ABSTRACT

Objectives To explore the association between depressive symptoms and recent head-related trauma (diagnosed concussion, subconcussive impacts) in semiprofessional male Australian Football (AF) players.

Methods Sixty-nine semiprofessional male players from a West Australian Football League (WAFL) club participated in the study ($M_{\text{age}}=21.81$, $SD=2.91$ years). Depressive symptoms were measured using the Centre for Epidemiological Studies Depression Scale. Injuries and potential confounding variables (eg, pre-existing mental health condition; alcohol or drug hangovers; experiencing a stressful event) were self-reported anonymously using the WAFL Injury Report Survey. Both tools were administered every 2-weeks over the first 22-weeks of the WAFL season. Controlling for potential confounding variables and other injuries, a repeated measures generalised estimating equations model assessed the risk of clinically relevant depressive symptoms occurring, when diagnosed concussion or subconcussive impacts were experienced.

Results A total of 10 concussions and 183 subconcussive impacts were reported. Players who experienced a concussion were almost nine times more likely to experience clinically relevant depressive symptoms (OR 8.88, 95% CI 2.65 to 29.77, $p<0.001$). Although elevated, depressive symptoms following subconcussive impacts were not statistically significant (OR 1.13, 95% CI 0.67 to 1.92, $p=0.641$).

Conclusion These findings indicate that semiprofessional AF athletes may be at risk of experiencing depressive symptoms after concussion. Severity (concussion vs subconcussive impacts) and dose (number of impacts) appear to have an important relationship with depressive symptom outcomes in this cohort and should be considered for further research and management of player welfare.

INTRODUCTION

Mental health was recently elevated to an Australian National Health Research Priority area.¹ Young adults (18–24 years) are experiencing mental illness at rates one-third higher than the average population,² with suicide the leading cause of death for men aged 15–24

What are the new findings

- A greater number of injuries were reported using self-report methodology in comparison to the club medical team data.
- Recent diagnosed concussion was associated with a significant increased risk of experiencing clinically relevant depressive symptoms.
- Subconcussive impacts and other injuries were not significantly associated with an increase in depressive symptoms.

years in Australia.³ Semiprofessional^{4–6} and elite⁷ Australian Football (AF) players are within this vulnerable age group. Yet, while there is increasing literature regarding the mental health of Australian elite athletes in general,⁸ there is a paucity of research pertaining in AF across all levels.

Depression is a common mental health illness which is both complex and multifaceted in nature.^{9,10} Engagement in team sport may reduce the risk of an athlete experiencing depression¹¹ because of the protective nature of social connection,¹² social support¹³ and physical fitness.¹⁴ Conversely, athletes are at elevated risk of experiencing depressive symptoms¹⁵ due to sport-specific factors, including pressure to perform,^{13,16} musculoskeletal injury¹⁶ and, perhaps, concussion.^{11,16}

Despite an increase in concussion surveillance studies in elite AF,^{17–19} little is known about community or semiprofessional Western Australian players. While one study using head impact-sensory data indicated male semiprofessional West Australian Football League (WAFL) players may be exposed to more than 29 ($SD=37$) impacts per game,⁶ there are no other known WAFL concussion or subconcussive impact exposure or injury surveillance data. Exposure to head-related trauma is of concern, with numerous American athlete studies identifying concussion

Figure 1 Participant eligibility and inclusion details for data analysis. ^Age: under 18 years of age as of the first data collection occasion. *Senior game: failed to report playing a minimum of one senior game (league or reserves) during the data collection period. **Stressful event: players who reported a *stressful event* were excluded only for the corresponding occasion when they identified a *stressful event* had occurred. Given no players reported a *stressful event* for all occasions, no players were excluded from the total analysis. and repetitive subconcussive impacts²⁰ to be associated with long-term health issues, including neurodegeneration and depressive symptoms in later life.^{21–23}

Emerging research has explored the prevalence of depressive symptoms following recent concussion,^{24–25} predominately within American high school and collegiate athletes including football and rugby.^{16–26–32} Findings indicate depressive symptoms may be elevated up to 2-weeks after concussion²⁸; however, it is unknown if these findings are applicable to AF. It is important for players and medical staff to consider the potential short-term psychological effects of concussion.^{16–25}

This can assist in earlier identification and referral to the appropriate care pathway allowing for treatment aimed at improving both a player's physical and mental welfare. Furthermore, despite the potential for subconcussive impacts to elicit similar long-term neurological sequelae as concussion,^{22–33–34} no studies to date have investigated whether recent subconcussive trauma evokes similar depressive symptom responses.

