameters of the Natural Real Rate Process

8.1.1 Larger variance

Table 3 reports the effects of an increase of the standard deviation of r^n to 4.5% (a 20% increase), while keeping the persistence constant, under three alternative regimes - optimal commitment policy, discretionary optimization and a truncated Taylor rule.

Under OCP, the zero floor is hit around 23% more often, while welfare losses more than double. Figure 13 shows that the higher volatility implies that both the preemptive easing of policy and the commitment to future loosening are somewhat stronger. In turn, figure 14 shows that under ODP preemptive easing is much stronger, the deflation bias bigger, and table 3 shows that welfare losses increase by a factor of 2.6. Finally, under TTR, the zero floor is hit three times more often, while welfare losses are up by 40%.

	OCP	ODP	TTR
$\text{std}(r^n)$	4.46	4.46	4.46
$\text{std}(\pi)$	x 1.52	x 1.50	x 1.20
$\text{std}(x)$	x 1.46	x 1.45	x 1.20
$\text{std}(i)$	x 1.14	x 1.14	x 1.19
Loss	x 2.12	x 2.60	x 1.42
$\text{Pr}(i = 0) \%$	x 1.23	x 1.19	x 3.24

Table 3: Properties of Selected Rules with Higher $\text{std}(r^n)$

	OCP	ODP	TTR
$\rho(r^n)$	0.80	0.80	0.80
$\text{std}(\pi)$	x 2.14	x 2.94	x 2.44
$\text{std}(x)$	x 1.55	x 1.76	x 1.42
$\text{std}(i)$	x 1.02	x 1.04	x 1.52
Loss	x 2.69	x 5.47	x 4.39
$\text{Pr}(i = 0) \%$	x 1.09	x 1.21	x 11.2

Table 4: Properties of Selected Rules with More Persistent \widehat{r}^n

8.1.2 Stronger persistence of shocks

Table 4 and figures 15-17 show the effect of an increase in the persistence of shocks to the natural real rate to 0.8, while keeping the variance of r^n unchanged.

Under OCP (figure 15), preemptive easing is a bit stronger while future monetary loosening is much more prolonged. As a result of the stronger persistence, welfare losses under OCP more than double. Under ODP (figure 16), preemptive easing is much stronger, the deflation bias is substantially larger, and welfare losses increase by a factor of 5.5. And under TTR (figure 17), deviations of inflation and the output gap from target become larger and more persistent, the frequency of hitting the zero floor increases by a factor of 11, and welfare losses more than quadruple.

8.1.3 Lower mean

The effects of a lower steady state of the natural real rate at 2% - keeping the variance and persistence of r^n constant - are illustrated in figures 18 and 19 and summarized in table 5.²²

Under OCP, preemptive easing is a bit stronger while future monetary policy loosening is much more prolonged; losses more than double. Interestingly, under

²²Notice that for simple rules such as TTR, it is the sum $r^* + \pi^*$ which provides a "buffer" against the zero lower bound. Therefore, up to a constant shift in the rate of inflation, varying r^* is equivalent to testing for sensitivity with respect to π^* .

	OCP	ODP	TTR
r^*	2%	2%	2%
std(π)	x 1.74	x 1.79	x 1.00
std(x)	x 1.55	x 1.62	x 1.00
std(i)	x 0.89	x 0.87	x 0.98
Loss	x 2.55	x 4.47	x 1.48
Pr($i = 0$) %	x 1.51	x 1.59	x 9.27

Table 5: Properties of Selected Rules with Lower r^*

ϕ_π	1.01	1.5	2	3	10	100
ϕ_x						
0	x 1.89	x 1.80	x 1.71	x 1.57	x 0.95	x 0.18
0.5	x 1.03	x 1	x 0.97	x 0.90	x 0.59	x 0.18
1	x 0.65	x 0.63	x 0.62	x 0.58	x 0.50	x 0.17

Table 6: Relative Losses under TTRs with Different Response Coefficients

ODP preemptive easing is so strong that the nominal rate is zero more than half of the time. The deflation bias is larger, and losses increase by a factor of 4.5. And under TTR, the zero floor is hit nine times more often while losses increase by 50%.

