KRYLOV METHODS FOR LOW-RANK REGULARIZATION *

SILVIA GAZZOLA[†], CHANG MENG[‡], AND JAMES G. NAGY[‡]

Abstract. This paper introduces new solvers for the computation of low-rank approximate solutions to large-scale linear problems, with a particular focus on the regularization of linear inverse problems. Although Krylov methods incorporating explicit projections onto low-rank subspaces are already used for well-posed systems that arise from discretizing stochastic or time-dependent PDEs, we are mainly concerned with algorithms that solve the so-called nuclear norm regularized problem, where a suitable nuclear norm penalization on the solution is imposed alongside a fit-to-data term expressed in the 2-norm: this has the effect of implicitly enforcing low-rank solutions. By adopting an iteratively reweighted norm approach, the nuclear norm regularized problem is reformulated as a sequence of quadratic problems, which can then be efficiently solved using Krylov methods, giving rise to an inner-outer iteration scheme. Our approach differs from the other solvers available in the literature in that: (a) Kronecker product properties are exploited to define the reweighted 2-norm penalization terms; (b) efficient preconditioned Krylov methods replace gradient (projection) methods; (c) the regularization parameter can be efficiently and adaptively set along the iterations. Furthermore, we reformulate within the framework of flexible Krylov methods both the new inner-outer methods for nuclear norm regularization and some of the existing Krylov methods incorporating low-rank projections. This results in an even more computationally efficient (but heuristic) strategy, that does not rely on an inner-outer iteration scheme. Numerical experiments including image deblurring, computed tomography and inpainting show that our new solvers are competitive with other state-of-the-art solvers for low-rank problems, and deliver reconstructions of increased quality with respect to other classical Krylov methods.

Key words. low-rank solver, nuclear norm regularization, Krylov methods, flexible Krylov methods, Kronecker product, imaging problems

AMS subject classifications. 65F20, 65F30

1. Introduction. Consider the following linear system

$$(1.1) \quad \mathbf{A}\mathbf{x} = \mathbf{b}, \quad \text{where } \mathbf{A} \in \mathbb{R}^{M \times N}, \mathbf{x} \in \mathbb{R}^N, \mathbf{b} = \mathbf{b}^{\text{ex}} + \boldsymbol{\eta} \in \mathbb{R}^M.$$

We are mainly interested in large-scale linear systems (1.1) arising from inverse problems, where \mathbf{A} is a discretization of the linear forward operator, \mathbf{x} is a quantity of interest, and \mathbf{b} is the observed perturbed data ($\mathbf{b}^{\text{ex}} = \mathbf{A}\mathbf{x}^{\text{ex}}$ being the ideally exact data, and $\boldsymbol{\eta}$ being unknown Gaussian white noise). Our focus is on two-dimensional imaging problems, where the unknown vector $\mathbf{x} \in \mathbb{R}^N$ is obtained by stacking the columns of an unknown true image \mathbf{X} of size $n \times n$, with $n = \sqrt{N}$ (this operation and its inverse are denoted by $\mathbf{x} = \text{vec}(\mathbf{X})$ and $\mathbf{X} = \text{vec}^{-1}(\mathbf{x})$, respectively).

Discrete inverse problems are ill-posed in nature [13] and, because of the presence of noise in (1.1), regularization needs to be applied so that the solution of (1.1) is a meaningful approximation to \mathbf{x}^{ex} . One typically achieves regularization by replacing the original problem (1.1) with a closely related one that is less sensitive to perturbations: effective regularization methods do so by incorporating known or desired properties of \mathbf{x} into the solution process. In imaging applications, Tikhonov (ℓ_2) regularization, ℓ_1 regularization and total variation are typical techniques to be exploited, see, for example, [4, 7, 8, 9, 17]. In the field of geophysics, ℓ_0 regularization (also called compact regularization) is sometimes considered (e.g., [21, 34]).

39 In this paper we consider regularization methods that compute a low-rank approximate solution
 40 $\mathbf{X} = \text{vec}^{-1}(\mathbf{x})$ of (1.1): this is generally meaningful when the unknown \mathbf{x} encodes a high-dimensional
 41 quantity and, in particular, in the case of a two-dimensional image. Indeed, two-dimensional images
 42 are often assumed to have low-rank or to be well-approximated by low-rank two-dimensional arrays
 43 (see [27] and the references therein).

44 Numerical linear algebra solvers for the estimation of low-rank solutions to linear systems
 45 have been developed in the literature, mainly targeting well-posed linear discrete problems, such as
 46 those arising when considering the numerical solution of stochastic PDEs (see [22] and the references
 47 therein). In particular, the authors of [22] devise a restarted GMRES-like method (RS-LR-GMRES)
 48 that involves low-rank projections of the basis vectors of the solution subspace, as well as a low-rank
 49 projection of the current solution at the end of each cycle. Since, in general, the basic operations
 50 involved in standard GMRES (such as matrix-vector products and vector sums) increase the ranks
 51 of the computed quantities, low-rank projections are needed to assure that the computed solution
 52 is low-rank. In the framework of compressive sensing, the authors of [2] consider a modified version
 53 of the conjugate gradient method that incorporates appropriate rank-truncation operations. All
 54 the methods mentioned so far employ, often in a heuristic way, Krylov subspace methods together
 55 with rank-reduction operations (e.g., projections onto a chosen set of low-rank matrices). Since
 56 many Krylov subspace methods are iterative regularization methods for (1.1), this brings us to the
 57 question of how incorporating rank-reduction operations would affect the solution of the discrete
 58 inverse problem (1.1), with a particular focus on imaging applications.

59 Low-rank matrix estimation can be naturally formulated as a nonconvex optimization problem
 60 having either: (i) a least-squares data fitting term as objective function and a rank constraint; (ii)
 61 the rank of $\mathbf{X} = \text{vec}^{-1}(\mathbf{x})$ as objective function and a constraint on the least-squares data fitting
 62 term. The last instance is commonly referred to as *affine rank minimization problem*, and both
 63 formulations are in general NP-hard [27]. In this paper we consider the unconstrained and convex
 64 optimization problem

$$65 \quad (1.2) \quad \min_{\mathbf{x}} \|\mathbf{A}\mathbf{x} - \mathbf{b}\|_2^2 + \lambda \|\text{vec}^{-1}(\mathbf{x})\|_*,$$

66 where $\lambda > 0$ is a regularization parameter and $\|\cdot\|_*$ denotes the nuclear norm of $\text{vec}^{-1}(\mathbf{x}) = \mathbf{X}$,
 67 defined as the sum of the singular values of \mathbf{X} . Indeed, if the singular value decomposition (SVD)
 68 of \mathbf{X} is given by $\mathbf{X} = \mathbf{U}_{\mathbf{X}} \mathbf{\Sigma}_{\mathbf{X}} \mathbf{V}_{\mathbf{X}}^T$, where $\mathbf{U}_{\mathbf{X}}, \mathbf{V}_{\mathbf{X}} \in \mathbb{R}^{n \times n}$ are orthogonal matrices, and $\mathbf{\Sigma}_{\mathbf{X}} \in \mathbb{R}^{n \times n}$
 69 is the diagonal matrix whose diagonal entries are $\sigma_1(\mathbf{X}) \geq \dots \geq \sigma_n(\mathbf{X}) \geq 0$, then

$$70 \quad \|\mathbf{X}\|_* = \sum_{i=1}^n \sigma_i(\mathbf{X}).$$

71 Problem (1.2) is referred to as a *nuclear norm regularized (NNR) problem*. In particular, the nuclear
 72 norm is a convex function that has been proven to be the best convex lower approximation of the
 73 rank function over the set of matrices \mathbf{X} such that $\|\mathbf{X}\|_2 \leq 1$ (see [27] and the references therein).
 74 The nuclear norm has been used in many applications, such as low-rank matrix completion and
 75 compressed sensing; see, e.g., [3, 10, 16, 24, 27], where the constrained formulation of problem (1.2)
 76 has also been considered (note that, for a proper choice of $\lambda > 0$, constrained and unconstrained
 77 formulations are equivalent; see, e.g., [29]). In the framework of compressive sensing, under the
 78 assumption that the matrix \mathbf{A} satisfies a certain null-space property, recovery guarantees for the

79 affine rank minimization problem are proven in [5, 25]. We also consider the following formulation

$$80 \quad (1.3) \quad \min_{\mathbf{x}} \|\mathbf{Ax} - \mathbf{b}\|_2^2 + \lambda \|\text{vec}^{-1}(\mathbf{x})\|_{*,p}, \quad \text{where} \quad \|\mathbf{X}\|_{*,p} = \sum_{i=1}^n (\sigma_i(\mathbf{X}))^p, \quad 0 < p \leq 1.$$

81 Problem (1.3) is referred to as *NNR p problem*, and it generalizes problem (1.2) (which is obtained
82 taking $p = 1$ in (1.3)). The constrained version of (1.3) is already considered in [25], where
83 the authors empirically show an improved recovery performance of the constrained formulation
84 of problem (1.3) with $p < 1$ with respect to $p = 1$. Note, however, that the choice $p < 1$ in (1.3)
85 results in a nonconvex minimization problem.

