21

## 22 Abstract

23 This paper provides an overview of the existing health monitoring and assessment methods for  
24 masonry arch bridges. In addition, a novel “integrated” holistic non-destructive approach for  
25 structural monitoring of bridges using ground-based non-destructive testing (NDT) and the satellite  
26 remote sensing techniques is presented. The first part of the paper reports a review of masonry arch  
27 bridges and the main issues in terms of structural behaviour and functionality as well as the main  
28 assessment methods to identify structural integrity-related issues. A new surveying methodology is  
29 proposed based on the integration of multi-source, multi-scale and multi-temporal information  
30 collected using the Ground Penetrating Radar (GPR – 200, 600 and 2000 MHz central frequency  
31 antennas) and the Interferometric Synthetic Aperture Radar (InSAR – C-band SAR sensors)  
32 techniques. A case study (the “Old Bridge” at Aylesford, Kent, UK – a 13<sup>th</sup> century bridge) is  
33 presented demonstrating the effectiveness of the proposed method in the assessment of masonry  
34 arch bridges. GPR has proven essential at providing structural detailing in terms of subsurface  
35 geometry of the superstructure as well as the exact positioning of the structural ties. InSAR has  
36 identified measures of structural displacements caused by the seasonal variation of the water level  
37 in the river and the river bed soil expansions. The above process forms the basis for the “integrated”  
38 holistic structural health monitoring approach proposed by this paper.

41 destructive testing (NDT) assessment, ground penetrating radar (GPR); Interferometric Synthetic  
42 Aperture Radar (InSAR); Remote Sensing monitoring

43

## 44 1 Introduction

45 Arch bridge structures are very common and historical types of asset vital to the economy, mobility  
46 and development of communities. The oldest example of an arch bridge is the Mycenaean bridge of  
47 Kazarma, dating back to 1300 BC and still partially operational. From that time onwards, stones and

48 bricks have been used as primary construction materials for arch bridges up to the steel revolution  
49 period, when iron became the more dominant structural material.

50 Masonry arch bridges are very solid and compact forms of structures, suitable to resist floods and  
51 time degradation. In this regard, a comprehensive research by [1] counted 931 Roman masonry arch  
52 bridges in 26 different European countries, with many of them still standing and used to carry  
53 vehicles.

54 No doubt an effective assessment and routine monitoring of bridge structures are nowadays crucial  
55 for maintenance, regardless of their historical value and mobility function. As an example, more  
56 recent reinforced concrete structures require routine, precise and reliable monitoring due to  
57 increasing traffic volumes and operational speeds of transports. On the other hand, historical  
58 bridges, and mostly arch bridges, represent a cultural heritage asset where sampling or digging parts  
59 of the structures is often constrained for structural investigations.

60 Non-destructive testing (NDT) methods are being increasingly used to meet the above requirements  
61 for assessment and monitoring of modern and historical bridges during their service-life period. In  
62 this regard, efforts have been dedicated to the monitoring of dynamic responses of bridges,  
63 including deflections and displacements induced by thermal expansions and vibrations. Health of  
64 bridges can be assessed using various monitoring methods and sensors, such as ground penetrating  
65 radar (GPR), GPS, accelerometers and levelling [2-5]. Recent applications of the ground-based  
66 microwave interferometry have been also reported in the literature for both static and dynamic  
67 monitoring of bridges [6-7]. However, constraints given by installation costs of in-contact sensors  
68 and time duration of periodical field surveys have not allowed collection of time-series monitoring  
69 for many bridges in the long term.

70 Scour and differential settlements of bridge decks are also elements of major concerns for their  
71 structural integrity [8-9]. Scour is defined as the excavation and removal of material from the bed  
72 and banks of streams as a result of the erosive action of flowing water [10]. This action in the vicinity  
73 of bridge piers can cause removal of ground material at the foundation level, increasing the risk of  
74 structural collapse. This occurrence can be emphasised by changes in water flow rates during  
75 flooding that can affect the structural stability of bridge piers. According to Prendergast and Gavin  
76 [11], scour can be monitored by a range of instrumentation including single-use devices, pulse or  
77 radar devices, buried or driven rod systems, sound-wave devices, fiber-Bragg grating devices and  
78 electrical conductivity equipment. However, information available from the literature on this type  
79 of failure have proven that collapse for many of these structures (more than 600) can verify in a  
80 relatively short period of a few decades [12,13]. These figures also confirm that stand-alone and  
81 integrated use of ground-based techniques, including NDT methods, does not represent the most  
82 comprehensive solution to this specific structural issue.

83 Within this context, use of satellite data-based synthetic aperture radar (SAR) interferometry  
84 (InSAR) has proven to be effective at measuring displacements of infrastructures and natural terrain.  
85 A main advantage of this technique is that millimetre-scale changes of multiple discrete points can  
86 be monitored remotely in time and over large spatial areas [14-15]. Early-stage use of InSAR was in  
87 the analyses of large-scale deformations caused by earthquakes or volcanoes with several spatial  
88 resolution constraints [16]. This drawback was addressed by the use of recently-developed C-band  
89 SAR sensors, with a centimetre accuracy and a higher availability of images with a wider spatial

90 coverage, as well as the X-band SAR sensors, working in the X-band range. X-band SAR sensors are  
91 capable to collect images with a higher spatial resolution providing measurements with a millimetre  
92 accuracy. In addition, the considerable amount of orbiting SAR sensors have allowed acquisition of  
93 satellite images with a very short temporal baseline [17]. These improvements have recently  
94 contributed to a tremendous increase of applications to linear infrastructures [18,19] and bridges  
95 [20-24]. On the other hand, it worth emphasising that stand-alone use of the InSAR technique cannot  
96 be accounted as a unique solution for providing comprehensive structural health monitoring, as no  
97 information can be collected on the source of damage [18].

98 Within this framework, it is the opinion of the Authors that a more comprehensive structural health  
99 monitoring strategy can be pursued by the integration of multi-source, multi-scale and multi-  
100 temporal information collected using ground-based non-destructive testing (NDT) methods and  
101 satellite remote sensing. This is more emphasised in the case of historical bridges, where use of  
102 traditional destructive techniques is often constrained for conservation purposes and time of  
103 intervention is crucial to avoid irreversible and inestimable structural failure.

104

## 105 **2 Aim and Objectives**

106 The main aim of this paper is to investigate the potential of integrating information from satellite  
107 remote sensing and ground-based non-destructive methods for a comprehensive monitoring of  
108 historical masonry arch bridges subject to seasonal changing patterns (variations of the water flow  
109 level of rivers crossed). To achieve this aim, the following objectives are identified:

- 110 • to provide a good overview on main structural issues in masonry arch bridges in order to  
111 identify advantages and limitations of existing assessment methods (i.e., conventional and  
112 non-destructive);
- 113 • to prove the viability of using GPR as a rapid and effective NDT technique in providing  
114 structural detailing of the bridge deck. To this purpose, applicability of high-frequency and  
115 low-frequency antenna systems was investigated to achieve structural information such as  
116 thickness and geometry of bridge components and the exact positioning of the structural ties  
117 at different depths and resolutions;
- 118 • to assess amount of displacements of the bridge structure linked with seasonal variations of  
119 the water flow level of the river crossed by the bridge;
- 120 • to test the feasibility of the Permanent Scatterers Intereferometry (PSI) technique in bridge  
121 monitoring applied to a medium-range ground-resolution datasets (i.e., C-band), paving the  
122 way to future implementations using higher resolution sensors (e.g., X-band).