There is limited research exploring depressive symptoms or head-related trauma in semiprofessional AF

players, and no known research has examined the association between these two domains in a male AF population. Given the majority of semiprofessional AF players are within the high-risk age category for mental ill health,⁴ and associations between concussion and depressive symptoms have been identified in other sports,^{16–29–30} the aims of this study were: (1) identify the prevalence of concussion and subconcussive impacts in male WAFL players over a competitive season; and (2) investigate associations between depressive symptoms and concussion or subconcussive impacts.

METHODS

Study design and setting

This prospective cohort study with repeated measures design used coded (deidentified), self-report survey methodology to gather injury, demographic and depressive symptom data over 22-weeks within the WAFL. The WAFL is a male semiprofessional league, which constitutes the second-tier competition for AF within Western Australia. Self-report methodology was employed because it is a simple, valid and reliable method to collect injury data in non-elite sporting environments.³⁵ The Strengthening the Reporting of Observational Studies in Epidemiology checklist for longitudinal studies guided the reporting of this study (online supplementary file 1).³⁶

Participants

Inclusion criteria included any male player aged 18 years and older who played at least one senior WAFL game during the 2015 season. Of the 98 senior players registered to the participating WAFL club, one player declined to participate citing 'no interest' and a further 28 individuals failed to meet the inclusion criteria due to age and minimum game requirements (figure 1). Therefore, 69 players were included. The sample size was calculated based on previous Centre for Epidemiologic Studies Depression Scale (CES-D) research^{32–37} with the probability (power) of 80% and the type I error probability $\alpha=0.05$. The a priori power calculation indicated a convenience sample of 50 participants over the age of 18 was adequate to examine the study hypothesis (online supplementary file 2).

Survey development

WAFL Injury Report Survey

The WAFL Injury Report Survey (WIRS) was developed by a panel of researchers and an industry representative following a review of previous literature and current injury and depressive symptom survey methodology in contact sport.^{11–38} Face validity was established using five male WAFL players from different clubs, who reviewed the survey over three occasions. Formative review by both researchers and players, in conjunction with previous literature,³⁵ indicated fortnightly survey intervals would elicit more accurate responses than four weekly, and be less cumbersome than weekly. The modified WIRS was piloted with one WAFL team (n=40) over two

consecutive training sessions to assess test–retest reliability which demonstrated a strong level of agreement on demographic survey items (93%–100% agreement, $k=0.82$ – 1.00) and all injury variables (95%–100% agreement, $\alpha=0.78$ – 1.00).

Injury was defined as any injury or physical complaint sustained during a match or training, self-perceived by the player to cause pain; or impact, hinder or affect performance.³⁹ Injury was classified as a self-reported *subconcussive impact* (head, neck or face), upper body injury (trunk, upper extremity), lower body injury (pelvis, lower extremities) or a medically diagnosed *concussion* (diagnosed by a medical practitioner). As the study focused on head-related injuries, for data analysis purposes, upper body and lower body injuries were grouped to form the variable *other injury*.

Depressive symptoms

Depressive symptoms are a facet of an individual's emotional well-being, and commonly present as negative feelings or thoughts including low mood, sleep disturbance or feelings of worthlessness.⁴⁰ Although the presence of these symptoms does not infer a depression diagnosis, the number and severity of symptoms experienced at any one time could indicate a depressed mood. Depressive symptoms were measured fortnightly using the CES-D20.⁴⁰ This 20-item questionnaire is a reliable ($\alpha=0.85$ – 0.90) screening tool for identifying depressive symptoms in the general population and with young adult males in sporting environments,^{8 11 16} including postinjury and postconcussion.¹⁶ The tool demonstrates good sensitivity (87%) and specificity (77%).^{8 11 41} Depressive symptom scores were calculated as total scores (sum score of the CES-D20 per occasion) with scores ranging from 0 to 60, with an increased score indicating an increased presence of clinically relevant depressive symptoms.^{11 40 42} Consistent with common CES-D20 analysis procedures,^{11 40–43} scores were dichotomised with a cut-off score of 16 or above indicating depressive symptoms are present. The CES-D20 shows moderate test–retest reliability over 2-weeks to 12-months (0.45–0.70) which is expected due to the natural fluctuation in symptoms.^{40 41} Given the multifactorial nature of depressive symptoms,^{9 10 25} potential confounding variables to depressive symptom reporting were taken into consideration for analysis. These included a player's age,^{11 44} relationship status, change in relationship status, employment status, change in employment status,⁴⁴ alcohol/other drug use,^{25 45 46} illness,^{47 48} experiencing a recent stressful event (stressful event)²⁵ and reporting a pre-existing diagnosed mental health (DxMH) condition.^{11 29 44 49}