86 Many different optimization methods, such as singular value thresholding (i.e., projected gradi-
87 ent descent) and continuation methods [10], have been proposed for the solution of problem (1.2) or
88 its constrained counterpart. In particular, the so-called IRLS(- p) (i.e., iteratively reweighted least
89 squares) family of methods has recently attracted a lot of attention [5, 25, 27]. IRLS(- p) solves
90 the affine rank minimization problem by solving a sequence of problems whose objective function
91 only involves an iteratively updated weighted 2-norm term. The authors of [23] apply the IRLS(- p)
92 framework to the unconstrained problem (1.3), requiring the solution of a sequence of sub-problems

$$93 \quad (1.4) \quad \min_{\mathbf{x}} \|\mathbf{Ax} - \mathbf{b}\|_2^2 + \lambda \|\mathbf{W}_k \text{vec}^{-1}(\mathbf{x})\|_F^2,$$

94 where \mathbf{W}_k is an appropriate weight matrix to be employed to solve the k th sub-problem, and $\|\cdot\|_F$
95 denotes the Frobenius norm of a matrix. A gradient (projection) algorithm is typically used to
96 solve each sub-problem (1.4). Since an IRLS(- p) approach is also commonly applied to objective
97 functions involving a quadratic fit-to-data term and a general p -norm penalization on \mathbf{x} , and since
98 efficient strategies based on Krylov methods have been devised to solve each quadratic sub-problem
99 in the IRLS(- p) sequence [28, 30], this brings us to the question of how Krylov methods can be best
100 employed to solve each problem (1.4) (recall that $\|\text{vec}^{-1}(\mathbf{x})\|_{*,p}$ can be regarded as a p -norm of the
101 vector whose entries are the singular values of $\mathbf{X} = \text{vec}^{-1}(\mathbf{x})$).

102 The goal of this paper is to propose new efficient Krylov methods for the estimation of low-rank
103 solutions to (1.1). We will mainly consider an IRLS(- p) approach to problem (1.3) (rather than
104 incorporating low-rank projections into a linear solver for (1.1)), the upside being that low-rank is
105 implicitly enforced into the solution by penalizing the p -norm of the singular values for a suitable
106 choice of λ . Our main contributions are the new IRN-GMRES-NNR p and IRN-LSQR-NNR p meth-
107 ods for (1.3), where automatic strategies for choosing a suitable λ are naturally incorporated. Here
108 and in the following, the IRN acronym indicates an iteratively reweighted norm (rather than an
109 iteratively reweighted least squares problem, [30]). One of the key points in deriving the new meth-
110 ods is expressing in matrix form the invertible linear operator mapping \mathbf{x} to the reweighted 2-norm
111 of the singular values of $\mathbf{X} = \text{vec}^{-1}(\mathbf{x})$: this can be achieved in a computationally affordable way by
112 exploiting Kronecker product properties. Each iteratively reweighted quadratic sub-problem of the
113 form (1.4) can then be expressed as a Tikhonov regularization problem in general form, which can
114 be straightforwardly transformed into standard form. In this way, the inverse of the linear operator
115 mapping \mathbf{x} into the reweighted 2-norm of the singular values of $\mathbf{X} = \text{vec}^{-1}(\mathbf{x})$ formally acts as a
116 preconditioner for \mathbf{A} , and the so-called hybrid methods [26] based on the preconditioned Arnoldi (if
117 \mathbf{A} is square) or Golub-Kahan bidiagonalization algorithms can be used to efficiently approximate
118 the solution of each problem of the form (1.4). Once a hybrid method is adopted, many automatic,
119 adaptive, and efficient parameter choice strategies can be employed to choose a suitable λ ; see [18]
120 for an overview. Therefore, contrarily to many existing methods for (1.3), IRN-GMRES-NNR p and

121 IRN-LSQR-NNR p have the advantage of not requiring a regularization parameter (either λ or the
 122 desired rank of the solution) to be available in advance of the iterations, nor the repeated solution
 123 of (1.3) for different regularization parameters.

124 Although inherently efficient, both the IRN-GMRES-NNR p and IRN-LSQR-NNR p methods
 125 are inner-outer iteration schemes, where each outer iteration requires running a “preconditioned”
 126 Krylov subspace method until convergence (inner iteration) before updating the weights (and there-
 127 fore the “preconditioner”) in the next outer iteration. In order to avoid inner-outer iterations and
 128 with the aim of generating only one approximation subspace for the solution of (1.3), where a new
 129 “preconditioner” is incorporated as soon as a new approximate solution becomes available (i.e., at
 130 each iteration), we propose to solve (1.3) using flexible Krylov subspace methods, such as those based
 131 on the flexible Arnoldi [31] and Golub-Kahan [4] algorithms. The use of flexible Krylov methods for
 132 p -norm regularization of inverse problems was already proposed in [4, 7]; however, differently from
 133 the available solvers, our new approach involves iteratively defining both weights and transform
 134 matrices (i.e., the linear operator mapping $\text{vec}^{-1}(\mathbf{x})$ into its singular values). Switching from IRN-
 135 GMRES-NNR p and IRN-LSQR-NNR p to their flexible counterparts (dubbed FGMRES-NNR p and
 136 FLSQR-NNR p , respectively) allows for savings in computations and, although FGMRES-NNR p
 137 and FLSQR-NNR p are purely heuristic, it leads to approximate solutions whose accuracy on many
 138 test problems is comparable to the ones of other well established solvers for (1.2). Motivated by
 139 the same idea of avoiding inner-outer iteration cycles while adaptively incorporating (low-rank)
 140 information into the approximation subspace for the solution, we also propose a flexible version
 141 of the projected and restarted Krylov subspace methods (such as RS-LR-GMRES, [22]) that were
 142 originally devised for square matrices, considering also extensions to rectangular matrices \mathbf{A} .

143 This paper is organized as follows. In Section 2 we review the available low-rank Krylov methods
 144 for square linear systems and, after surveying the available flexible Krylov solvers, we formulate
 145 new low-rank flexible Krylov solvers for both square and rectangular problems, where the basis
 146 vectors for the approximation subspace are truncated to low-rank. In Section 3 we derive the new
 147 iteratively reweighted methods for (1.3) as fixed-point methods, and we describe how to efficiently
 148 solve each reweighted problem of the form (1.4) using preconditioned Krylov methods: this leads
 149 to the IRN-GMRES-NNR p and IRN-LSQR-NNR p methods; their flexible counterparts (FGMRES-
 150 NNR p and FLSQR-NNR p , respectively) are also derived. Some implementation details, such as
 151 stopping criteria and regularization parameter choice strategies for the new methods, are unfolded
 152 in Section 4. Numerical results on image deblurring, computed tomography and inpainting are
 153 presented in Section 5, including comparisons between the proposed methods, low-rank projection
 154 methods, projected gradient methods, and standard Krylov subspace methods. Conclusions are
 155 drawn in Section 6.

156 *Definitions and notations.* Matching lower and upper case letters are used to denote the
 157 “vectorized” and “matricized” versions of a given quantity, respectively; e.g., $\mathbf{c} = \text{vec}(\mathbf{C})$ and
 158 $\mathbf{C} = \text{vec}^{-1}(\mathbf{c})$. We denote the i th entry of a vector \mathbf{c} by $[\mathbf{c}]_i$, and the (i, j) th entry of a matrix \mathbf{C}
 159 by $[\mathbf{C}]_{ij}$ or, using MATLAB-like notations, $[\mathbf{c}]_i = \mathbf{c}(i)$, $[\mathbf{C}]_{ij} = \mathbf{C}(i, j)$. Using again MATLAB-like
 160 notations, $\mathbf{d} = \text{diag}(\mathbf{C})$ defines a vector \mathbf{d} whose entries are the diagonal elements of a matrix
 161 \mathbf{C} . $\text{Tr}(\mathbf{C})$ denotes the trace of a matrix \mathbf{C} . $\mathcal{R}(\mathbf{C})$ denotes the range (or column space) of a
 162 matrix \mathbf{C} , and $\mathcal{K}_m(\mathbf{A}, \mathbf{b})$ denotes the m -dimensional Krylov subspace defined by \mathbf{A} and \mathbf{b} , i.e.,
 163 $\mathcal{K}_m(\mathbf{A}, \mathbf{b}) = \text{span}\{\mathbf{b}, \mathbf{A}\mathbf{b}, \mathbf{A}^2\mathbf{b}, \dots, \mathbf{A}^{m-1}\mathbf{b}\}$. We denote by $\mathbf{I} \in \mathbb{R}^{d \times d}$ the identity matrix of order
 164 d , and by \mathbf{e}_i the i th canonical basis vector of \mathbb{R}^d , where d should be clear from the context. Note
 165 that, in the following, we will quite often interchange \mathbf{x} and \mathbf{X} and, with a slight abuse of notations,
 166 we will denote the action of a linear operator on \mathbf{x} or \mathbf{X} by $\mathcal{A}(\mathbf{X}) = \mathbf{A}\mathbf{X} = \mathbf{A}\mathbf{x}$, and the action of

167 the adjoint operator by $\mathcal{A}^*(\mathbf{Y}) = \mathcal{A}^*\mathbf{Y} = A^T \text{vec}(\mathbf{Y})$.