123

## 124 **3 Masonry Bridges**

125 Masonry is defined as a structural material made by the assemblage of natural (stones) or artificial  
126 (bricks) elements, with or without mortar, suitable for the realisation of the bearing elements of a  
127 structure [25]. In view of a similar morphology, brick bridges should be analysed together with stone  
128 bridges as a part of them [26]. The typical structure of a masonry arch bridge is shown in Figure 1.

**Fig. 1** Main elements of a masonry arch bridge (UIC Code 778-3R) [27].

129

130

131 Stone arch bridges rely on several advantages compared to concrete bridges. A larger proportion of  
 132 locally available resources are used in stone bridges as they can be built with local labour and stones.  
 133 On the contrary, raw materials and machines have to be moved on site for the construction of  
 134 concrete bridges and specialised technical expertise are required. Compared to expensive  
 135 aggregates, local stones are strong and affordable materials often available in the vicinity of the  
 136 construction site. In regard to the construction costs, concrete bridges require more investments and  
 137 use of specialist equipment that do not compensate for the cost of additional man-days usually  
 138 required for the construction of stone arch bridges. Risk of floods washing the stone arch culverts  
 139 away is reduced by their own weight. In addition, the interconnecting arch and the heavy weight  
 140 prevent typical technical challenges related to concrete bridge abutments (i.e., the tilting and sliding  
 141 exerted by the backfilled soil mass).

142 Nevertheless, concrete bridges appear as a more suitable technology option in case of higher labour  
 143 costs and larger spans are involved. In this regard, the maximum single span in stone bridges is  
 144 usually less than 20 meters. In case of larger single spans, reinforced concrete is a better option as  
 145 the volume of stone masonry becomes heavier. Capacity building of local artisans and contractors  
 146 is another challenge to consider, as lack of expertise may be costly to replace. To this effect,  
 147 industrialised countries have opted to use pre-stressed concrete rather than investing money on  
 148 expert masons and casual labourers. In this framework, the stone arch technique for construction of  
 149 bridges is nowadays less employed or it has been abandoned [26].

150

### 151 3.1 Structural issues in masonry arch bridges

152 Main failures in historical arch bridges relate to the development of a mechanism chain with  
 153 formation of hinges, by sliding, or by a combination of these. Compression strength in models

154 accounting for these failures is not relevant. However, the masonry compression strength must be  
155 considered in two other instances, i.e., i) looking at the developing hinges where maximum  
156 compression forces are reached, and ii) considering arch bridges under maximum equal load.  
157 Maximum equal load can be reached by widening the road lane and therefore increasing the dead  
158 load of the bridge.

159 Structural defects can be normally related to four main factors, i.e., (i) construction, (ii) long-term  
160 loading, (iii) transient loading and (iv) the environment [25]. A combination of defects deriving from  
161 the contribution of all the above factors is usually verified in existing masonry bridges (Figure 2). It  
162 is also worth noting that modern traffic loads, heavier than in the past, could affect seriously the  
163 structural integrity of older bridges. On the contrary, well-maintained masonry arches not subject  
164 to heavy loads are probably among the most durable constructions.

165

166 **Fig 2** Most frequent damage types and location in arch bridges. A) cracks in the abutment joint or pier with  
167 arch; B) cracks in spandrel beam and parapet wall; C) cracks in corners; D) loosening of voussoirs; E)  
168 detachment at the arch key; F) longitudinal cracks; G) disconnection of the arch ring; H) opening of the  
169 spandrel beam; I) opening at the abutment wall; J) crosswise cracking; K) cracking at the arch key; L)  
170 deposits.

171

#### 172 4 Assessment Methods for Masonry Arch Bridges

173 Several methods with different levels of complexity have been developed for prediction of in-service  
174 behaviour and load-carrying capacity of masonry arch bridges. These range from expeditious  
175 procedures based on empirical rules, to limit-state-analysis-based approaches [28], up to the most  
176 advanced non-linear computational formulations (e.g., finite-element and discrete-element  
177 methods).

178 According to Lourenço [29], selection of the most appropriate method depends on several factors. It  
179 is worth to mention, amongst others: (i) the structure under analysis; (ii) the desired level of  
180 accuracy; (iii) knowledge of material properties and experimental data available; (iv) financial  
181 resources; (v) time requirements and experience of the analyst. As a general recommendation, the  
182 best approach must guarantee a trade-off between amount of input information, overall fitting to  
183 different scenarios and viability of the outputs.

184 Three main classes of methodologies for structural analysis of masonry arch bridges and assessment  
 185 of load-carrying capacity can be identified [30]: (i) semi-empirical models, (ii) equilibrium-based  
 186 models and (iii) numerical models. To this effect, it worth mentioning that use of non-linear  
 187 numerical models (e.g., finite-element methods) is capable to provide a realistic simulation of the  
 188 structural behaviour of masonry arch bridges through advanced computational tools via non-linear  
 189 models. Within this framework, the provision of significant input data is a major task in numerical  
 190 modelling, regardless of the complexity of the numerical model. Therefore, the continuous  
 191 monitoring of historical masonry structures and collection of reliable information by advanced  
 192 monitoring techniques is crucial to ensure an effective structural assessment.

193

#### 194 4.1 Inspection and monitoring techniques for the investigation of masonry arch bridges

##### 195 4.1.1 Destructive testing methods

196 As well as the information on the geometric parameters of a bridge, numerical models require data  
 197 about material properties. Information are often collected from test specimens, taken from the  
 198 original structure [31]. To this purpose, destructive tests can be applied to samples and natural-scale  
 199 structural elements, leading to permanent damage. Their use is more constrained or not possible in  
 200 case of historical bridges. Semi-destructive tests are also performed with a lower intrusiveness in the  
 201 structure or material under investigation. Nevertheless, these methods cause a local loss of  
 202 functional properties and require repairing of the structure at the end of the testing process [32].  
 203 Main destructive testing methods used for the monitoring of masonry bridges are summarised in  
 204 Tab. 1.

205

206 **Table 1** Main destructive testing methods used for the monitoring of masonry bridges.

Method	Description	References
Core Drilling	Scope of this method is to extract material and provide geometrical information on the internal structure of the bridge. Cores are then visually analysed in order to collect information about layer thickness, and hollow sections, amongst others.	Proske and val Gelder [31] Berndt and Schone [33]
Flat-Jack Testing	Release of a stress in a small area of a structure by a plane cut perpendicular to its surface. The pressure is increased until the point of non-linearity is identified in the load-strain curve. A wide range of information can be estimated for structural assessment of old masonry buildings, including the masonry stress state, compression strength and the elastic modulus.	Vicente et al. [34] Bindia and Tiraboschi [35]

207

##### 208 4.1.2 Non-destructive testing methods

209 Non-destructive testing is a multi-disciplinary scientific area concerning the evaluation, inspection,  
 210 testing and characterisation of materials and structures through methods that do not significantly  
 211 alter the original properties and arrangement of materials or structures [36]. There exist several types  
 212 of NDT techniques (Tab. 2) relying on different theoretical principles, and producing different sets  
 213 of outputs/information in regard to the physical properties of a structure [37]. NDT methods allow  
 214 for a non-intrusive and detailed survey of civil engineering infrastructures. To this effect, they have

215 become popular in the health monitoring of infrastructure heritage assets, where non-intrusiveness  
 216 to the structure is a key requirement [38].

217

218 **Table 2** Main non-destructive testing methods used for the monitoring of masonry bridges.