Survey procedures

Players completed the WIRS and CES-D20 every 2-weeks (fortnight), post-training on the same night for 22-weeks of the regular playing season (11 data collection occasions). Players recalled total injuries received per injury category during the game and each training session every

fortnight. Within the fortnightly survey period, a player would normally participate in up to six evening training sessions and two games (one per weekend). A unique identification code enabled participant's responses to be tracked over time while ensuring responses were coded.

Additional data

Anonymous medical team data (MTD) were also provided by the club, as a sum of each injury type per week for the corresponding 22-week period of time. Using the same four injury classifications as the WIRS, the MTD were based on the sum of injuries reported to the club physiotherapist, doctor or head trainer during training or competition. No further information was provided to the research team.

Statistical analysis

SPSS V.24.0 was used for all statistical analysis. Repeated measures non-uniform Bland-Altman limits of agreement analysis was used to assess the level of agreement (95% limits)⁵⁰ between total sum of self-reported WIRS and MTD injuries. Injury prevalence was calculated based on the number of participants who reported the injury type, divided by the total sample population. Injury rate was also presented per frequency of athlete exposures (AE), where one match or one practice per person was considered one AE.^{51–53} AE rates are challenging to calculate at a non-elite level, as players may not always attend all training sessions.⁵⁴ Due to the study parameters, a conservative AE estimate was used, where the total number of sessions was calculated based on the standard six training sessions and two games per occasion, taking into consideration any scheduled byes (ie, no games), and the number of responses per occasion for the study period. The AE rates were calculated based on the sum of injuries divided by the number of AEs, and presented per 1000 AEs^{51 53} with 95% CI⁵³:

$$\text{AE Rate} = \frac{\sum \text{Number of Injuries}}{\sum \text{Athlete-Exposures}} \times 1000$$

$$95\% \text{ CI} = \left(\left(\frac{\sum \text{Number of Injuries}}{\sum \text{Athlete-Exposures}} \right) \pm \left(1.96 \times \frac{\sqrt{\sum \text{Number of Injuries}}}{\sum \text{Athlete-Exposures}} \right) \right) \times 1000$$

An independent t-test (non-parametric alternative Mann-Whitney U test) was used to assess differences in baseline depressive symptom scores between players who did or did not receive concussion during the season.

A two-stage regression modelling strategy was used to account for the multifactorial nature of depressive symptoms.⁹ First, in a generalised linear mixed model (GLMM), with normal probability distribution, identity link function was used to investigate the longitudinal association between depressive symptoms (CES-D20 scores) and nine potential confounding variables. A GLMM was used as it allows for longitudinal repeated measures data with multiple independent variables.⁵⁵ These confounders included: age

**Table 1** WIRS fortnightly response rate over the 22-week playing season (n=69)

Occasion	1	2	3	4	5	6	7	8	9	10	11
Responses	59	60	52	58	55	57	56	56	58	51	52
Missing*	10	9	17	11	14	12	13	13	11	18	17

Data were collected during the playing season on the same night, each fortnight (11 occasions). Therefore, each occasion reflects a 2-week period.

*Not all participants responded on every occasion. Due to the deidentified nature of the study, if a player missed an occasion, a response was unable to be captured. A total of 614 responses were captured.

WIRS, WAFL Injury Report Survey.

(continuous variable, measured as a constant), relationship status, change in relationship status, employment status, change in employment status, alcohol/other drug use, illness, stressful event and pre-existing DxMH condition (dichotomous variables measured per occasion). These confounders were examined within the same model to reduce the risk of bias.⁵⁶ Additionally, quaslikelihood under independence model criterion (QIC) was examined to determine the model fit, where the lower the value the better the model fit.⁵⁷

Second, a generalised estimating equation (GEE) model for dichotomous outcome modelled the risk of depressive symptoms, using the binary cut-off (CES-D20 ≥ 16)^{11 40 42 43 58} when an injury (concussion, subconcussive impact or other injury measured as continuous variables) was reported on each occasion. Multiple strengths of the GEE include: accounting for individual's repeated measures data over time,^{59 60} not relying on specific time points and accounting for missing data.⁵⁹ This model enables concussion and subconcussive impacts to be compared, while controlling for other injuries. This method has been used in other AF injury risk studies^{7 61 62} and to explore depressive symptoms and general injury in college athletes.^{32 58 60} The level of statistical significance was set at $p < 0.05$.