168 **2. Low-rank projection methods: classical and new approaches.** As recalled in Section
 169 1, when solving square well-posed linear systems coming from the discretization of some instances
 170 of stochastic or time-dependent PDEs, a suitable rearrangement of the solution is expected to be
 171 low-rank: for this reason, schemes that incorporate low-rank projections within the basis vectors
 172 and the approximate solution obtained by a Krylov method have been proposed in the literature. In
 173 the following we summarize the working ideas underlying the so-called restarted low-rank-projected
 174 GMRES (RS-LR-GMRES) method proposed in [22].

175 The starting points for the derivation of RS-LR-GMRES are the basic properties and relations
 176 underlying GMRES. Indeed, one can define GMRES for the solution of (1.1) with a square
 177 $\mathbf{A} \in \mathbb{R}^{N \times N}$ and initial guess $\mathbf{x}_0 = \mathbf{0}$ by generating a matrix $\mathbf{V}_m = [\mathbf{v}_1, \dots, \mathbf{v}_m] \in \mathbb{R}^{N \times m}$ with or-
 178 thonormal columns, such that $\mathcal{R}(\mathbf{V}_m) = \mathcal{K}_m(\mathbf{A}, \mathbf{b})$, and imposing that the residual $\mathbf{r}_m = \mathbf{b} - \mathbf{A}\mathbf{x}_m$
 179 is orthogonal to $\mathbf{U}_m = \mathbf{A}\mathbf{V}_m$. In practice, at the k th iteration of GMRES, one computes

180 (2.1)
$$\mathbf{u}_k = \mathbf{A}\mathbf{v}_{k-1} \quad \text{and} \quad \|\mathbf{v}_k\|_2 \mathbf{v}_k = (\mathbf{I} - \mathbf{V}_{k-1} \underbrace{(\mathbf{V}_{k-1}^T \mathbf{V}_{k-1})^{-1} \mathbf{V}_{k-1}^T}_{=\mathbf{I}}) \mathbf{u}_k,$$

181 and the approximate solution is computed as

182 (2.2)
$$\mathbf{x}_k = \mathbf{V}_k \mathbf{y}_k, \quad \text{where} \quad (\mathbf{U}_k^T \mathbf{A} \mathbf{V}_k) \mathbf{y}_k = \mathbf{U}_k^T \mathbf{b}.$$

183 This procedure is mathematically equivalent to the somewhat more standard procedure that, at the
 184 k th iteration of GMRES, updates the partial Arnoldi factorization and computes the approximate
 185 solution as follows:

186 (2.3)
$$\mathbf{A}\mathbf{V}_k = \mathbf{V}_{k+1} \mathbf{H}_k, \quad \mathbf{x}_k = \mathbf{V}_k \mathbf{y}_k, \quad \text{where} \quad \mathbf{y}_k = \arg \min_{\mathbf{y} \in \mathbb{R}^k} \|\mathbf{H}_k \mathbf{y} - \|\mathbf{b}\|_2 \mathbf{e}_1\|_2.$$

187 Note that, in particular, the matrix \mathbf{V}_k appearing in (2.2) coincides with the matrix \mathbf{V}_k appearing
 188 in (2.3). However, since matrix-vector products and vector sums of low-rank vectorized matrices
 189 increase the rank of the latter, relations (2.1) and (2.2) obviously do not guarantee that the new
 190 basis vectors \mathbf{v}_k for the solution nor the new solution \mathbf{x}_k are low-rank. To force the basis vector
 191 for the solution and the approximate solution to be low-rank, a truncation operator should be
 192 incorporated into the GMRES algorithm. Given a vectorized matrix $\mathbf{c} = \text{vec}(\mathbf{C})$, and given a
 193 desired low-rank κ for \mathbf{C} , one can define a truncation operator $\tau_\kappa(\mathbf{c})$ by the following standard
 194 operations:

195 (2.4)
$$\begin{cases} 1. & \text{Take } \mathbf{C} = \text{vec}^{-1}(\mathbf{c}); \\ 2. & \text{Compute the SVD of } \mathbf{C}, \mathbf{C} = \mathbf{U}_\mathbf{C} \mathbf{\Sigma}_\mathbf{C} \mathbf{V}_\mathbf{C}^T; \\ 3. & \text{Compute } \mathbf{C}_\kappa = \mathbf{U}_\mathbf{C}(:, 1 : \kappa) \mathbf{\Sigma}_\mathbf{C}(1 : \kappa, 1 : \kappa) \mathbf{V}_\mathbf{C}(:, 1 : \kappa)^T; \\ 4. & \text{Take } \tau_\kappa(\mathbf{c}) = \text{vec}(\mathbf{C}_\kappa). \end{cases}$$

196 RS-LR-GMRES is a restarted version of the standard GMRES method where the basis vectors
 197 for the solution are truncated at each inner iteration, and the solution itself is truncated at the
 198 beginning of each outer iteration. *Note that truncating the basis vectors does not guarantee that
 199 the solution has low rank (which is the reason we still need to truncate the approximate solution).*
 200 *The reason for truncating the basis vectors is to keep the original solution rank from increasing
 201 drastically, since it is computed as a linear combination of basis vectors.* More precisely, at the ℓ th

202 outer iteration of RS-LR-GMRES, one takes $\mathbf{v}_1 = \mathbf{r}_{\ell-1}/\|\mathbf{r}_{\ell-1}\|_2$, where $\mathbf{r}_{\ell-1} = \mathbf{b} - \mathbf{A}\mathbf{x}_{\ell-1}$, and, at
 203 the k th inner iteration, one computes

$$204 \quad (2.5) \quad \mathbf{u}_k = \mathbf{A}\mathbf{v}_{k-1} \quad \text{and} \quad \|\mathbf{v}_k\|_2 \mathbf{v}_k = \tau_\kappa \left((\mathbf{I} - \mathbf{V}_{k-1}(\mathbf{V}_{k-1}^T \mathbf{V}_{k-1})^{-1} \mathbf{V}_{k-1}^T) \mathbf{u}_k \right).$$

205 Once m inner iterations are performed, the approximate solution at the ℓ th outer iteration is
 206 computed as

$$207 \quad (2.6) \quad \mathbf{x}_\ell = \tau_\kappa (\mathbf{x}_{\ell-1} + \mathbf{V}_m \mathbf{y}_m), \quad \text{where} \quad (\mathbf{U}_m^T \mathbf{A} \mathbf{V}_m) \mathbf{y}_m = \mathbf{U}_m^T \mathbf{r}_{\ell-1}.$$

208 The operations in (2.5) and (2.6) heavily depend on the value κ of the truncated rank, which
 209 eventually coincides with the rank of the approximate solution. In the framework of stochastic
 210 PDEs, a suitable estimate for κ can be obtained by first performing coarse-grid computations (see
 211 [22] for details, and [19, 33] for similar approaches). Comparing (2.5) and (2.1) one can see that,
 212 as in standard GMRES, RS-LR-GMRES computes a new basis vector for the solution by applying
 213 the linear operator \mathbf{A} to the previous basis vector \mathbf{v}_{k-1} and orthogonalizing it against the previous
 214 basis vectors \mathbf{v}_i , $i = 1, \dots, k-1$. However, since the basis vectors are truncated to low rank,
 215 the matrix \mathbf{V}_k does not have orthonormal columns anymore, and $\mathcal{R}(\mathbf{V}_m)$ is not a Krylov subspace
 216 anymore. This remark leads us to the derivation of alternative low-rank projection solvers, which
 217 can be (re)casted into the framework of flexible Krylov methods and can work with both square
 218 and rectangular systems (1.1).

219 *Low-rank flexible GMRES (LR-FGMRES) and low-rank flexible LSQR (LR-FLSQR).* Flexible
 220 Krylov methods are a class of linear solvers that can handle iteration-dependent preconditioners:
 221 they were originally introduced in [31] for FGMRES, where a preconditioner for GMRES was al-
 222 lowed to change from one iteration to the next (either because at each iteration the preconditioner
 223 is implicitly defined by applying an iterative linear solver, or because the preconditioner can be
 224 updated with newly-computed information; see [32] for an overview). In the framework of regular-
 225 izing linear solvers, flexible Krylov methods were proposed in [4, 7, 9], where the iteration-dependent
 226 “preconditioner” was associated to an iteratively reweighted norm approach to Tikhonov-like reg-
 227 ularized problems involving penalization terms expressed in some p -norm, $0 < p \leq 1$ (and, indeed,
 228 these “preconditioners” have the effect of enforcing specific regularity into the approximation sub-
 229 space for the solution, rather than accelerating the convergence of the iterative solvers). Leveraging
 230 flexible Krylov subspaces in this setting comes with the upside of avoiding restarts of the itera-
 231 tive solver, which is the approach commonly used when adopting an iteratively reweighted norm
 232 method. When considering low-rank projections of the basis vectors within RS-LR-GMRES, we
 233 enforce the basis vectors to have low-rank, so to better reproduce available information about the
 234 solution of (1.1) (i.e., the solution should be low-rank). It is therefore natural to consider flexible
 235 Krylov methods that involve truncation of the basis vectors at each iteration, as a computationally
 236 cheaper alternative to RS-LR-GMRES that does not involve restarts.