Method	Description	References
Sonic transmission	Direct transmission involves the passing of a compressional wave through the thickness of the wall (or the structure) under investigation. The velocity magnitudes may be plotted in a contour map format. This allows a fast evaluation of the relative conditions of the masonry walls or an evaluation of the internal fabric of a structure, such as a masonry arch bridge.	AA.VV. [39] McCann and Forde [37]
Sonic tomography	This technique is an improvement of the sonic transmission test method as tests are performed along non-perpendicular paths to the wall surface as well as in a direct mode.	Colla [36] Williamson [40]
Seismic reflection	The initiation and reception of the sonic wave are both performed on the same face of the masonry such as in the case of the indirect transmission mode. The stress wave recorded is the direct stress wave reflected from any internal flaw or the rear face of the structure investigated.	McCann and Forde [37]
Impact-echo system	A stress pulse is introduced into a test object by mechanical impact on the surface. The pulse propagates into the object along spherical wave-fronts as compression or shear waves, or P- and S-waves. Arrival of reflected waves (or echoes) at the surface where impact was generated produces displacements that are measured by a receiving transducer and recorded by a data acquisition system.	AA. VV. [39]
Electrical impedance tomography	The method allows a 3D imaging of the dampness distribution in a brick wall by measuring its electrical properties.	Biernat et al. [41] Hola et al. [42]
Electrical resistivity measurements	The distribution of conductivity is determined through repeated measurements (for different configurations of the excitation probes) of potentials on the surface of the masonry.	Fauchard et al. [43] Bungey et al. [44]
Ground penetrating radar	The energy reflected by the dielectric discontinuities within the subsurface is recorded by means of a receiving antenna and it is subsequently processed and displayed through a display unit.	Benedetto and Pajewski, [45] Daniels, [46]
Infrared thermography	This technique is based on a process in which heat at any temperature is converted into a thermal image using specialised scanning cameras.	Solla et al. [47] Orban et al. [48]
Radiography	Very short wavelength electromagnetic radiations penetrate through solid media, being partially absorbed by the medium. The radiation passing through the material can be detected, recorded and monitored by electronic sensing equipment.	McCann and Forde [37]
Laser scanner	Laser scanner, also referred to as Light Detection And Ranging (LiDAR), is used for 3D data acquisition of both topographic and close-range objects. The equipment allows an automated dense sampling of the object surface within a short time range.	Lubowiecka et al. [49] Riveiro et al. [50]
Airborne DinSAR	The airborne interferometric SAR system can detect ground displacements and motions due to natural hazard-events (i.e. earthquakes, landslides) providing high operational flexibility. Flexibility on diversifying directions of the flight-trajectory during the acquisition stage can overcome some of the limitations of satellite acquisitions, e.g. the detection of deformations along the North-South direction.	Perna et al. [51] Perna et al. [52] Perna et al. [53]
Unmanned Aerial vehicles	Unmanned Aerial Vehicles (UAVs) are flexible observation platforms suitable to cover inaccessible areas on demand. Research is focussing on the development of miniaturised sensing technologies complying with UAV payload constraints and capable of providing high-resolution images.	Rosen et al. [54]
Interferometric SAR	SAR system is an active satellite system that provides electromagnetic images of the Earth's surface by emitting electromagnetic pulses at frequencies ranging between 0.23 GHz and 40 GHz. The basic principle of InSAR relies on the phase comparison between multiple SAR images of the same investigated area collected at different time periods with similar looking angles from space.	Ferretti et al. [55] Colesanti et al. [56]

219

220 For the purpose of this paper, GPR and InSAR techniques are described in more details in the  
221 following subsections. For a deeper analysis of advantages and limitations of these techniques,  
222 readers are suggested to refer to Bianchini Ciampoli et al. [18].

223

#### 224 4.1.2.1 *Ground Penetrating Radar*

225 The basic principles of GPR are well-established [57]. A transmitting antenna emits an  
226 electromagnetic (EM) pulse into the ground which is partly reflected when a target with different  
227 dielectric properties is encountered, and partly transmitted to deeper layers. The energy reflected  
228 from discontinuities in impedance is received by means of a receiving antenna and is subsequently  
229 processed and displayed by means of a display unit. If the transmitting and receiving antennas are  
230 moved at a constant speed along a linear path, a cross-sectional image of the material can be  
231 generated. Alternatively, if scans are collected in a regular grid pattern, a three-dimensional image  
232 of the target can be produced.

233 After the data acquisition stage, GPR datasets can be edited and several processing techniques can  
234 be applied in order to produce a clearer image for data interpretation and evaluation purposes.  
235 Preliminary processing steps are the application of temporal and spatial filtering and the use of time  
236 gain adjustments of signals recorded [58,59].

237 GPR has been successfully used to monitor bridge decks within the context of identification,  
238 assessment and health monitoring of rebars, rebar cover length, depth of cracks, settlements, ingress  
239 of moisture and delamination, layers of materials, cavities, location of rebars and other structural  
240 features (beams and columns) as well as bridge abutments (leakage, cracks and settlements) [49,60-  
241 65]. GPR is one of the most recommended NDT methods for use in masonry arch bridges in view of  
242 its rapidity in data collection, high accuracy and penetration depths as well as the provision of an  
243 overall qualitative internal image [37]. GPR has also proven potential at providing information about  
244 the hidden geometry [66], bridge foundation detailing [67], ring stone conditions [68], moisture  
245 content, fills conditions and asphalt cracking [62]. Usually, high-frequency antennas above 1 GHz  
246 are used to achieve the resolution for detection of shallow targets within the structure [69]. In some  
247 instances, such as the evaluation of the internal structure of a masonry arch bridge or a harbour dock  
248 wall, a higher penetration of the electromagnetic energy is required and lower frequency antennas  
249 in the range 100÷500 MHz must be used.

250 Lubowiecka et al. [49] used the GPR technique for the estimation of homogeneity and heterogeneity  
251 features in a bridge structure. In order to model the structural behaviour of the bridge, a finite  
252 element-based structural model was defined by integrating GPR and laser scanner data. In this  
253 regard, Saarenketo [70] argued that, due to the complexity of information involved in a bridge  
254 survey, stand-alone use of GPR cannot provide a comprehensive framework for structural health  
255 monitoring purposes. However, it is recommended for initial mapping and subsurface target  
256 location. GPR was also coupled with laser scanner by Solla et al. [66] to assess historical masonry  
257 arch bridges. The technique has proven good potential in providing valuable information about  
258 hidden geometric features of the bridge, and the integration with laser scanner data allowed to create  
259 finite-difference time-domain (FDTD) models of the bridge. Solla et al. [66] used GPR to survey

260 several stone arch bridges located in Spain. Results revealed previously unknown geometrical data  
261 and hidden internal characteristics of the bridges, including the presence of internal voids, ancient  
262 arches and restorations. Use of numerical modelling was done in order to identify the effects of  
263 noise-related factors to the GPR signal and extract more viable information from the GPR datasets.  
264 Numerical modelling was also used by Diamanti et al. [68] to simulate GPR testing scenarios and  
265 investigate ring separation effects in brick masonry arch bridges. Outcomes have proven a good  
266 correlation between numerical and actual GPR experiments. Conde et al. [71] presented a  
267 multidisciplinary approach for the structural assessment of masonry arch bridges, carrying out a  
268 comprehensive field survey fully based on the use of NDT techniques. To this purpose, laser  
269 scanning, GPR, sonic tests and ambient vibration testing were integrated. Results demonstrated a  
270 significant impact of the tensile nonlinear properties of masonry and the importance of fill materials  
271 on the structural integrity of arch bridges. Moreover, advantages of using a three-dimensional  
272 modelling approach were also pointed out, as critical transverse effects in the response of the  
273 structure were successfully identified. Similarly, Bergamo et al. [72] combined GPR data with  
274 information collected from destructive and non-destructive testing methods for the evaluation of  
275 historical masonry arch bridges. The study investigated advantages of each technique in order to  
276 identify an optimised in-situ testing procedure. The authors found the integration between GPR and  
277 the thermographic analysis as effective for detection of moisture, discontinuities and non-  
278 homogeneities in bridges.