8.2 Instrument Rule Specification

8.2.1 The strength of response

Table 6 reports the dependence of welfare losses on the size of response coefficients in a truncated Taylor rule. It turns out that losses can be reduced substantially by having the interest rate react more aggressively to inflation and output gap deviations from target. For instance, losses are almost halved with $\phi_\pi = 3$ and $\phi_x = 1$, relative to the benchmark case with $\phi_\pi = 1.5$ and $\phi_x = 0.5$. And they are reduced further to one fifth, with $\phi_\pi = 100$.²³

8.2.2 Forward, contemporaneous or backward-looking reaction

For given response coefficients of a truncated Taylor rule, welfare losses turn out to be smallest under a backward-looking rule and highest under a forward-looking specification. While losses are still small in absolute value, with $\phi_\pi = 1.5$ and $\phi_x = 0.5$ they are up by 25% under the forward-looking rule and are around

²³It is interesting to explore the behavior of truncated Taylor rules as $\phi_\pi \rightarrow \infty$ and $\phi_x \rightarrow \infty$. However, the algorithm used here runs into convergence problems with $\phi_\pi > 100$ and $\phi_x > 3$.

15% lower under the backward-looking rule, relative to the contemporaneous one. The frequency of hitting the zero floor is similarly higher under a forward-looking specification and lower under a backward-looking one. The reason for the dominance of the backward looking rule can be that under it the interest rate tends to be kept lower following periods of deflation, in a way that resembles the optimal history dependence under commitment. On the other hand, under forward-looking rules, the effective response to a given shock to the natural real rate is lower, given the assumed autoregressive nature of the natural real rate.

8.3 Endogenous Inflation Persistence and the Zero Floor

Wolman (1998) among others has argued that stickiness of inflation is crucial in generating costs of deflation associated with the zero floor. To follow up on this hypothesis, I extend the present framework by incorporating endogenous inflation persistence.²⁴ Lagged dependence of inflation may result if firms that do not reoptimize prices index them to past inflation. In this case the (log-linearized) inflation dynamics can be represented with the following modified Phillips curve (Christiano, Eichenbaum and Evans (2001), Woodford (2003)):

$$\hat{\pi}_t = \beta E_t \hat{\pi}_{t+1} + \kappa x_t \quad (41)$$

where $\hat{\pi}_t = \pi_t - \gamma \pi_{t-1}$ is a quasi-difference of inflation and γ measures the degree of price indexation.

An important thing to keep in mind is that in principle the welfare-relevant loss function is endogenous to the structure of the model. Hence strictly speaking one cannot compare welfare in the two environments - with and without inflation persistence - using the same loss criterion. On the other hand, Woodford (2003) shows that in the case of indexation to past inflation, the welfare-relevant loss function takes the same form as (3), except that inflation is replaced by its quasi-difference $\hat{\pi}_t$. This implies that inflation persistence (as measured by γ) does not affect welfare under an optimal targeting rule which takes into account the existing degree of economy-wide indexation. However, since micro evidence on price changes rejects the presence of such indexation, I use the same criteria as in the baseline model to evaluate the performance of rules in an environment

²⁴In this case lagged inflation becomes a state variable and the first-order conditions are adjusted accordingly.

	PLT	PLT	ODP	ODP	TTR	TTR
γ	0.5	0.8	0.5	0.8	0.5	0.8
std(π)	x 1.46	x 2.21	x 1.80	x 1.02	x 1.54	x 2.35
std(x)	x 1.01	x 1.02	x 1.12	x 0.81	x 0.98	x 0.95
std(i)	x 1.00	x 1.00	x 1.01	x 1.02	x 1.06	x 1.10
Loss	x 1.50	x 2.77	x 3.74	x 2.66	x 1.83	x 3.70
Pr($i = 0$) %	x 1.00	x 1.00	x 1.04	x 1.15	x 1.46	x 2.00

Table 7: Performance of Selected Rules with Endogenous Inflation Persistence

with endogenous inflation persistence.

Table 7 reports the properties of selected regimes relative to an environment without endogenous inflation persistence. Under the optimal constant price level targeting rule, an increase in the persistence of inflation to 0.8 results in doubling of inflation volatility and almost tripling of the baseline loss measure. Similarly, inflation volatility more than doubles and welfare losses nearly quadruple under the baseline truncated Taylor rule when the stickiness of inflation increases to 0.8. Interestingly, the properties of optimal discretionary policy are found to depend in a non-linear way on the degree of inflation persistence. Namely, while an increase in inflation persistence to 0.5 raises inflation volatility by 80% and nearly quadruples losses, a further increase of inflation persistence to 0.8 leads to relatively smaller losses. The reason is that high inflation persistence serves as an additional channel of policy, making it possible for the central bank to "steer away" from an approaching liquidity trap by choosing higher current inflation.