237 Considering first the case of a square $\mathbf{A} \in \mathbb{R}^{N \times N}$, we can use the flexible Arnoldi algorithm
 238 [31] to naturally incorporate low-rank basis vectors for the solution of (1.1). In general, starting
 239 with $\mathbf{x}_0 = \mathbf{0}$, at the k th iteration, FGMRES updates a partial flexible Arnoldi factorization and
 240 computes the k th approximate solution as follows:

$$241 \quad (2.7) \quad \mathbf{A}\mathbf{Z}_k = \mathbf{V}_{k+1}\mathbf{H}_k, \quad \mathbf{x}_k = \mathbf{Z}_k \mathbf{y}_k, \quad \text{where} \quad \mathbf{y}_k = \arg \min_{\mathbf{y} \in \mathbb{R}^k} \|\mathbf{H}_k \mathbf{y} - \|\mathbf{b}\|_2 \mathbf{e}_1\|_2,$$

242 where $\mathbf{V}_{k+1} = [\mathbf{v}_1, \dots, \mathbf{v}_{k+1}] \in \mathbb{R}^{N \times (k+1)}$ has orthonormal columns, $\mathbf{H}_k \in \mathbb{R}^{(k+1) \times k}$ is upper
 243 Hessenberg, and $\mathbf{Z}_k = [\mathbf{P}_1 \mathbf{v}_1, \dots, \mathbf{P}_k \mathbf{v}_k] \in \mathbb{R}^{N \times k}$ has columns that span the approximation subspace

244 for the solution (\mathbf{P}_i is an iteration-dependent preconditioner that is applied to \mathbf{v}_i and, in the
 245 particular case of low-rank truncation, $\mathbf{P}_i \mathbf{v}_i = \tau_{\kappa_B}(\mathbf{v}_i)$, is the truncation operator defined in (2.4),
 246 so that $\text{rank}(\text{vec}^{-1}(\mathbf{Z}_k \mathbf{e}_i)) = \kappa_B$, $i = 1, \dots, k$). The subscript B for the truncation rank κ_B
 247 suggests that the truncation is done on the original basis vectors \mathbf{v}_i 's. The resulting algorithm
 248 is dubbed ‘‘LR-FGMRES’’, and it is summarized in Algorithm 2.1. Note that the approximate
 249 solution computed as in (2.7) is also truncated to guarantee rank κ (in general, we assume $\kappa_B \neq \kappa$).
 250 Also LR-FGMRES is started with $\mathbf{x}_0 = \mathbf{0}$, to guarantee that the basis vectors for the solution
 251 (rather than a correction thereof) are low-rank.

Algorithm 2.1 LR-FGMRES

- 1: Inputs: \mathbf{A} , \mathbf{b} , τ_{κ_B} , τ_{κ}
 - 2: Take $\mathbf{v}_1 = \mathbf{b} / \|\mathbf{b}\|_2$
 - 3: **for** $i = 1, 2, \dots$ until a stopping criterion is satisfied **do**
 - 4: Compute $\mathbf{z}_i = \tau_{\kappa_B}(\mathbf{v}_i)$ and $\mathbf{w} = \mathbf{A}\mathbf{z}_i$
 - 5: Compute $h_{ji} = \mathbf{w}^T \mathbf{v}_j$ for $j = 1, \dots, i$ and set $\mathbf{w} = \mathbf{w} - \sum_{j=1}^i h_{ji} \mathbf{v}_j$
 - 6: Compute $h_{i+1,i} = \|\mathbf{w}\|_2$, and if $h_{j+1,j} \neq 0$, take $\mathbf{v}_{i+1} = \mathbf{w} / h_{i+1,i}$
 - 7: **end for**
 - 8: Compute $\mathbf{y}_k = \arg \min_{\mathbf{y}} \|\mathbf{H}_k \mathbf{y} - \mathbf{b}\|_2 \mathbf{e}_1\|_2^2$ and take $\mathbf{x}_k = \tau_{\kappa}(\mathbf{Z}_k \mathbf{y}_k)$
-

252 A few remarks are in order. Differently from the k th iteration in the inner cycle of the RS-
 253 LR-GMRES method (2.5), the k th iteration of LR-FGMRES expands the approximation subspace
 254 by modifying (i.e., truncating) the previous orthonormal basis vector for the space $\mathcal{R}([\mathbf{b}, \mathbf{A}\mathbf{Z}_k])$.
 255 Analogously to RS-LR-GMRES, the basis vectors for the approximate LR-FGMRES solution are
 256 all of rank κ_B , are not orthogonal, and do not span a Krylov subspace. Differently from RS-LR-
 257 GMRES, the basis vector for the space $\mathcal{R}([\mathbf{b}, \mathbf{A}\mathbf{Z}_k])$ are orthogonal. Also, the k th LR-FGMRES
 258 approximate solution is obtained by solving an order- k projected least squares problem that is
 259 formally analogous to the GMRES one (see (2.3) and (2.7)).

260 With LR-FGMRES in place, the extension to more general matrices $\mathbf{A} \in \mathbb{R}^{M \times N}$, with M
 261 not necessarily equal to N , can be naturally devised considering the flexible Golub-Kahan (FGK)
 262 process [4]. Taking $\mathbf{x}_0 = \mathbf{0}$ as initial guess, the k th FGK iteration updates partial factorizations
 263 of the form

264 (2.8)
$$\mathbf{A}\mathbf{Z}_k = \mathbf{U}_{k+1}\mathbf{M}_k \text{ and } \mathbf{A}^T\mathbf{U}_{k+1} = \mathbf{V}_{k+1}\mathbf{T}_{k+1},$$

265 where the columns of $\mathbf{U}_{k+1} \in \mathbb{R}^{M \times (k+1)}$, $\mathbf{V}_{k+1} \in \mathbb{R}^{N \times (k+1)}$ are orthonormal, $\mathbf{M}_k \in \mathbb{R}^{(k+1) \times k}$ is
 266 upper Hessenberg, $\mathbf{T}_{k+1} \in \mathbb{R}^{(k+1) \times (k+1)}$ is upper triangular, and $\mathbf{Z}_k = [\mathbf{P}_1 \mathbf{v}_1, \dots, \mathbf{P}_k \mathbf{v}_k] \in \mathbb{R}^{N \times k}$
 267 has columns that span the approximation subspace for the solution (\mathbf{P}_i is an iteration-dependent
 268 preconditioner that is applied to \mathbf{v}_i and, in the particular case of low-rank truncation, $\mathbf{P}_i \mathbf{v}_i =$
 269 $\tau_{\kappa_B}(\mathbf{v}_i)$, as defined in (2.4), so that $\text{rank}(\text{vec}^{-1}(\mathbf{Z}_k \mathbf{e}_i)) = \kappa_B$, $i = 1, \dots, k$). The flexible LSQR
 270 method (FLSQR) uses the FGK process (2.8) to generate iterates of the form $\mathbf{x}_k = \mathbf{Z}_k \mathbf{y}_k$, where
 271 the vector \mathbf{y}_k is computed as $\mathbf{y}_k = \arg \min_{\mathbf{y}} \|\mathbf{M}_k \mathbf{y} - \mathbf{b}\|_2 \mathbf{e}_1\|_2^2$. When rank-truncation of the basis
 272 vectors takes place at each iteration, and the final approximate solution is rank-truncated as well,
 273 the resulting algorithm is dubbed ‘‘LR-FLSQR’’, and it is summarized in Algorithm 2.2. Note that,
 274 similarly to RS-LR-GMRES, both LR-FGMRES and LR-FLSQR are quite heuristic. Although the
 275 low-rank projection idea can be formulated in the flexible framework, we lack a formal formulation of