279

#### 280 4.1.2.2 *InSAR for bridge monitoring*

281 InSAR is a well-acknowledged remote sensing technique which has been applied since 1980s to  
282 evaluate the deformation of the Earth's surface [16], for geophysical monitoring of natural hazards,  
283 e.g., earthquakes [73], ice motion [74], volcanism [75], landslides [76], and in subsidence and  
284 structural stability assessments. The SAR system is an active satellite system that provides  
285 electromagnetic images of the Earth's surface by emitting electromagnetic pulses at frequencies  
286 ranging between 0.23 GHz and 40 GHz. The received component of the spread field caused by the  
287 scattering phenomena on the ground is therefore analysed in order to provide the final output.

288 A unique advantage of SAR satellites is the availability of new datasets of SAR images collected at  
289 every satellite orbit around the Earth. The time elapsed between two consecutive observations of the  
290 same area, known as the revisiting period, depends on the satellite's orbit and can reach up to a one  
291 day-period.

292 The basic principle of InSAR relies upon the phase comparison between multiple SAR images of the  
293 same investigated area collected at different time frames with similar looking angles from the space  
294 [77-80]. The phase difference is proportional to the surface deformation occurring at the time interval  
295 between the acquisition of two consecutive images. However, it is also affected by the contribution  
296 of topographic and atmospheric factors. Differential InSAR (DInSAR) refers to the interferometric  
297 analysis of a pair of SAR images to identify and detect displacements on the Earth surface by  
298 removing the topographic contribution through a Digital Elevation Model (DEM). Figure 3 shows  
299 the relationship between the ground displacement measured along the satellite Line of Sight (LOS)  
300 and the signal phase shift.

Fig. 3 Main working principles of the DInSAR technique.

301

302

303

304 Following an extensive application of the DInSAR technology during the 90s, the atmospheric  
 305 contribution to the signal phase was identified as significant and affecting the quality of data  
 306 collected. In addition, the DInSAR allows for the detection of the phase difference only between two  
 307 SAR images. These limitations were overcome by the development of Permanent Scatterers  
 308 Interferometry (PSI) techniques, such as the PSInSAR [14] and the Small Baseline Subset [15,81].

309 These techniques are based on the statistical processing of multiple SAR images and a multi-  
 310 temporal interferogram analysis, for extracting long-term high phase stability benchmarks of  
 311 coherent PS point targets, namely Persistent Scatterers (PS) [14,55]. This allows to identify and  
 312 remove atmospheric-related noise and improve the accuracy of deformation measurements.

313 The main innovation of the PSI approach is in the possibility to analyse specific points on the ground  
 314 surface, i.e., the PS, and monitor the historical trend of their deformations. PS are characterised by a  
 315 stable amplitude and a coherent phase across all set of images in a dataset [14,55]. PS are usually  
 316 fixed features on the ground such as exposed rocks, manmade structures and infrastructures (e.g.,  
 317 railways, buildings, bridges, transmission towers), rocky outcrops, and any other permanent feature  
 318 that reflects a stable signal back to the satellite. The SBAS approach [81,82] is suitable to provide  
 319 dense coverage and higher precision for spatially smooth occurrences where no-point targets might  
 320 be identified but large, correlated displacements occur over natural targets. Recently applications in  
 321 Urban-cities were presented by [83] and [84] that confirm the innovativeness of the matters.

322 Finally, recent innovative results were obtained also using UAVS [52] and Airborne DInSAR [51]  
 323 which starting from the pioneering experiments of the last decade, is today affirming as a disruptive  
 324 technology through the use of drones and UAVs.

325 The PSI technique, such as the PS-InSAR by Ferretti et al. [14] and Ferretti et al. [55] is more effective  
 326 for high-spatial resolution occurrences, especially in case of very stable reflectors (i.e. man-made,  
 327 infrastructures monitoring, bridges) that might have independent displacements compared to the  
 328 surrounding areas [14,55]. The PSI technique was applied for the purpose of this research, and the  
 329 results are presented in Section 5.2.2.

330 The PSI technique works by the application of the following steps [55,57,85]:

- 331 i. a statistical analysis of the amplitudes of the electromagnetic returns is developed on a pixel-  
 332 by-pixel base to compute an index of stability over time for each pixel;
- 333 ii. identification of permanent scatterer candidates (PSC). These are pixels with a value of  
 334 stability index that exceeds a fixed threshold;

- 335 iii. computation of the interferometric phase  $\Delta\phi_i$  for any PSC, at any  $i^{\text{th}}$  interferogram;  
336 iv. identification and removal of the atmospheric phase contributions, orbital and noise-related  
337 effects from the interferometric phase.

338 As a result of the above process, stable reflectors, i.e. the PS, can be identified over the inspected  
339 area. This allows surface displacements to be measured with a millimetre accuracy [14,86]. At the  
340 end of the process, displacement evolution trends can be generated for every PS, or an average  
341 velocity map can be produced to provide an overview of the average ground motion over the entire  
342 area of interest. Use of the PSI technique in the monitoring of bridges and transport infrastructures  
343 (such as roads and railways) has been presented in several research [17,87-90] proving the  
344 applicability of the method and the interest of the scientific community.

345

## 346 5 Case Study: the Aylesford Arch Bridge

347 The “Old Bridge” at Aylesford, Kent, UK is a multi-span bridge dating from around 1250 (Figure 4).

348

349

350 **Fig. 4** Main features of the “Old Bridge” at Aylesford in Kent, UK. (a) side view of the bridge spans with  
351 details of the main central arch span width and (b) width of the carriageway.

352

353 The bridge is constructed of local “ragstone” with seven arches including a central segmental arch  
354 and six pointed and double-chamfered outer arches. The bridge width is about 4 m between the  
355 centres of the stone-coped parapet. The end arches are partly buried by the river bank. The stone  
356 piers have cutwaters on the upstream and downstream sides on rebuilt concrete foundations. On  
357 each side, are octagonal and triangular canted pedestrian refuges resting on buttresses over the piers.  
358 Below the bridge is a barge-bed constructed from large baulks of timber. The bridge underwent a  
359 major alteration in the early 1800s, when the two central arches were replaced by a single arch of  
360 18m span, removing a pier to allow passage for larger river traffic.

361 The bridge traffic is closed to cars and motorbikes, although it remains in use for pedestrians, cyclists  
362 and horses. It is a scheduled ancient monument under the control of the English Heritage.

363

364 5.1 Equipment and surveying methodology

365 5.1.1 GPR

366 GPR data were collected using several systems (Figure 5). The high-frequency acquisitions were  
367 carried out using the RIS Hi-BrigHT GPR antenna array manufactured by IDS GeoRadar (Part of  
368 Hexagon) (Figure 5a). The system consists of two rows of eight double-polarised 2000 MHz antennas  
369 with a spacing of 10 cm that allows scanning with a footprint 80cm wide.

