Size of the Junctional Nests can Predict *in situ* Melanoma Behavior

KEY-WORDS – Carcinoma *in situ*; Neoplasm Metastasis; Melanoma; Skin Neoplasms; Neoplasm Staging; Prognosis; Recurrence.

In recent years, the diagnosis of *in situ* melanoma (MIS), considered of excellent prognosis, has increased.¹ Some authors have reported isolated cases of MIS presenting recurrence, metastasis and death.^{2,3} However, so far, no study has identified the causes of this unexpected behavior.

Cook *et al* (2002), studying thin metastasizing melanomas, suggested that those lesions with follicular invasion and expansive junctional nodules should be considered vertical growth phase melanomas. They also described a case without these or others features of high-risk lesion, that still metastasized.⁴

Kutzner *et al* (2012) reported a new variant of superficial spreading melanoma based on histological and genetic evidence consisting exclusively or predominantly by large, irregular, atypical melanocytic junctional nests. The authors emphasized that the 11 cases were initially diagnosed as MIS and, after several serial sections, atypical melanocytes infiltrating the dermis were identified in five cases.⁵

We identified 445 cases of primary MIS in two hospitals of Rio de Janeiro state, between 1998 and 2010, reviewing the slides to classify them as "large nests *in situ* melanomas" and other histopathological aspects. All cases were treated surgically with, at least, 5 mm free margins. The results were correlated to the outcome. For those "large nests *in situ* melanomas", we used Aperio ImageScope system to measure the largest nest diameter.

Eighteen cases (4.04%) presented almost exclusively by large irregular nests, matching the description of the variant reported by Kutzner *et al*.⁵ Among these, we identified a patient who developed recurrence 61 months after the diagnosis. Five patients between the other 427 cases presented recurrence and three developed regional metastasis.

The correlation between this variant and the occurrence of relapse or metastasis showed no statistical significance by Fisher exact test ($\alpha=0.05$, $p=0.313$). However, considering the size of the junctional nests, the largest nests were found in the only case of recurrence among the 18 cases with large nests, except one of the group with no recurrence (Fig. 1). This difference was relevant on Student t test ($t=-7.270$; $f.g.=16$; $p<0.0001$). Although we had a case in the group without recurrence with nests of a similar diameter, the presence of other 16 cases with much smaller nests in the same group allowed statistical support for this finding.

Among those eighteen cases, twelve had also aneuploidy and three showed late regression, but none of these variants (aneuploidy and regression) had statistically significant correlation with recurrence and/or metastasis.

Our findings agree with the concept of expansive junctional nodules as high-risk feature previously reported by Cook *et al* in 2003⁴ and Kutzner *et al* in 2012.⁵

Carta ao Editor

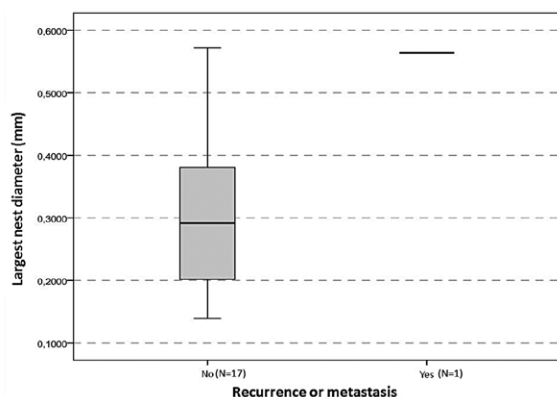

Figura 1 - Largest nest diameter of 18 MIS showing almost exclusive large nests and development of recurrence or metastasis ($p < 0.0001$).

We have found one case of MIS with local recurrence, in which the main histopathological feature was the predominance of expansive and large junctional nests. The papillary dermis showed a light fibrosis but, since there was no decrease of the number of melanoma cells, these alterations have not filled the criteria for regression. In search for melanoma cells in the dermis serial sections were performed but those cells were not found, confirming the initial diagnosis.

Although based in only one case, we believe that the size of the nests could explain this unexpected behavior, since its largest nest (0.57mm – Fig. 2) was larger than the mean largest nest size (0.3mm) of the group with no recurrence.

To our knowledge, this is the first time that expansive nests have been measured and compared to outcome. Since there are few studies on the subject in the literature, this finding contributes to alert pathologists and clinicians about the importance of recognizing this variant.

Figura 2 - Primary MIS with posterior recurrence: A) constituted almost exclusively by large nests; B) the largest nest width measuring 0.57mm (B) (H&E).

Even though these rare cases of MIS with poor prognosis remains unexplained, we believe that the presence and size of expansive junctional nests must not be overlooked when the diagnosis of MIS is suspected. One limitation of our study is the small number of MIS with bad outcome and also with large nests. Further studies with larger number of cases may contribute to confirm this found and possibly establish a cut off size for a large nest.