Algorithm 2.2 LR-FLSQR

-
- 1: Inputs: \mathbf{A} , \mathbf{b} , τ_{κ_B} , τ_κ
 - 2: Take $\mathbf{u}_1 = \mathbf{b}/\|\mathbf{b}\|_2$
 - 3: **for** $i = 1, 2, \dots$, until a stopping criterion is satisfied **do**
 - 4: Compute $\mathbf{w} = \mathbf{A}^T \mathbf{u}_i$, $t_{ji} = \mathbf{w}^T \mathbf{v}_j$ for $j = 1, \dots, i-1$
 - 5: Set $\mathbf{w} = \mathbf{w} - \sum_{j=1}^{i-1} t_{ji} \mathbf{v}_j$, compute $t_{ii} = \|\mathbf{w}\|$ and take $\mathbf{v}_i = \mathbf{w}/t_{ii}$
 - 6: Compute $\mathbf{z}_i = \tau_{\kappa_B}(\mathbf{v}_i)$ and $\mathbf{w} = \mathbf{A} \mathbf{z}_i$
 - 7: Compute $m_{ji} = \mathbf{w}^T \mathbf{u}_j$ for $j = 1, \dots, i$ and set $\mathbf{w} = \mathbf{w} - \sum_{j=1}^i m_{ji} \mathbf{u}_j$
 - 8: Compute $m_{i+1,i} = \|\mathbf{w}\|$ and take $\mathbf{u}_{i+1} = \mathbf{w}/m_{i+1,i}$
 - 9: **end for**
 - 10: Compute $\mathbf{y}_k = \arg \min_{\mathbf{y}} \|\mathbf{M}_k \mathbf{y} - \mathbf{b}\|_2 \|\mathbf{e}_1\|_2^2$ and take $\mathbf{x}_k = \tau_\kappa(\mathbf{Z}_k \mathbf{y}_k)$
-

276 the problem that is being solved, and also a justification of why they work. Strategies for selecting
 277 κ_B and κ are not so clear either. To stabilize the behavior of LR-FGMRES as the iterations
 278 proceed, one may consider imposing additional Tikhonov regularization on the projected least-
 279 squares problem in (2.7), in a hybrid fashion; the same holds for LR-FLSQR (see Sections 3.3 and
 280 5 for more details).

281 **3. Proposed Method.** In this section, we first derive the IRN method for the solution of the
 282 NNR p problem (1.3). The starting point for our derivations is the approximation of the nondifferent-
 283 tiable nuclear norm regularizer by a smooth Schatten function (similarly to what is proposed in [25]
 284 for the affine rank minimization problem). The optimality conditions associated to the smoothed
 285 problem give rise to a nonlinear system of equations in \mathbf{X} , which is handled by a fixed-point it-
 286 eration scheme. We show that each iteration amounts to the solution of a Tikhonov-regularized
 287 problem involving an iteratively reweighted 2-norm regularization term, which can be efficiently
 288 solved employing “preconditioned” Krylov methods. Flexible Krylov methods are introduced to
 289 approximate the solution of the IRN problem within only one adaptively defined approximation
 290 subspace for the solution, bypassing the inner-outer iteration scheme required by standard Krylov
 291 methods.

292 **3.1. Derivation.** Define the smooth Schatten- p function as

$$293 \quad \mathcal{S}_p^\gamma(\mathbf{X}) = \text{Tr}((\mathbf{X}^T \mathbf{X} + \gamma \mathbf{I})^{p/2}), \quad \text{with } \gamma > 0.$$

294 Note that $\mathcal{S}_p^\gamma(\mathbf{X})$ is differentiable for $p > 0$ and convex for $p \geq 1$. In particular, for $p = 1$ and $\gamma = 0$
 295 (i.e., no smoothing),

$$296 \quad \mathcal{S}_1^0(\mathbf{X}) = \text{Tr}((\mathbf{X}^T \mathbf{X})^{1/2}) = \|\mathbf{X}\|_*.$$

297 We start by considering the following smooth approximation to (1.3):

$$298 \quad (3.1) \quad \min_{\mathbf{X} \in \mathbb{R}^{n \times n}} \|\mathcal{A}(\mathbf{X}) - \mathbf{B}\|_F^2 + \lambda \mathcal{S}_p^\gamma(\mathbf{X}).$$

299 The following derivations are valid for $p > 0$ (and we keep them generic, being aware that $p = 1$
 300 approximates (1.2)). The optimality conditions associated to (3.1) read

$$301 \quad 0 = \nabla_{\mathbf{X}} (\|\mathcal{A}(\mathbf{X}) - \mathbf{B}\|_F^2 + \lambda \mathcal{S}_p^\gamma(\mathbf{X}))$$

$$302 \quad (3.2) \quad = 2\mathcal{A}^*(\mathcal{A}(\mathbf{X}) - \mathbf{B}) + \lambda p (\mathbf{X} \mathbf{X}^T + \gamma \mathbf{I})^{p/2-1} \mathbf{X},$$

303 where we have used that

$$304 \quad \nabla_{\mathbf{X}} \text{Tr}((\mathbf{X}^T \mathbf{X} + \gamma \mathbf{I})^{p/2}) = p \mathbf{X} (\mathbf{X}^T \mathbf{X} + \gamma \mathbf{I})^{p/2-1} = p (\mathbf{X} \mathbf{X}^T + \gamma \mathbf{I})^{p/2-1} \mathbf{X}.$$

305 Equivalently, the nonlinear system of equations (3.2) with respect to \mathbf{X} can be expressed as

$$306 \quad \mathbf{X} = \left(\mathcal{A}^* \mathcal{A} + \hat{\lambda} (\mathbf{X} \mathbf{X}^T + \gamma \mathbf{I})^{p/2-1} \right)^{-1} \mathcal{A}^* \mathbf{B}$$

$$307 \quad = \left(\mathcal{A}^* \mathcal{A} + \hat{\lambda} ((\mathbf{X} \mathbf{X}^T + \gamma \mathbf{I})^{p/4-1/2})^T (\mathbf{X} \mathbf{X}^T + \gamma \mathbf{I})^{p/4-1/2} \right)^{-1} \mathcal{A}^* \mathbf{B}, \quad \text{with } \hat{\lambda} = \lambda p/2,$$

308 which is naturally associated to the following fixed-point iteration scheme

$$309 \quad (3.3) \quad \mathbf{X}_{k+1} = \left(\mathcal{A}^* \mathcal{A} + \hat{\lambda} ((\mathbf{X}_k \mathbf{X}_k^T + \gamma \mathbf{I})^{p/4-1/2})^T (\mathbf{X}_k \mathbf{X}_k^T + \gamma \mathbf{I})^{p/4-1/2} \right)^{-1} \mathcal{A}^* \mathbf{B},$$

310 which leads to the solution of (3.1). Equivalently,

$$311 \quad \mathbf{X}_{k+1} = \arg \min_{\mathbf{X}} \left\| \begin{bmatrix} \mathcal{A} \\ \sqrt{\hat{\lambda}} (\mathbf{X}_k \mathbf{X}_k^T + \gamma \mathbf{I})^{p/4-1/2} \end{bmatrix} \mathbf{X} - \begin{bmatrix} \mathbf{B} \\ \mathbf{0} \end{bmatrix} \right\|_F^2,$$

312 i.e., (3.3) are the normal equations associated to the penalized least squares problem written above
313 or, equivalently,

$$314 \quad (3.4) \quad \mathbf{X}_{k+1} = \arg \min_{\mathbf{X}} \|\mathcal{A} \mathbf{X} - \mathbf{B}\|_F^2 + \hat{\lambda} \left\| (\mathbf{X}_k \mathbf{X}_k^T + \gamma \mathbf{I})^{p/4-1/2} \mathbf{X} \right\|_F^2.$$

315 We now reformulate problem (3.4) in vectorial form.

316 Let $\mathbf{U}_{\mathbf{X}_k} \boldsymbol{\Sigma}_{\mathbf{X}_k} \mathbf{V}_{\mathbf{X}_k}^T = \mathbf{X}_k$ be the SVD of \mathbf{X}_k ; thanks to the invariance of the Frobenius norm
317 under orthogonal transformations, the regularization term in the above problem can be rewritten
318 as

$$319 \quad \left\| (\mathbf{X}_k \mathbf{X}_k^T + \gamma \mathbf{I})^{p/4-1/2} \mathbf{X} \right\|_F^2 = \left\| \mathbf{U}_{\mathbf{X}_k} (\boldsymbol{\Sigma}_{\mathbf{X}_k}^2 + \gamma \mathbf{I})^{p/4-1/2} \mathbf{U}_{\mathbf{X}_k}^T \mathbf{X} \right\|_F^2 = \left\| (\boldsymbol{\Sigma}_{\mathbf{X}_k}^2 + \gamma \mathbf{I})^{p/4-1/2} \mathbf{U}_{\mathbf{X}_k}^T \mathbf{X} \mathbf{V}_{\mathbf{X}_k} \right\|_F^2.$$

320 Using well-known Kronecker product properties

$$321 \quad \left\| (\boldsymbol{\Sigma}_{\mathbf{X}_k}^2 + \gamma \mathbf{I})^{p/4-1/2} \mathbf{U}_{\mathbf{X}_k}^T \mathbf{X} \mathbf{V}_{\mathbf{X}_k} \right\|_F^2 = \left\| \text{vec} \left((\boldsymbol{\Sigma}_{\mathbf{X}_k}^2 + \gamma \mathbf{I})^{p/4-1/2} \mathbf{U}_{\mathbf{X}_k}^T \mathbf{X} \mathbf{V}_{\mathbf{X}_k} \right) \right\|_2^2$$

$$322 \quad = \left\| \left(\mathbf{V}_{\mathbf{X}_k}^T \otimes \left((\boldsymbol{\Sigma}_{\mathbf{X}_k}^2 + \gamma \mathbf{I})^{p/4-1/2} \mathbf{U}_{\mathbf{X}_k}^T \right) \right) \mathbf{x} \right\|_2^2 = \left\| \left(\mathbf{I} \otimes (\boldsymbol{\Sigma}_{\mathbf{X}_k}^2 + \gamma \mathbf{I})^{p/4-1/2} \right) (\mathbf{V}_{\mathbf{X}_k}^T \otimes \mathbf{U}_{\mathbf{X}_k}^T) \mathbf{x} \right\|_2^2.$$