370 The survey was divided into three scanning 'Zones' to ease the data management stage (Figure 6).  
371 The bridge deck was surveyed collecting four equally-spaced longitudinal scans along the main axis  
372 of the bridge (Figure 7). In view of the cross-polarised configuration of the RIS Hi-BrigHT system,  
373 transversal scans (i.e., scans across the bridge width) were not collected. However, the cross-  
374 polarisation feature allowed to provide reliable C-scan maps at different depths.

375

376

377 **Fig. 5** GPR antenna systems used for the investigation of the Aylesford bridge: the IDS Hi-BrigHT 2000 MHz  
378 antenna system a) and the IDS RIS MF Hi-Mod system equipped with the TR Dual-F 200 MHz and 600 MHz  
379 antenna b).

380

381

382 **Fig. 6** The "Old Bridge": drawing of the three survey zones.

383

384

385

**Fig. 7** Survey scheme of the “Old Bridge” followed using the 2000 MHz antenna system.

386

387 In addition to the above, identification of reinforcement bars from structural ties through the bridge  
 388 structure was also carried out. To this purpose, four scans were performed using the TR Dual-F 200  
 389 MHz and 600 MHz antenna system (reference penetration depth of 1.5 m and 2.5 m, respectively)  
 390 from the IDS RIS MF Hi-Mod (Figure 5b). The GPR apparatus contains an array of two antennas  
 391 with frequencies optimised for underground utility detection. Same reference coordinates taken for  
 392 the high-frequency GPR surveys as well as the same three areas were considered for this  
 393 investigation (Figure 8). It worth noting that four main scanning lines (i.e., white arrows in Figure  
 394 8a) were collected across the width of the bridge at the central axis of the area covered by the RIS  
 395 Hi-BrigHT antenna array.

396

**Fig. 8** Survey scheme of the “Old Bridge” followed using the 200 MHz and 600 MHz dual frequency antenna system: perspective view (a), and plan view (b).

399

### 400 5.1.2 SAR Imagery

401 Details of the dataset used for the interferometric analyses are listed in Tab. 3. At this stage of the  
 402 research, a dataset of C-band SAR with a medium-range resolution accuracy was collected and  
 403 processed to test the feasibility of the PSI application for the monitoring of the Area of Interest (AoI).  
 404 The analysis of the area is expected to be detailed by processing higher resolution X-Band SAR data  
 405 in a future stage of the research, in order to analyse the detected phenomena at a larger scale.

406 In this study, different single look complex (SLC) SAR images acquired in the interferometric wide  
 407 swath (IW) mode from the Sentinel-1a satellites (Figure 9) were used and processed. The Sentinel1A  
 408 mission is equipped with a C-SAR sensor with a medium-range resolution operating at C-band. The

409 sensor has a central frequency of 5.4 GHz, corresponding to a wavelength of 5.55 cm. The IW mode  
 410 has a 250 km swath and a spatial resolution (single look) of 5 m in ground range and 20 m in azimuth.  
 411 After the application of the multi-looking operation, the spatial resolution of every pixel is 20mx20m.

412  
 413 **Fig. 9** SENTINEL-1 acquisition modes.  
 414

415 **Table 3** Main information on the Sentinel 1A SAR imagery used.

Sensor	Data Ownership Rights	Frequency	Resolution	Number of Images	Revisit Time (Days)	Acquisition Time Range
Sentinel-1 A	The European Space Agency (ESA)	5.4 GHz	Centimetre	21	12	06/2015 ÷ 03/2017

416  
 417 The data used in this study were acquired in the period comprised between June 2015 and March  
 418 2017, and images were provided by the European Space Agency (ESA).

419 It worth noting that number of images in descending selected orbit (chosen for the selection of SAR  
 420 images in ascending geometry) that covered the inspected area of interest were not enough for PSI  
 421 processing purposes within the period of interest. Therefore, results achieved in this paper are  
 422 exclusively referred to the ascending geometry.

423  
 424 **5.2 Results**

425 **5.2.1 GPR investigations**

426 Investigations carried out for the assessment of the entity of existing areas of surface damage with  
 427 the 2000 MHz antenna system showed evidence of surface reinstatement at all the three identified

428 zones. This was allowed by the combined analysis of B-scan and C-scan maps from the data  
429 collected. An example of identification of the sources of surface damage using the above approach  
430 is provided in Figure 10. Depth-to-time conversion was achieved by assuming a wave propagation  
431 velocity  $v$  of 10 cm/ns, i.e., an average dielectric permittivity  $\epsilon_r$  in the multi-layered structure of 9.  
432 This is in line with values indicated in literature review for materials composing the investigated  
433 bridge subsurface structure [46].

434

435 **Fig. 10** Surface reinstatement over identified surface damages in Zone 3 from (a) a C-scan (5 cm deep) and (b)  
436 a B-scan view.

437

438 Structural detailing has proven a second layer of base material placed beneath the asphalt layer and  
439 directly on top of the stonework. This was likely arranged to avoid irregularities in the stone surface  
440 and to provide a more uniform distribution of loads at the bottom of the structure.

441 Overall, the survey carried out with the 2000 MHz antenna system identified the total depth of the  
442 bridge deck above the historic stonework to be variable across the bridge length, with the minimum  
443 depth being at the centre of the widest arch. Figure 11 shows some of the most representative B-  
444 scans collected over the three zones.

445

446

447 **Fig. 11** B-scans collected at the three zones from scan lines within the 2000 MHz antenna system array. Top  
 448 contour line (red): interface between the asphalt (top) and the base (bottom) layers; bottom contour line  
 449 (yellow): interface between the base layer (top) and the historic stonework (bottom). Zone 1 (a), zone 2 (b)  
 450 and zone 3 (c).

451

452 In general, it is possible to estimate the thickness  $h_{ij}$  of the  $i^{\text{th}}$  layered medium at the  $j^{\text{th}}$  zone using  
 453 information on the velocity of propagation of the EM signal in the medium  $v$  ( $v = 10$  cm/ns, assumed  
 454 as a constant average velocity across the multi-layered structural configuration of the bridge deck)  
 455 and the time delay  $\Delta t_{ij}$  between two consecutive reflection pulses in a GPR signal (i.e., reflections  
 456 from the top to the bottom interfaces of the  $i^{\text{th}}$  layer at the  $j^{\text{th}}$  zone). These three variables are related  
 457 each other's by the following expression:

$$458 \quad v = 2h_{ij} / \Delta t_{ij} \quad (1)$$

459 The thickness values  $h_{ij}$  estimated from the scan lines of the antenna array have been averaged across  
 460 the width of the carriageway in order to obtain average thickness values  $\bar{h}_{ij}$  at the three zones.

461 With the purpose of providing an overview of i) the thickness of the asphalt layer and ii) the total  
 462 depth of the bridge deck above the historic stonework, their average thickness value  $\bar{h}_{ij}$  at each of  
 463 the three zones and the corresponding standard deviation  $\sigma_{ij}$  were calculated (Figures 12 and 13).

464

465

466 **Fig. 12** Thickness of the asphalt layer at the three zones investigated. Solid lines on each bar graph represent  
 467 the standard deviation of the values. Dashed lines stand for the range of values between maximum and  
 468 minimum values observed within the dataset of each zone.

469

470 Thickness values of the asphalt layer are not uniform and vary from 3 cm to 12 cm in Zone 1, 3÷13  
 471 cm in Zone 2 and 4÷12 cm in Zone 3 (Figure 12). The average thickness is 8 cm. In regard to the range  
 472 between minimum and maximum layer thickness over the three zones, the smallest variation (both  
 473 standard deviation  $\sigma_{min}$  and  $\Delta h_{min \div MAX}$ ) was collected in Zone 1. On the contrary, the largest  
 474 variation in terms of  $\Delta h_{min \div MAX}$  was collected in Zone 2. Zone 3 turned out to be the area with the  
 475 largest variability of the asphalt layer thickness, according to the highest value of observed standard  
 476 deviation ( $\sigma_{MAX} = 6$  cm).