Patient and public involvement

Patients and/or the public were involved in the design, or conduct, or reporting, or dissemination plans of this research.

RESULTS

Injury prevalence

Players (n=69) were on average 21.9 years (SD=2.96, range: 18–31 years), and completed 8.90 data collection occasions (SD=3.30) with 48% completing all 11 occasions (n=33) (table 1).

The sample had a concussion prevalence of 13% (n=9), with a total of 12 concussions reported by nine players during the data collection period. A subconcussive impact prevalence of 51% (n=35) was recorded (table 2). A total of 14 players (20%) reported no injuries at all over the data collection period.

A total of 495 injuries were reported in the WIRS. Comparatively, MTD indicated a total of 175 injuries across the same period of time with the same playing cohort. Although the WIRS identified a greater sum of injuries than the MTD, the Bland-Altman analysis found the two measures had a good level of agreement as the majority of points were positioned within the 95% CI limits of agreement (online supplementary file 3). This indicates both injury reports were proportionally measuring the same outcome.

Confounding variables to depressive symptom reporting

A GLMM confirmed a significant association between DxMH and CES-D20 scores ($\beta=10.02$, 95% CI 2.52 to 17.53, $p=0.009$). Therefore, participants who identified DxMH on the first data collection occasion were excluded from all further analyses as per the exclusion criteria for the study. The GLMM confirmed that *stressful event* ($\beta=2.72$, 95% CI 1.29 to 4.15, $p < 0.001$) also significantly increased CES-D20 scores, hence, to control for this influence, data from participants who reported a *stressful event* were excluded for the corresponding occasion when they identified injury had occurred (figure 1). The remaining seven demographic variables were not significantly associated with depressive symptoms ($p > 0.287$). Model QICs were examined with all nine confounders (n=69, QIC=372.420), seven confounders (excluding DxMH and stressful event, n=67, QIC=295.222) and the final model (inclusion of injury variables and no adjustment for confounders, n=67, QIC=280.816). The final injury model without adjustment for confounders provided the best model fit.

Table 2 Prevalence and rate of self-reported injuries over the 11 occasions (n=69)

	Participants (n)	Injury sum	Prevalence (%)	AE	AE 95% CI
Concussion	9	12	13	2.56	1.11 to 4.01
Subconcussive impacts	35	194	51	41.36	35.54 to 47.19
Upper body	38	132	55	28.14	23.34 to 32.95
Lower body	46	157	67	33.48	28.24 to 38.71
Total injuries	55	495	80	105.54	96.25 to 114.84

Estimated total athlete exposures: 4690.

AE: estimated rate per 1000 athlete exposures, where an AE is defined as one player participating in one match or one practice.

AE, athlete exposure.

Table 3 Mean depressive symptom scores (CES-D20) based on the number of subconcussive impacts reported per occasion*

Total subconcussive impacts per occasion	n	Depressive symptoms†	
		Mean	SD
0	407	7.34	5.53
1	48	7.90	6.16
2	33	7.49	5.29
3	9	9.00	5.36
4	4	11.00	10.00
5	1	15.00	‡

A dose–response relationship for concussion per player was unable to be explored, as a maximum of one concussion was reported per occasion.

*Excluded participants who had reported a stressful event or diagnosed mental health (DxMH), or incomplete CES-D20 (total sample included n=67); total of 502 cases were included from 67 participants over 11 occasions.

†Depressive symptoms is the CES-D20 sum score. CES-D20 ≥16 denotes presence of clinically relevant depressive symptoms.

‡SD unable to be calculated due to sample size (n=1).

CES-D20, Centre for Epidemiologic Studies Depression Scale.

Depressive symptoms and head-related trauma

Based on these exclusion criteria, 10 incidences of concussion and 183 subconcussive impacts were analysed. Shapiro-Wilk analysis indicated that *total CES-D20* scores were not normally distributed ($p<0.001$). At baseline, although elevated, there was no significant difference ($p=0.287$) between depressive symptom scores for athletes who experienced a concussion ($M=9.69$, $SD=3.81$, $Mdn=9.00$), compared with athletes who did not experience a concussion during the testing period ($M=7.04$, $SD=5.57$, $Mdn=6.50$).