323 Problem (3.4) is therefore equivalent to

$$324 \quad (3.5) \quad \mathbf{x}_{k+1} = \arg \min_{\mathbf{x}} \|\mathbf{A} \mathbf{x} - \mathbf{b}\|_2^2 + \hat{\lambda} \underbrace{\left(\mathbf{I} \otimes (\boldsymbol{\Sigma}_{\mathbf{X}_k}^2 + \gamma \mathbf{I})^{p/4-1/2} \right)}_{=:(\mathbf{W}_p^\gamma)_k} \overbrace{(\mathbf{V}_{\mathbf{X}_k}^T \otimes \mathbf{U}_{\mathbf{X}_k}^T)}^{=:\mathbf{S}_k} \mathbf{x} \|_2^2.$$

325 In the above formulation, $(\mathbf{W}_p^\gamma)_k$ is a diagonal weighting matrix and \mathbf{S}_k is an orthogonal matrix;
326 both $(\mathbf{W}_p^\gamma)_k$ and \mathbf{S}_k depend on the current approximation \mathbf{x}_k of the solution \mathbf{x} . Intuitively, the

327 matrix \mathbf{S}_k maps \mathbf{x} into the “singular value domain” of \mathbf{X}_k (and acts as an iteration-dependent
 328 sparsity transform), and the matrix $(\mathbf{W}_p^\gamma)_k$ assigns suitable weights that allow to approximate a
 329 p -norm of the singular values. Therefore, the penalization term in (3.5) can be interpreted as a
 330 reweighted vectorial 2-norm, with respect to a transformation of the solution \mathbf{x} . For this reason,
 331 the proposed approach is dubbed “IRN-NNR $_p$ ” and is summarized in Algorithm 3.1.

Algorithm 3.1 IRN-NNR $_p$

- 1: Inputs: \mathbf{A} , \mathbf{b} , $(\mathbf{W}_p^\gamma)_0 = \mathbf{I}$, $\mathbf{S}_0 = \mathbf{I}$
 - 2: **for** $k = 0, 1, \dots$ until a stopping criterion is satisfied **do**
 - 3: Solve problem (3.5)
 - 4: “Decrease” γ
 - 5: Update $(\mathbf{W}_p^\gamma)_{k+1}$ and \mathbf{S}_{k+1}
 - 6: **end for**
-

332 The next subsection derives new strategies for the efficient solution of the sequence of sub-
 333 problems (3.5) appearing in Algorithm 3.1.

334 **3.2. Solution of problem (3.5) via Krylov methods.** First rewrite problem (3.5) using
 335 an appropriate change of variable as

$$336 \quad (3.6) \quad \hat{\mathbf{x}}_{k+1} = \arg \min_{\hat{\mathbf{x}}} \|\mathbf{A}\mathbf{S}_k^T (\mathbf{W}_p^\gamma)_k^{-1} \hat{\mathbf{x}} - \mathbf{b}\|_2^2 + \hat{\lambda} \|\hat{\mathbf{x}}\|_2^2, \text{ with } \hat{\mathbf{x}} = (\mathbf{W}_p^\gamma)_k \mathbf{S}_k \mathbf{x}.$$

337 Note that

$$338 \quad (3.7) \quad \mathbf{S}_k^T = \mathbf{S}_k^{-1} = \mathbf{V}_{\mathbf{X}_k} \otimes \mathbf{U}_{\mathbf{X}_k} \quad \text{and} \quad (\mathbf{W}_p^\gamma)_k^{-1} = \mathbf{I} \otimes (\boldsymbol{\Sigma}_{\mathbf{X}_k}^2 + \gamma \mathbf{I})^{1/2-p/4},$$

339 so that the above transformations (inversion of an orthogonal and a diagonal matrix) are numeri-
 340 cally affordable by exploiting properties of Kronecker products. The Tikhonov-regularized problem
 341 (3.6) in standard form is equivalent to the Tikhonov-regularized problem (3.5) in general form.
 342 Many Krylov subspace methods based on the Golub-Kahan Bidiagonalization (GKB) or Arnoldi
 343 algorithms can be employed to approximate the solution of (3.6). Moreover, if the regularization
 344 parameter $\hat{\lambda}$ is not known a priori, many efficient strategies to set its value adaptively within the
 345 sequence of projected problems can be used (i.e., in the framework of hybrid methods; see [18, 8]).
 346 The matrices \mathbf{S}_k and $(\mathbf{W}_p^\gamma)_k^{-1}$ can be formally thought of as preconditioners for the original problem
 347 (1.1), whose purpose is to enforce additional regularization into the solution subspace, rather than
 348 speeding-up the convergence of linear solvers applied to (1.1).

349 *Methods based on the GKB algorithm.* The m th step of the GKB algorithm applied to the
 350 matrix $\mathbf{A}\mathbf{S}_k^T (\mathbf{W}_p^\gamma)_k^{-1}$ with starting vector \mathbf{b} (i.e., taking $\mathbf{x}_0 = \mathbf{0}$) can be expressed by the following
 351 partial matrix factorizations

$$352 \quad (3.8) \quad (\mathbf{A}\mathbf{S}_k^T (\mathbf{W}_p^\gamma)_k^{-1}) \mathbf{V}_m = \mathbf{U}_{m+1} \bar{\mathbf{B}}_m \quad \text{and} \quad ((\mathbf{W}_p^\gamma)_k^{-1} \mathbf{S}_k \mathbf{A}^T) \mathbf{U}_{m+1} = \mathbf{V}_{m+1} \mathbf{B}_{m+1}^T,$$

353 where $\mathbf{U}_j \in \mathbb{R}^{M \times j}$ and $\mathbf{V}_j \in \mathbb{R}^{N \times j}$ (with $j = m, m+1$ and $\mathbf{U}_j \mathbf{e}_1 = \mathbf{b} / \|\mathbf{b}\|_2$) have orthonormal
 354 columns, and $\mathbf{B}_{m+1} \in \mathbb{R}^{(m+1) \times (m+1)}$ is lower bidiagonal (with $\bar{\mathbf{B}}_m$ obtained by removing the last
 355 column of \mathbf{B}_{m+1}). The orthonormal columns of \mathbf{V}_m are such that

$$356 \quad \mathcal{R}(\mathbf{V}_m) = \mathcal{K}_m \left(((\mathbf{W}_p^\gamma)_k^{-1} \mathbf{S}_k \mathbf{A}^T) (\mathbf{A}\mathbf{S}_k^T (\mathbf{W}_p^\gamma)_k^{-1}), ((\mathbf{W}_p^\gamma)_k^{-1} \mathbf{S}_k \mathbf{A}^T) \mathbf{b} \right).$$

357 We find an approximate solution of (3.6) by imposing $\hat{\mathbf{x}} \in \mathcal{R}(\mathbf{V}_m)$, i.e., $\hat{\mathbf{x}}_m = \mathbf{V}_m \mathbf{y}_m$, where, by
 358 exploiting the first decomposition in (3.8) and the properties of the matrices appearing therein,
 359 $\mathbf{y}_m \in \mathbb{R}^m$ is such that

$$360 \quad (3.9) \quad \mathbf{y}_m = \arg \min_{\mathbf{y} \in \mathbb{R}^m} \|\bar{\mathbf{B}}_m \mathbf{y} - \|\mathbf{b}\|_2 \mathbf{e}_1\|_2^2 + \hat{\lambda}_m \|\mathbf{y}\|_2^2.$$

361 We used the notation $\hat{\lambda}_m$ for the regularization parameter to highlight that its value can be adap-
 362 tively set within the iterations. The approximate solution to problem (3.5) is such that

$$363 \quad (3.10) \quad \mathbf{x} = \mathbf{S}_k^T (\mathbf{W}_p^\gamma)_k^{-1} \hat{\mathbf{x}} \in \mathcal{K}_m \left((\mathbf{S}_k^T (\mathbf{W}_p^\gamma)_k^{-2} \mathbf{S}_k) \mathbf{A}^T \mathbf{A}, (\mathbf{S}_k^T (\mathbf{W}_p^\gamma)_k^{-2} \mathbf{S}_k) \mathbf{A}^T \mathbf{b} \right).$$

364 Looking at the above approximation subspace for the solution \mathbf{x} , it is evident that the “precondi-
 365 tioner” acts by first mapping into the “singular value domain” (by applying \mathbf{S}_k), enforcing sparsity
 366 in the singular values (by reweighting with $(\mathbf{W}_p^\gamma)_k^{-2}$), and eventually transforming back into the
 367 “solution domain” (by applying \mathbf{S}_k^T).