9 Conclusions

Recent treatments of the zero lower bound issue have suffered from some important limitations. These include assuming perfect foresight or forcing certainty equivalence, or treating the zero floor as an initial condition rather than an occasionally binding non-negativity constraint. This paper addresses these issues, providing a global solution to a standard stochastic sticky price model with an explicit occasionally binding ZLB on the nominal interest rate. As it turns out, the dynamics, and in some cases the unconditional means, of the nominal rate, inflation and the output gap are strongly affected by uncertainty in the presence of the zero interest rate floor.

In particular, optimal discretionary policy involves a deflationary bias and

interest rates are cut more aggressively when the risk of deflation is high, implying that they are kept lower both before and after a liquidity trap. The extent of such lowering of rates is found to increase in the variance and persistence of shocks to the natural real rate, and to decrease in its unconditional mean. Moreover, the preemptive lowering of rates is even more important under discretionary policy in the presence of endogenous inflation persistence. Compared to that, under optimal commitment policy the need for preemptive lowering of interest rates is limited since the central bank can commit to a period of looser monetary policy conditional on the economy's recovery from a possible liquidity trap.

Imposing the zero lower bound correctly in the stochastic model allows us to evaluate quantitatively the performance of a variety of monetary policy regimes. Thus, commitment to the optimal rule reduces welfare losses to one-tenth of those achievable under discretionary policy. Constant price level targeting delivers losses which are only 60% bigger than under the optimal policy. In contrast, under a truncated Taylor rule losses are 20 times bigger than under the optimal policy. Another interesting finding is that the unconditional welfare losses associated with simple instrument rules are almost unaffected by the zero lower bound *per se* and instead derive from the suboptimal responses to shocks characteristic of simple rules. This is related to the fact that under simple instrument rules the zero lower bound is hit very rarely, while optimal policy involves a zero nominal interest rate around one third of the time.

In fact in an extension of the model with money, optimal policy might be expected to visit the liquidity trap even more often. Hitting the zero lower bound in that case would be good because it eliminates the opportunity cost of holding cash balances. An interesting question to address in that setup would be how the optimal mean of the nominal interest rate is affected by the existence of the zero lower bound. Solving the fully non-linear problem would be another useful extension, which however increases the dimensionality of the computational problem. A limitation of the solution technique employed here is that it is practical only for models with a limited number of states.

Appendix A: Numerical Algorithm

This section illustrates the algorithm used to solve the problem in the case of discretionary optimization. The cases with commitment and with simple rules are solved in a similar way. I apply the routines for rational expectations models included in the COMPECON toolkit of Miranda and Fackler (2001). These solve for the optimal response x as a function of the state s , when equilibrium responses are governed by an arbitrage-complementarity condition of the form

$$f[s_t, x_t, E_t h(s_{t+1}, x_{t+1})] = \phi_t \quad (42)$$

where s follows the state transition function

$$s_{t+1} = g(s_t, x_t, \varepsilon_{t+1}) \quad (43)$$

and x_t and ϕ_t satisfy the complementarity conditions

$$a(s_t) \leq x_t \leq b(s_t), \quad x_{jt} > a_j(s_t) \Rightarrow \phi_{jt} \leq 0, \quad x_{jt} < b_j(s_t) \Rightarrow \phi_{jt} \geq 0, \quad (44)$$

where ϕ_t is a vector whose j^{th} element, ϕ_{jt} , measures the marginal loss from activity j . In equilibrium, ϕ_{jt} must be non-positive (nonnegative) if x_{jt} is greater (less) than its lower (upper) bound, otherwise agents can gain by reducing (increasing) activity j . If x_{jt} is neither at its upper nor at its lower bound, ϕ_{jt} must be zero to preclude arbitrage possibilities.