477 Figure 13 reports the bar graphs of the average value of the total depth of the bridge deck above the  
 478 historic stonework at each of the three zones and corresponding standard deviation.

479

480

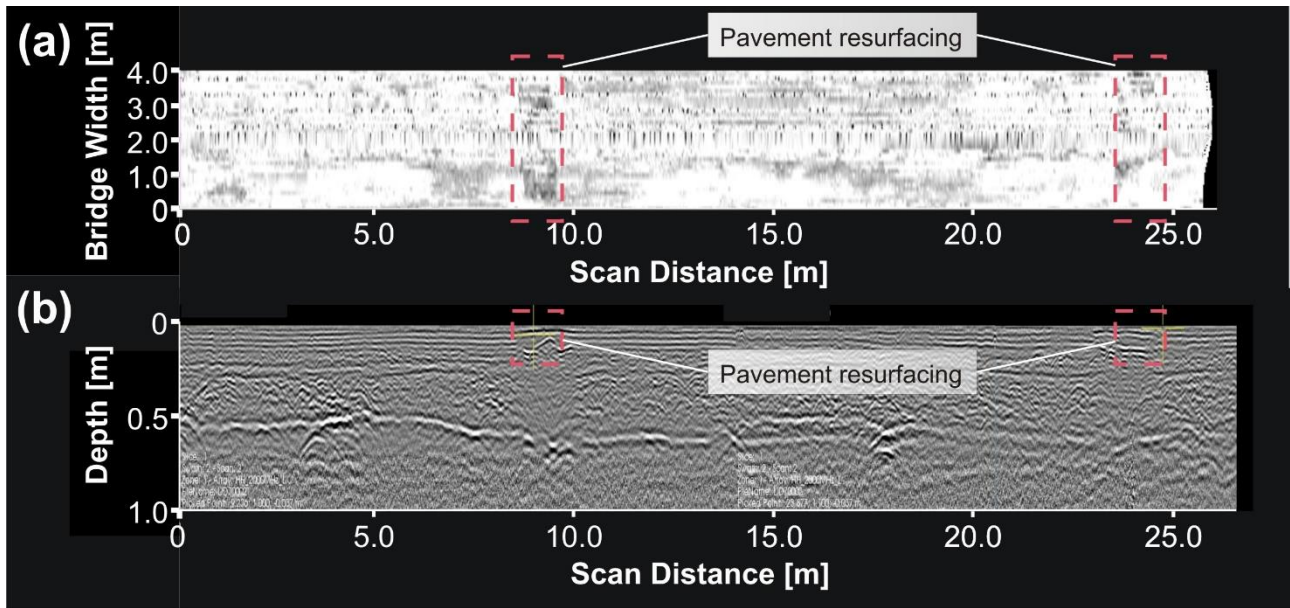

481 **Fig. 13** Total depth of the bridge deck above the historic stonework at the three zones investigated. Solid line  
 482 on each bar graph represents the standard deviation of the values. Dashed lines stand for the range between  
 483 maximum and minimum values observed within the dataset of each zone.

484

485 Data analysis has demonstrated that total depth of the bridge deck above the historic stonework is  
 486 not uniform and varies across the surface of the bridge. The minimum value is observed in Zone 2,  
 487 whereas the maximum depth is in Zone 3; the average depth is 42 cm. Similarly to the case of the  
 488 asphalt layer thickness, the smallest variation in terms of both standard deviation and  $\Delta h_{min \rightarrow MAX}$   
 489 (i.e., the range between minimum and maximum values of total depth of the bridge deck above the  
 490 historic stonework within the concerning zone/dataset) was collected in Zone 1. In this regard, Zone  
 491 3 confirms to be the area with the largest variability ( $\Delta h_{min \rightarrow MAX} = 53$  cm) and standard deviation ( $\sigma$   
 492 = 13 cm).

493 It worth noting that reliability of data for depths beyond 40 cm could be lower compared to shallow  
 494 depths, due to the limited penetration of the high-frequency antenna system. In addition, the  
 495 considerable variations observed for the asphalt layer thickness and the total depth of the bridge  
 496 deck above the historic stonework are likely related to the reconstruction underwent by the bridge  
 497 in the past (i.e., replacement of the two central arches) and the large areas of resurfacing identified  
 498 (Figure 14).

499

500

501 **Fig. 14** Evidence of pavement resurfacing across the whole width of the carriageway identified in Zone 1  
 502 from (a) a C-scan (4 cm depth) and (b) a B-scan view.

503

504 In regard to the use of the low-frequency antenna system, the 200 MHz and 600 MHz dual frequency  
 505 GPR was able to identify and locate the structural tie bars (Figure 15). Where location of these targets  
 506 was unclear, cross-matching with information collected from manual measurements and laser  
 507 scanner equipment were considered for the interpretation of the GPR data. This allowed to identify  
 508 hyperbolic reflection features to relate uniquely to the position of the structural ties, in case of weak  
 509 or multiple reflection patterns. More information about surveying methods, data processing and  
 510 presentation of data from the application of these techniques can be found in Alani et al. (2017).  
 511 Targets were positively identified within Zone 1 (5 tie bars – Figure 15) and Zone 2 (4 tie bars). No  
 512 structural tie bars were found in Zone 3.

513

514 **Fig. 15** Structural tie bars identified in Zone 1 using the 600 MHz central frequency antenna (IDS RIS MF Hi-  
 515 Mod GPR system).

516

### 517 5.2.2 Persistent Scatterers Interferometry (PSI) analyses

518 Results from the application of the PS-InSAR technique to the acquired datasets are reported in  
 519 Figure 16. Use of this technique has proven effective in identifying a set of 11 Permanent Scatterers  
 520 in the vicinity of the bridge.

521 The multi-temporal InSAR image processing workflow used to identify PS coherent targets and  
522 estimate their annual average motion velocity and temporal history of displacements along the  
523 satellite LOS direction, was developed according to the PS Interferometric Stacking Module. This  
524 tool is available in the software SARscape integrated in Envi [91-93], under the license of the Eohops  
525 Project MOBI approved by ESA (European Space Agency). Furthermore, a SRTM v3 DEM (Digital  
526 Elevation Model) was collected and implemented into the interferometric process [94,95] in order to  
527 identify and subtract the phase-related parameters linked with the topography.

528 Outputs were exported into a GIS software and the PSs were displayed as a function of the average  
529 annual motion velocities.

530

531

**Fig. 16** Plan view and 3D view of the PSs on the bridge.

532

533 Amongst the cloud of PSs obtained from the interferometric analysis, a subset of eleven PSs with a  
534 temporal coherence from 0.65 to 0.80 have been identified as significant for bridge monitoring  
535 purposes. Identified points have a temporal coherence ranging between 0.65 and 0.80. This implies  
536 that use of a medium-resolution cell on the ground allowed to detect numerous points on the area  
537 with a stable intensity. These spots were identified as PSs. In this regard, it is fair to comment that  
538 these spots do not provide point information at the position of single structural elements of the  
539 bridge. However, they constitute an essential information within the resolution area covered by the  
540 satellite image with a huge potential for integration with other ground-based techniques.