A higher depressive symptom score was reported following concussion ($M=12.90$, $SD=7.36$) compared with subconcussive impact/s per occasion ($M=8.06$, $SD=5.94$). However, experiencing any head-related trauma elicited greater mean depressive symptom scores in comparison

to other injuries ($M=7.62$, $SD=5.92$), or no injuries ($M=7.56$, $SD=5.51$).

Four out of 10 concussive episodes (40%) were associated with players experiencing clinically relevant depressive symptoms ($CES-D20 \geq 16$). In comparison, only 8% of players with a minimum of one subconcussive impact, 8% of players who recalled no injuries and 7% of players who reported other injuries reported clinically relevant depressive symptoms. Descriptively, a dose–response relationship with a greater depressive symptom score was observed, when multiple subconcussive impacts were reported per occasion (table 3).

Risk of depressive symptoms following head-related trauma

The GEE model indicated players who reported a concussion were almost nine times more likely to experience clinically relevant depressive symptoms within a 2-week period (table 4). Controlling for all other injuries including concussion, while not statistically significant, the GEE OR identified subconcussive impacts increased the probability of clinically relevant depressive symptoms by 13% per impact reported (table 4). Other injuries per occasion were not significantly associated with depressive symptoms.

DISCUSSION

To our knowledge, this is the first study to longitudinally explore depressive symptoms and recent head-related trauma in WAFL players over a competitive season. We present the first injury surveillance data on concussion and subconcussive impacts within WAFL and found participants who reported diagnosed concussion, reported clinically relevant depressive symptoms at higher rates than previously reported in athletes in other sports.

Injury prevalence

Our results identified a greater number of concussions (10 concussions per 67 players) than Victorian Community AF (2.23 concussions per team/season) or elite AF (1.5 concussions, per club of approximately 45 players),^{63 64} although methodological differences to previous AF studies are noted. Novel to previous findings,

Table 4 GEE model: repeated measures assessment of risk of depressive symptoms* following injury

Parameter	β	SE	OR	OR 95% CI	P value
Intercept	-2.51	0.28	0.08	0.05 to 0.14	<0.001
Diagnosed concussion	2.18	0.62	8.878	2.65 to 29.77	<0.001†
Subconcussive impact	0.13	0.27	1.133‡	0.67 to 1.92	0.641
Other injury	-0.17	0.23	0.840	0.53 to 1.32	0.451

*Depressive symptoms assessed as a binary variable, with Centre for Epidemiologic Studies Depression Scale (CES-D20) sum score ≥16, indicating presence of clinically relevant depressive symptoms.

†Bold values denote statistical significance at $p<0.05$; OR derived from $\text{Exp}(\beta)$. OR>1.00 indicates an increase in the risk of depression.

‡Despite a non-significant association, OR ($\text{Exp}(\beta)$) denotes an increase in depressive symptoms, per *subconcussive impact* reported. GEE, generalised estimating equation.

the 67 players involved in our study reported 183 subconcussive impacts over the season which are not commonly formally reported as an injury unless they cause facial fractures or a player misses a game.³⁸ Given the substantial number of subconcussive impacts reported and that concussion is difficult to diagnose,⁶⁵ it may be advisable for future injury reporting systems to include a category to specifically capture subconcussive impacts.

We demonstrated self-report questionnaires can successfully gather injury data in semiprofessional AF. Strong agreement was found between the WIRS findings and the club's medical records, although the number of injuries captured by the WIRS was larger. This is consistent with self-report research^{66 67} which suggests players under-report their injuries, particularly head trauma, to medical staff. Perhaps the WIRS coded self-report nature, reduced a player's hesitation to disclose injury information; however, further research is recommended to explore potential reasons and differences in reporting within this cohort.

Association between depressive symptoms and head-related trauma

The second aim of our study was to explore whether concussion and subconcussive impacts were associated with an increase in a player's self-reported depressive symptoms within the 2-week period of being reported. The prevalence of depression in the Australian young male adult population is estimated to be 12%.⁶⁸ Although the CES-D20 does not diagnose depression, only 8% of players who did not report an injury, reported depressive symptom scores of clinical relevance. Though a direct comparison cannot be made, this may indicate that in the current non-injured sample, depressive symptoms were less prevalent than in the general population for young male Australian adults.

In contrast, following concussion, a greater proportion of players reported clinically relevant depressive symptoms (40%). This is in comparison to baseline, population prevalence and when compared with American college athletes (4%–14%; using CES-D20 or other measures).^{16 28} The reason for these discrepancies is unclear; however, it may be due to methodological differences in data collection, including the different measures to assess depressive symptoms, the smaller number of concussions available for analysis, the level of competition, the type of contact sport, game demands or other personal predisposing factors.