368 *Methods based on the Arnoldi algorithm.* If \mathbf{A} is square, the m th step of the Arnoldi algorithm
 369 applied to the matrix $\mathbf{A} \mathbf{S}_k^T (\mathbf{W}_p^\gamma)_k^{-1}$ with starting vector \mathbf{b} (i.e., taking $\mathbf{x}_0 = \mathbf{0}$) can be expressed
 370 by the following partial matrix factorization

$$371 \quad (3.11) \quad (\mathbf{A} \mathbf{S}_k^T (\mathbf{W}_p^\gamma)_k^{-1}) \mathbf{V}_m = \mathbf{V}_{m+1} \mathbf{H}_m,$$

372 where $\mathbf{V}_j \in \mathbb{R}^{N \times j}$ (with $j = m, m+1$ and $\mathbf{V}_j \mathbf{e}_1 = \mathbf{b} / \|\mathbf{b}\|_2$) have orthonormal columns such that

$$373 \quad \mathcal{R}(\mathbf{V}_m) = \mathcal{K}_m (\mathbf{A} \mathbf{S}_k^T (\mathbf{W}_p^\gamma)_k^{-1}, \mathbf{b}),$$

and $\mathbf{H}_m \in \mathbb{R}^{(m+1) \times m}$ is upper Hessenberg. Similarly to the GKB case, we find an approximate
 solution of (3.6) by imposing $\hat{\mathbf{x}} \in \mathcal{R}(\mathbf{V}_m)$ and by solving a projected Tikhonov problem of order m .
 The approximate solution to problem (3.5) is such that

$$\mathbf{x} = \mathbf{S}_k^T (\mathbf{W}_p^\gamma)_k^{-1} \hat{\mathbf{x}} \in \mathbf{S}_k^T (\mathbf{W}_p^\gamma)_k^{-1} \mathcal{K}_m (\mathbf{A} \mathbf{S}_k^T (\mathbf{W}_p^\gamma)_k^{-1}, \mathbf{b}),$$

374 where

$$375 \quad \mathbf{S}_k^T (\mathbf{W}_p^\gamma)_k^{-1} \mathcal{K}_m (\mathbf{A} \mathbf{S}_k^T (\mathbf{W}_p^\gamma)_k^{-1}, \mathbf{b}) = \text{span} \{ \mathbf{S}_k^T (\mathbf{W}_p^\gamma)_k^{-1} \mathbf{b}, \dots, (\mathbf{S}_k^T (\mathbf{W}_p^\gamma)_k^{-1} \mathbf{A})^{m-1} \mathbf{S}_k^T (\mathbf{W}_p^\gamma)_k^{-1} \mathbf{b} \}$$

$$376 \quad = \mathcal{K}_m (\mathbf{S}_k^T (\mathbf{W}_p^\gamma)_k^{-1} \mathbf{A}, \mathbf{S}_k^T (\mathbf{W}_p^\gamma)_k^{-1} \mathbf{b}).$$

377 Contrarily to the GKB case, we immediately notice that, **in this context**, \mathbf{x} does not belong to a
 378 meaningful approximation subspace. Indeed, just by looking at the first vector: \mathbf{b} is in the image
 379 space and $(\mathbf{W}_p^\gamma)_k^{-1}$ is supposed to act on the singular value space of \mathbf{X}_k , so $(\mathbf{W}_p^\gamma)_k^{-1} \mathbf{b}$ is hard to
 380 interpret; furthermore, \mathbf{S}_k^T is supposed to link the singular value space of \mathbf{X}_k to the image space,
 381 so $\mathbf{S}_k^T (\mathbf{W}_p^\gamma)_k^{-1} \mathbf{b}$ is also hard for us to interpret. **Although the generated solution subspace is not**
 382 **meaningful for our applications, it may still have the potential to be a good subspace in other**
 383 **contexts.** Similarly to what is proposed in [1, 4], where the Arnoldi algorithm is applied to a
 384 regularized problem that enforces sparsity in the wavelet domain, we propose to fix this issue by
 385 incorporating \mathbf{S}_k also as an orthogonal left “preconditioner” for the original system (1.1) so that, by
 386 exploiting the invariance of the vectorial 2-norm under orthogonal transformations, problem (3.6)
 387 can be equivalently reformulated as

$$388 \quad (3.12) \quad \hat{\mathbf{x}}_{k+1} = \arg \min_{\hat{\mathbf{x}}} \|\mathbf{S}_k (\mathbf{A} \mathbf{S}_k^T (\mathbf{W}_p^\gamma)_k^{-1} \hat{\mathbf{x}} - \mathbf{b})\|_2^2 + \hat{\lambda} \|\hat{\mathbf{x}}\|_2^2, \text{ with } \hat{\mathbf{x}} = (\mathbf{W}_p^\gamma)_k \mathbf{S}_k \mathbf{x}.$$

389 The (right and left) preconditioned Arnoldi algorithm applied to problem (3.12) can now be ex-
 390 pressed by the following partial matrix factorization

$$391 \quad (3.13) \quad (\mathbf{S}_k \mathbf{A} \mathbf{S}_k^T (\mathbf{W}_p^\gamma)^{-1}) \mathbf{V}_m = \mathbf{V}_{m+1} \mathbf{H}_m.$$

392 We find an approximate solution of (3.12) by imposing $\hat{\mathbf{x}} \in \mathcal{R}(\mathbf{V}_m) = \mathcal{K}_m(\mathbf{S}_k \mathbf{A} \mathbf{S}_k^T \mathbf{W}^{-1}, \mathbf{S}_k \mathbf{b})$, i.e.,
 393 $\hat{\mathbf{x}}_m = \mathbf{V}_m \mathbf{y}_m$, where, by exploiting (3.13) and the properties of the matrices appearing therein,
 394 $\mathbf{y}_m \in \mathbb{R}^m$ is such that

$$395 \quad (3.14) \quad \mathbf{y}_m = \arg \min_{\mathbf{y} \in \mathbb{R}^m} \|\mathbf{H}_m \mathbf{y} - \|\mathbf{b}\|_2 \mathbf{e}_1\|_2^2 + \hat{\lambda}_m \|\mathbf{y}\|_2^2.$$

396 Hence

$$397 \quad (3.15) \quad \mathbf{x} \in \mathbf{S}_k^T (\mathbf{W}_p^\gamma)^{-1} \mathcal{K}_m(\mathbf{S}_k \mathbf{A} \mathbf{S}_k^T (\mathbf{W}_p^\gamma)^{-1}, \mathbf{S}_k \mathbf{b}) = \mathcal{K}_m(\mathbf{S}_k^T (\mathbf{W}_p^\gamma)^{-1} \mathbf{S}_k \mathbf{A}, \mathbf{S}_k^T (\mathbf{W}_p^\gamma)^{-1} \mathbf{S}_k \mathbf{b}),$$

398 which is suitable for approximating the solution. The new methods based on the GKB algorithm
 399 (for generic matrices) and Arnoldi algorithm (only if $\mathbf{A} \in \mathbb{R}^{N \times N}$) are dubbed “IRN-LSQR-NNR p ”
 400 and “IRN-GMRES-NNR p ”, respectively, and are summarized in Algorithm 3.2.

Algorithm 3.2 IRN-LSQR-NNR p and IRN-GMRES-NNR p

- 1: Inputs: \mathbf{A} , \mathbf{b} , $(\mathbf{W}_p^\gamma)_0 = \mathbf{I}$, $\mathbf{S}_0 = \mathbf{I}$
 - 2: **for** $k = 0, 1, \dots$ until a stopping criterion is satisfied **do**
 - 3: **for** $m = 1, 2, \dots$ until a stopping criterion is satisfied **do**
 - 4: Update the factorizations (3.8) and (3.13), respectively
 - 5: Solve the projected problem (3.9) and (3.14), respectively, tuning $\hat{\lambda}_m$ if necessary
 - 6: **end for**
 - 7: “Decrease” γ
 - 8: Update the new $(\mathbf{W}_p^\gamma)_{k+1}$ and \mathbf{S}_{k+1}
 - 9: **end for**
-

401 **3.3. Solution through flexible Krylov subspaces.** Problem (1.3) reformulated as (3.6)
 402 allows us to naturally apply the flexible Golub-Kahan (FGK) and flexible Arnoldi algorithms.
 403 Indeed, instead of updating the “preconditioners” \mathbf{S}_k and $(\mathbf{W}_p^\gamma)_k$ at the k th outer iteration of the
 404 nested iteration schemes of Algorithm 3.2, we propose to consider new “preconditioners” as soon as
 405 a new approximation of the solution is available, i.e., at each iteration of a Krylov subspace solver.
 406 Therefore, at the $(i + 1)$ th iteration of the new solvers, the “preconditioners” $(\mathbf{W}_p^\gamma)_i$ and \mathbf{S}_i are
 407 computed as in (3.7), but using the SVD of the i th approximate solution

$$408 \quad \mathbf{X}_i = \text{vec}^{-1}(\mathbf{x}_i) = \mathbf{U}_{\mathbf{X}_i} \boldsymbol{\Sigma}_{\mathbf{X}_i} \mathbf{V}_{\mathbf{X}_i}^T, \quad \text{for } i = 1, \dots, k - 1,$$

409 with $(\mathbf{W}_p^\gamma)_0 = \mathbf{I}$ and $\mathbf{S}_0 = \mathbf{I}$. In order to incorporate iteration-dependent preconditioning, the
 410 flexible versions of the Golub-Kahan and Arnoldi factorizations have to be used.