541 As an example, a downward displacement is detected at the position of permanent scatterer PS1  
542 (coherence of 0.64). Considering a pixel resolution on the ground of  $20\text{m} \times 20\text{m}$ , and the low  
543 backscatter effect exerted by the river crossing the bridge, it is reasonable to relate this occurrence to  
544 the bridge. The deformation velocity of the PS1 point is around  $-1.45\text{ cm/year}$  in the LOS direction.  
545 Figure 17 shows the displacement history of point PS1 observed on the Aylesford Bridge within the  
546 observation time frame.

547

548

**Fig. 17** Displacement time series of point PS1 observed between June 2015 and March 2017.

549

550

Furthermore, various PSs are located nearby the spans and the stack of the bridge. Figure 18 is a 3D view of concerning PSs (PS2, PS3, PS6, PS7) identified in these areas. It worth to emphasise that use of medium-range resolution cells does not allow to relate the displacements to a specific structural element on the bridge deck. Nevertheless, it allows to identify areas of major concerns and black spots where maintenance activities could be potentially prioritised.

551

552

553

554

555

556

**Fig. 18** PSs located in proximity of the spans and the stack of the bridge.

557

558

From the observation of the displacement trends for the above set of PSs, it is possible to observe seasonal effects on the upward and downward displacements of the scattering features over time. In Figure 19, the displacement history of PS2 and PS7 is reported. It can be noticed an upward displacement taking place in winter time for both the PSs, whereas downward displacements are observed in late-springs and early summers.

559

560

561

562

563  
564

565  
566

567 **Fig. 19** Displacement time series of points PS2 (a) and PS7 (b) observed between June 2015 and March 2017.  
568 The point-dashed linear lines represent the average displacement trend for the concerning PS.

569

570 A detrending operation was applied to investigate potential cyclical (seasonal) trends of the  
571 displacements. To this effect, a trend in a time series is usually referred to as a change in the mean  
572 of a function over a certain observation time. Accordingly, following the application of a detrend  
573 process to the data, it is possible to remove a time-related effect from a particular event (such as a  
574 down-lift or an up-lift event) causing distorted interpretation of results. To this effect, a linear  
575 regression ( $LR_i$ ) of the temporal deformations was calculated for each  $i^{th}$  PS and the following  
576 equation was applied:

577 
$$PSp_i^*(t) = PSp_i(t) - LR_i(t) \quad (2)$$

578 where  $t$  is the observation time,  $PSp_i$  is the position of the  $i^{th}$  PS referred to the position of a stable  
579 point (displacement = 0) and  $PSp_i^*$  is the detrended behaviour.

580 Furthermore, a normalisation process of the data was applied in order to compare seasonal trends  
581 at various PSs with different amplitudes of displacements.

582 The millimetre displacements are expressed with reference to a known stable PS (displacement = 0)  
583 in the observation time. Specifically, various PSs with a similar trend of deformation were detected.  
584 The output of this analysis is reported in Figure 20, where the normalised displacement is displayed  
585 against the acquisition time within the observation period.

586

587 **Fig. 20** Normalised detrended displacements for the identified set of 11 PSs observed between June 2015 and  
 588 March 2017. The point-dashed (red) line represents the average displacement trend (PSavg).

589

590 The detrending and normalisation stages highlight an upward trend of displacements during late  
 591 summer periods and a downward displacement trend during springs and falls.

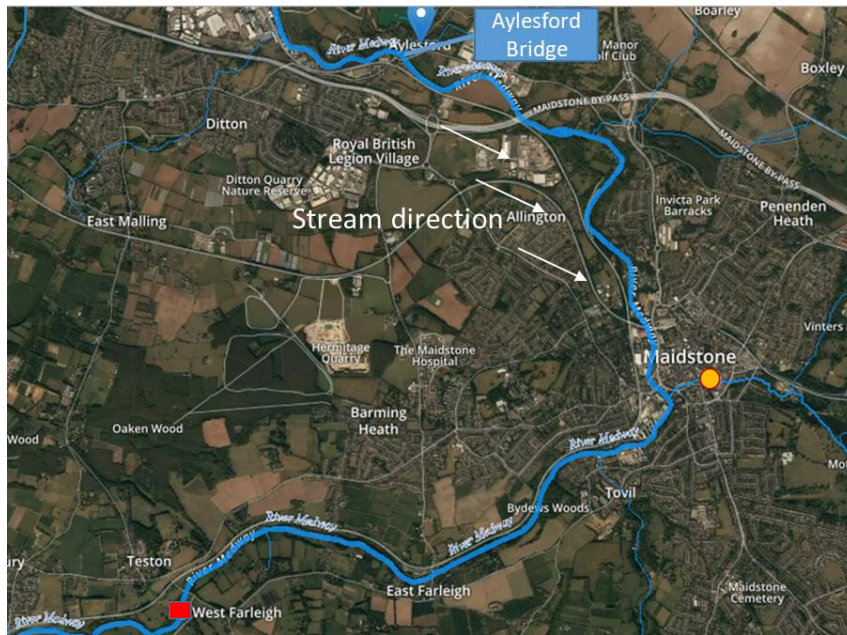

592 The seasonal behaviours observed as a result of the PS analysis were compared to the hydrometric  
 593 data of the concerning area. To this purpose, flood data of the Medway River were analysed from  
 594 datasets by the UK National River Flow Archive (NRFA), hosted by the Centre for Ecology &  
 595 Hydrology [96]. The archive is the main focal point for hydrometric data in the UK, providing  
 596 stewardship of, and access to, daily, monthly and flood peak river flow data from over 1,500 gauging  
 597 stations across the UK. The NRFA collates, quality controls, and archives hydrometric data from  
 598 gauging station networks across the UK including the extensive networks operated by the  
 599 Environment Agency (England), Natural Resources Wales and the Scottish Environment.

600 In more detail, data of the flood ( $m^3/s$ ) collected from the two nearest downstream stations to the  
 601 bridge location were used and analysed in this study:

602 - Station 40003 - Medway at Teston / East Farleigh (square marker in Figure 21)

603 - Station 40029 - Len at Lenside, tributary of the Medway River (round marker in Figure 21)

**Fig. 21** The two Stations considered for collection of the hydrometric data.

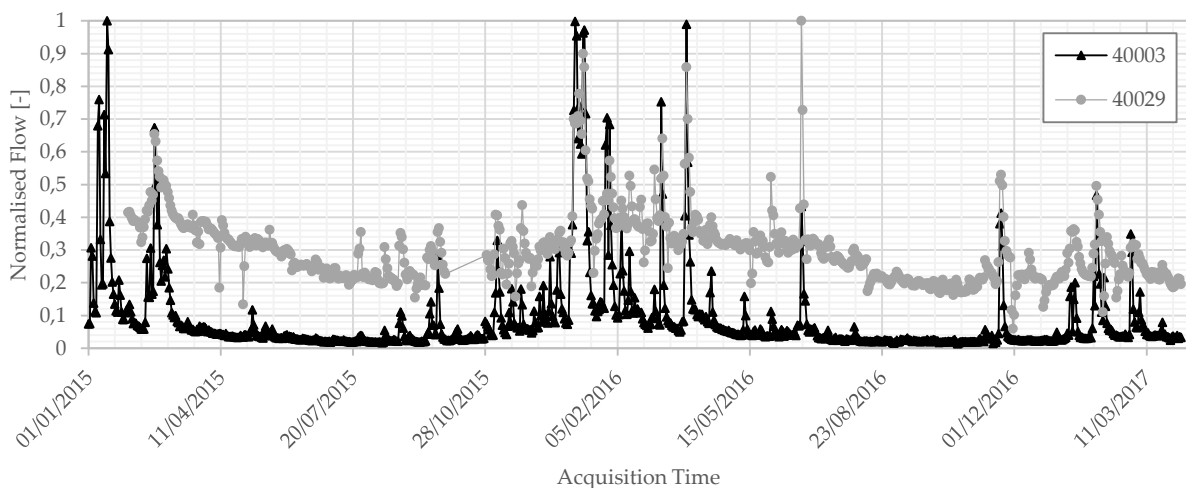

604

605

606

607 Possibility to analyse the hydrometric trend of the area since 1985 was available. In order to  
 608 investigate a potential correlation between hydrometric and displacement data and verify potential  
 609 delayed effects, a larger period of observation (i.e., from January 2015 to April 2017) was considered  
 610 compared to the time frame used in the PS analysis (i.e., from June 2015 to March 2017). The output  
 611 of the flood analysis is reported in Figure 22, where the normalised flow is plotted against the  
 612 acquisition time from stations 40029 and 40003.