Even if a player is not diagnosed with a concussion, their brain may still be exposed to external forces resulting from subconcussive impacts.^{34 69 70} Although descriptive statistics identified a dose–response relationship between multiple subconcussive impacts and an increase in depressive symptom score, the GEE analysis did not find a significant association with depressive symptom scores of clinical relevance. Subconcussive impacts and concussion may be inter-related, therefore providing a colinear relationship, further explaining the non-significant findings. Despite the emerging evidence of long-term outcomes including emotional changes and neurodegeneration^{21–23} following

subconcussive impacts^{34 69 70} perhaps, short-term changes in depressive symptoms following these impacts are not present or not detectable in this population. Alternatively, future research should consider if the intensity or magnitude of the impact, or multiple impacts in quick succession influences depressive symptoms.

In previous musculoskeletal injury studies, an increase in depressive symptoms was attributed to exclusion from play,⁷¹ however, specifically in concussed players, other literature indicated depressive symptoms were shown to decrease with time, regardless of participation or exclusion status.^{16 30} While these elements were not explored in the current cohort, our findings identified that recent other injuries were not associated with increases in depressive symptoms. Therefore, perhaps it is the impact, rather than the exclusion from play, that contributes to increases in depressive symptoms in concussed athletes.

Implications for practice

Access to medical resources declines as the level of professionalism decreases, hence self-report may assist non-elite clubs to capture reliable injury information.⁷² Although the association between recent concussion and increases in depressive symptoms needs further validation, given the potential risks associated with depressive states, clubs and coaches may need to consider these findings to ensure the well-being of their players. With the focus during concussion recovery often based on somatic symptoms and return-to-play strategies, emotional assessment may be required to identify those players exhibiting depressive symptoms. Given many players do not associate emotional changes (ie, depressive symptoms) with receiving head trauma,⁷³ further education and access to professional resources for players and staff is required.

Strengths and limitations

This study has a number of strengths. Engaging the entire club playing cohort likely reduced the risk of respondent bias. Additionally, maintaining player anonymity may have increased reporting compliance and reduced the risk of inaccurate reporting.⁶⁶ Furthermore, the longitudinal design of the study strengthens the rigour of the findings as players were tracked over the duration of the season.

Regarding limitations, assessing emotional response to injury presents numerous methodological difficulties. A primary limitation of this research involves the 2-week collection of injury and depressive symptom data because an injury may have occurred at any point within the 2-week period, therefore the days after injury may differ between players. Future research may explore how depressive symptoms fluctuate in the number of days after concussive or subconcussive impact (0–14 days) and implications to optimise follow-up. A secondary limitation relates to the generalisability of these findings. This study was limited to one semiprofessional WAFL club, therefore the generalisability of results to other levels is unknown. Due to the low number of concussions reported, and the three injury groups, it is likely that this analysis may be underpowered.

Issues with sample size may be addressed in future research by considering the use of penalised GEE analysis in alternate statistical packages where this procedure is available. Third, the self-report nature of the study means the WIRS relies on accurate and honest reporting from players, although the WIRS validation and test–retest reliability suggests the responses were accurate. Ideally, data would be collected using medical and allied health practitioner reports to ensure diagnostic accuracy. However, a semiprofessional environment, relying on medical teams to collect accurate and reliable injury data, can be difficult for numerous reasons. Players may choose to withhold injury information from medical staff for fear of being withheld from competition, not recognising that an injury has occurred, or not perceiving the injury as serious enough to warrant reporting.^{66 67 74} Under-reporting can be compounded at a semiprofessional and community level, due to reduced access to qualified medical staff.⁷² Therefore, coded self-report methodology may overcome some of these barriers and elicit greater compliance in injury and concussion reporting.⁶⁶ Finally, while effort was made to control for additional factors which may influence the presence of depressive symptoms, due to the multifactorial nature of mental health, other unmeasured factors may have influenced the findings.

CONCLUSION

Often the focus in AF is based around performance or physical health, yet our research considered an aspect of mental health. Specifically, it is the first study to consider the effect of recent concussion and subconcussive impacts on an AF player's depressive symptoms. In summary, WAFL players may elicit an increase in depressive symptoms, following recent exposure to concussion. However, it appears subconcussive impacts do not significantly elicit the same emotional response. Recognising AF players may experience emotional changes following concussion, can assist medical staff and coaches with providing education and ongoing care for players, thereby improving the well-being of their players.