In the context of the monetary policy model under discretion, f_{jt} is the derivative of the complementarity condition (15) with respect to the nominal interest rate, and ϕ_{jt} is the Lagrange multiplier ϕ_{1t} associated to the non-negativity constraint on the nominal interest rate:

$$-(\lambda x_t + \kappa \pi_t) = \phi_{1t} \quad (45)$$

Since there is no upper bound on the interest rate, $b(s_t) = +\infty$, and $x_t < b(s_t)$ always holds so that ϕ_{1t} is non-negative. This, together with $a(s_t) = 0$, implies that in the case of discretionary optimization, the above complementarity problem reduces to

$$i_t \geq 0, \quad \phi_{1t} \geq 0, \quad i_t > 0 \Rightarrow \phi_{1t} = 0, \quad (46)$$

which can be written also as

$$i_t \geq 0, \quad \phi_{1t} \geq 0, \quad i_t \phi_{1t} = 0 \quad (47)$$

An approximate solution is obtained with the method of collocation, which in this case consists of approximating the expectation functions $E_t x_{t+1}$ and $E_t \pi_{t+1}$ by linear combinations of known basis functions, θ_j , whose coefficients, c_j , are determined by requiring the approximants to satisfy the equilibrium equations exactly at n collocation nodes:

$$h[s, x(s)] \approx \sum_{j=1}^n c_j \theta_j(s) \quad (48)$$

The coefficients are determined by the following algorithm. For a given value of the coefficient vector c , the equilibrium responses x_i are computed at the n collocation nodes s_i by solving the complementarity problem (which is transformed into a standard root-finding problem). Then, given the equilibrium responses x_i at the collocation nodes s_i , the coefficient vector c is updated solving the n -dimensional linear system

$$\sum_{j=1}^n c_j \theta_j(s_i) = h(s_i, x_i) \quad (49)$$

This iterative procedure is repeated until the distance between successive values of c becomes sufficiently small (Miranda and Fackler 2001).

To approximate the expectation functions, $E_t x_{t+1}$ and $E_t \pi_{t+1}$, one needs to discretize the shock to r^n . Here the normal shock to the natural rate of interest is discretized using a K -node Gaussian quadrature scheme:

$$Eh[s, x(s)] \approx \sum_{k=1}^K \sum_{j=1}^n \omega_k c_j \theta_j [g(s_i, x, \varepsilon_k)] \quad (50)$$

where ε_k and ω_k are Gaussian quadrature nodes and weights chosen so that the discrete distribution approximates the continuous univariate normal distribution $N(0, \sigma_\varepsilon^2)$.

In the discretionary optimization problem I use linear splines on a uniform grid of 2000 points for values of the natural rate of interest between -10% and $+10\%$, so that each point on the grid corresponds to 1 basis point. In this problem, linear splines work better than Chebychev polynomials or cubic splines because the response function has a kink in the place where the zero bound becomes binding.

There are two types of approximation errors. On the one hand are the deviations from the equilibrium first-order conditions. In this case the "arbitrage benefits" are negligible for each of the three equilibrium equations (13), (14), and (15). Specifically, they are of the order of 10^{-16} for the IS and the Phillips curves, and 10^{-19} for the complementarity condition. On the other hand are the residuals from the approximation of the expectation functions. Except for a couple of residuals of the order of 10^{-4} , concentrated mostly in the place where the zero constraint becomes binding, the rest of the residuals are of the order of 10^{-8} . Given the measurement units, a residual of 10^{-4} corresponds to 0.001% of annual inflation or output gap error, which, provided that the residuals of this size are just a few, is a satisfactory level of accuracy for the problem at hand. In principle, the expectations residuals can be reduced further by concentrating more evaluation points in the neighborhood of the kink, and by using more quadrature nodes, albeit at the cost of computing time.

In the case of commitment, the problem is first cast in the form specified by (42), (43), (44) by substituting out ϕ_{2t} from (24) into (25) and the resulting expression for ϕ_{1t} into (26). In addition, the state transition vector is augmented by the two "costate" variables ϕ_{1t} and ϕ_{2t} , which are cast in recursive form using (24) and (25):

$$\phi_{1t} = \phi_{1t-1}(1 + \kappa\sigma)/\beta + \kappa\phi_{2t-1} - \lambda x_t - \kappa\pi_t \quad (51)$$

$$\phi_{2t} = \phi_{1t-1}\sigma/\beta + \phi_{2t-1} - \pi_t \quad (52)$$

With simple rules, the system is in the required form, and the only necessary adjustments are to the state transition vector in those cases when past endogenous variables enter the rule.