613

614

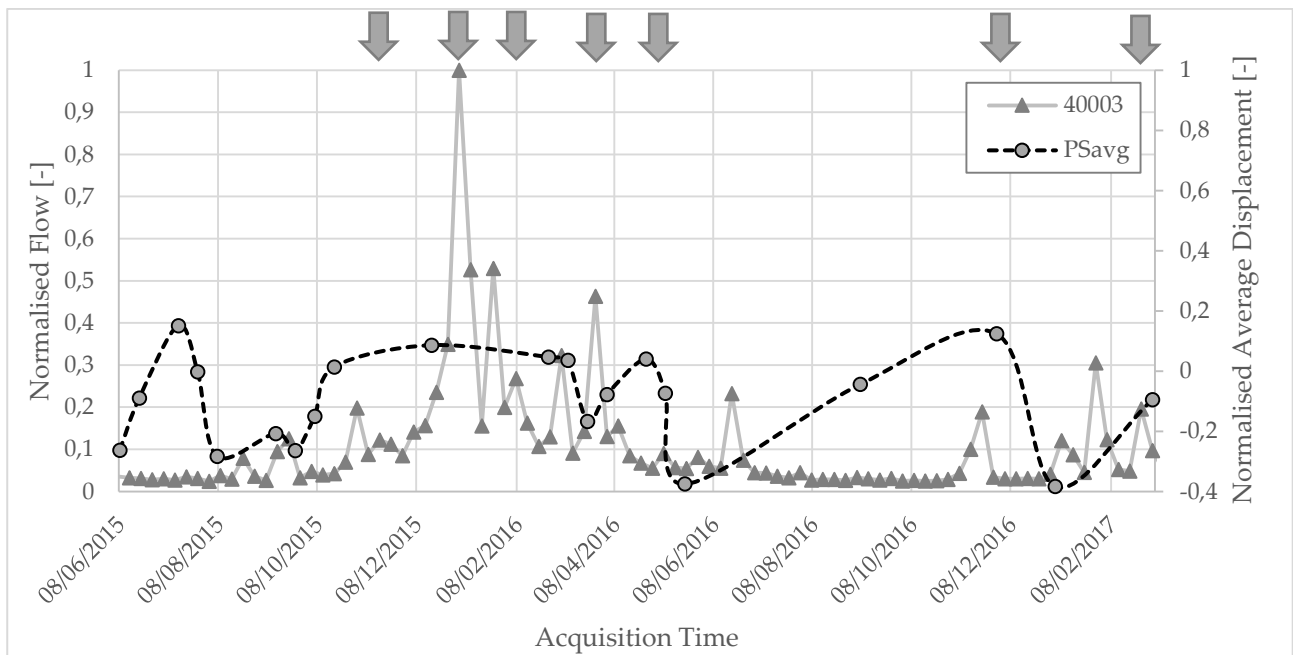

**Fig. 22** Normalised hydrometric flow data from stations 4003 (triangular markers) and 4029 (round markers).

616

617 A correlation between displacements identified by the InSAR analysis at the PS positions and the  
 618 flood trends recorded by the two stations is observed. More specifically, flood events occurred at

619 winter time periods in years 2016 and 2017 (arrows in Figure 23) are found to have a close trend to  
620 the peaks of upward displacements on the bridge observation area.

621

622

623 **Fig. 23** Comparison between the average trend of identified PSs and the hydrometric trend (weekly average  
624 – station 40003) observed between June 2015 and March 2017. Position of the arrows indicate flow peak  
625 periods matching with the upward displacements of the bridge.

626

627 An interpretation for this behaviour is most likely on the upward hydrostatic pressure generated by  
628 the swelling of the subgrade at the foundation level. This is in turn due to the period's rainfall and,  
629 accordingly, to the hydraulic head of the Medway River. Although the limited resolution of the  
630 dataset does not allow a detailed assessment of potential differential settlements for specific bridge  
631 components, the general seasonal trend observed for the PSs in the bridge area indicates that the  
632 whole structure is subject to cyclical patterns of upward and downward displacements, following  
633 soil saturation during the hydrological cycle.

634

## 635 6 Conclusions

636 In this paper, the authors have presented a proportion of the existing literature review within the  
637 subject area of assessment and health monitoring of masonry arch bridges. The history of masonry  
638 arch bridges, their architecture and the factors affecting their structural integrity have been reported.

639 The main methods for the assessment and monitoring of masonry bridges in terms of the location of  
640 defects and deformities using conventional methods and techniques were highlighted. Following  
641 this, a section was dedicated to presenting a summary of the main non-destructive testing (NDT)  
642 methods and the available research based outputs and their application.

643 The paper has also highlighted the viability of the utilisation of NDT methods in this area of  
644 endeavour. The importance of adopting new and more advanced monitoring strategies and  
645 techniques for effective conservation of structural features within the context of safeguarding the  
646 cultural heritage has been emphasised upon. To that effect, a novel “integrated” holistic health  
647 monitoring approach including the Ground Penetrating Radar (GPR) and the Interferometric  
648 Synthetic Aperture Radar (InSAR) techniques has been proposed and applied.

649 Results of these investigations produced vital information concerning the structural integrity of the  
650 “Old Bridge” at Aylesford, Kent, UK.

651 In more detail, GPR was essential in providing structural detailing of the bridge deck geometry. This  
652 was effected by using a high frequency antenna system (2000 MHz central frequency) allowing to  
653 establish and map the thickness of the tarmac layer as well as the under layers (bridge deck surface  
654 cover) and providing information about the total depth of the bridge deck above the historic  
655 stonework. These are crucial details for the identification of the non-homogeneous areas within the  
656 bridge superstructure. In addition, use of a low-frequency antenna system (200 and 600 MHz central  
657 frequencies) allowed to identify and locate the exact positioning of the structural ties.

658 Regarding the use of the InSAR technique, observations involved a period of 21 months. Results  
659 highlighted a clear matching between seasonal trends of displacements of permanent scatterers (PSs)  
660 located in the vicinity of the bridge and the flood trends recorded by the two nearest downstream  
661 stations to the bridge location. Coherence in the displacement trend for all the identified scatterers  
662 has proved the influence of the entire bridge structure to a cyclic sequence of upward and downward  
663 displacements, following soil saturation during the hydrological cycle.

664 This “integrated” holistic approach for the structural health monitoring of an ancient masonry  
665 bridge (the Old Bridge) proved particularly useful which in turn could be utilised and applied to  
666 similar structures.

667 It is believed that, this research has contributed and added value to the existing knowledge within  
668 the context of understanding the behaviour of structures such as bridges of historical and cultural  
669 values under dynamic and static conditions.

670