411 Namely, at the i th iteration, the new instance of the FGK algorithm updates partial factoriza-
 412 tions of the form (2.8), i.e., $\mathbf{A} \mathbf{Z}_i = \mathbf{U}_{i+1} \mathbf{M}_i$ and $\mathbf{A}^T \mathbf{U}_{i+1} = \mathbf{V}_{i+1} \mathbf{T}_{i+1}$, where

$$413 \quad \mathbf{Z}_i = [\mathbf{S}_0^T (\mathbf{W}_p^\gamma)_0^{-2} \mathbf{S}_0 \mathbf{v}_1, \dots, \mathbf{S}_{i-1}^T (\mathbf{W}_p^\gamma)_{i-1}^{-2} \mathbf{S}_{i-1} \mathbf{v}_i], \quad \mathbf{v}_1 = \mathbf{A}^T \mathbf{b} / \|\mathbf{A}^T \mathbf{b}\|_2.$$

414 Taking $\mathbf{x}_0 = \mathbf{0}$, the i th approximate solution is such that $\mathbf{x}_i = \mathbf{Z}_i \mathbf{y}_i$, where

415 (3.16)
$$\mathbf{y}_i = \arg \min_{\mathbf{y} \in \mathbb{R}^i} \|\mathbf{M}_i \mathbf{y} - \|\mathbf{b}\|_2 \mathbf{e}_1\|_2^2 + \hat{\lambda}_i \|\mathbf{y}\|_2^2.$$

416 Note that the subspace for the solution $\mathcal{R}(\mathbf{Z}_i)$ can be regarded as a generalization of the subspace
 417 (3.10) computed when considering preconditioned GKB within the IRN-LSQR-NNR p method. The
 418 new method is dubbed “FLSQR-NNR p ”, and is summarized in Algorithm 3.3.

419 For $\mathbf{A} \in \mathbb{R}^{N \times N}$ and $\mathbf{x}_0 = \mathbf{0}$, at the i th iteration, the new instance of the flexible Arnoldi
 420 algorithm updates a partial factorization of the form (2.7), with $k = i$, and generates

421
$$\mathbf{Z}_i = [\mathbf{S}_0^T (\mathbf{W}_p^\gamma)_0^{-1} \mathbf{S}_0 \mathbf{v}_1, \dots, \mathbf{S}_{i-1}^T (\mathbf{W}_p^\gamma)_{i-1}^{-1} \mathbf{S}_{i-1} \mathbf{v}_i], \quad \mathbf{v}_1 = \mathbf{b} / \|\mathbf{b}\|_2,$$

422 where both right and left preconditioners are used analogously to IRN-GMRES-NNR p . The i th
 423 approximate solution is such that $\mathbf{x}_i = \mathbf{Z}_i \mathbf{y}_i$, where

424 (3.17)
$$\mathbf{y}_i = \arg \min_{\mathbf{y} \in \mathbb{R}^i} \|\mathbf{H}_i \mathbf{y} - \|\mathbf{b}\|_2 \mathbf{e}_1\|_2^2 + \hat{\lambda}_i \|\mathbf{y}\|_2^2.$$

425 Note that the subspace for the solution $\mathcal{R}(\mathbf{Z}_i)$ can be regarded as a generalization of the subspace
 426 (3.15) computed when considering the preconditioned Arnoldi algorithm within the IRN-GMRES-
 427 NNR p method. The new method is dubbed “FGMRES-NNR p ”, and is summarized in Algorithm
 428 3.3.

Algorithm 3.3 FLSQR-NNR p and FGMRES-NNR p

- 1: Inputs: \mathbf{A} , \mathbf{b} , $(\mathbf{W}_p^\gamma)_0 = \mathbf{I}$, $\mathbf{S}_0 = \mathbf{I}$
 - 2: **for** $i = 1, 2, \dots$ until a stopping criterion is satisfied **do**
 - 3: Update a factorization of the form (2.8) and (2.7), respectively, to expand the space $\mathcal{R}(\mathbf{Z}_i)$
 - 4: Solve the projected problem (3.16) and (3.17), respectively, tuning $\hat{\lambda}_i$ if necessary
 - 5: “Decrease” γ
 - 6: Update the new $(\mathbf{W}_p^\gamma)_i$ and \mathbf{S}_i , using the SVD $\mathbf{X}_i = \text{vec}^{-1}(\mathbf{x}_i) = \mathbf{U}_{\mathbf{X}_i} \boldsymbol{\Sigma}_{\mathbf{X}_i} \mathbf{V}_{\mathbf{X}_i}^T$.
 - 7: **end for**
-

429 Note that, although the approach of Algorithm 3.3 is quite heuristic, it avoids nested iteration
 430 cycles and computes only one approximation subspace for the solution of (1.3), where low-rank
 431 penalization is adaptively incorporated. Because of this, in many situations, Algorithm 3.3 com-
 432 putes solutions of quality comparable to the ones computed by Algorithm 3.2, with a significant
 433 reduction in the number of iterations. We should also mention that, in the framework of affine rank
 434 minimization problems, [25] outlines an algorithm that avoids inner projected gradient iterations
 435 for the solution of each quadratic subproblem in the sequence generated within the IRN strategy.

436 Finally, we underline that, within the framework of flexible Krylov subspaces, the approximation
 437 subspaces $\mathcal{R}(\mathbf{Z}_i)$ for the i th approximate solution can be further modified, with some insight into
 438 the desired properties of the solution. Indeed, since the i th basis vector for the solution is of the form
 439 $\mathbf{z}_i = \mathbf{S}_{i-1}^T (\mathbf{W}_p^\gamma)_{i-1}^{-2} \mathbf{S}_{i-1} \mathbf{v}_i$ for FLSQR-NNR p , and $\mathbf{z}_i = \mathbf{S}_{i-1}^T (\mathbf{W}_p^\gamma)_{i-1}^{-1} \mathbf{S}_{i-1} \mathbf{v}_i$ for FGMRES-NNR p ,
 440 one can consider alternative “preconditioners” \mathbf{S}_{i-1} and $(\mathbf{W}_p^\gamma)_{i-1}$ that are still effective in delivering
 441 low-rank solutions. For instance, focusing on FGMRES, and given $\mathbf{v}_i = \mathbf{V}_i \mathbf{e}_i$, where \mathbf{V}_i is the matrix
 442 appearing on the right-hand side of the factorization (2.8), and given the SVD of $\text{vec}^{-1}(\mathbf{v}_i) =$
 443 $\mathbf{U}_{\mathbf{V}_i} \boldsymbol{\Sigma}_{\mathbf{V}_i} \mathbf{V}_{\mathbf{V}_i}^T$, one can take

444 (3.18)
$$\mathbf{S}_{i-1} = \mathbf{V}_{\mathbf{V}_i}^T \otimes \mathbf{U}_{\mathbf{V}_i}^T \quad \text{and} \quad (\mathbf{W}_p^\gamma)_{i-1}^{-1} = \mathbf{I} \otimes (\boldsymbol{\Sigma}_{\mathbf{V}_i})^{1-p/2},$$

445 and as a result,

$$\begin{aligned}
446 \quad & \mathbf{S}_{i-1} \mathbf{v}_i = \text{vec}(\mathbf{U}_{\mathbf{V}_i}^T \text{vec}^{-1}(\mathbf{v}_i) \mathbf{V}_{\mathbf{V}_i}) = \text{vec}(\boldsymbol{\Sigma}_{\mathbf{V}_i}), \\
447 \quad & (\mathbf{W}_p^\gamma)_{i-1}^{-1} \mathbf{S}_{i-1} \mathbf{v}_i = \text{vec}((\boldsymbol{\Sigma}_{\mathbf{V}_i})^{1-p/2} \boldsymbol{\Sigma}_{\mathbf{V}_i}) = \text{vec}((\boldsymbol{\Sigma}_{\mathbf{V}_i})^{2-p/2}), \\
448 \quad & \mathbf{S}_{i-1}^T (\mathbf{W}_p^\gamma)_{i-1}^{-1} \mathbf{S}_{i-1} \mathbf{v}_i = \text{vec}(\mathbf{U}_{\mathbf{V}_i} ((\boldsymbol{\Sigma}_{\mathbf{V}_i})^{2-p/2}) \mathbf{V}_{\mathbf{V}_i}^T) = \mathbf{z}_i,
\end{aligned}$$

449 so that the singular values of $\text{vec}^{-1}(\mathbf{v}_i)$ are rescaled: taking $0 < p \leq 1$, the power of $\boldsymbol{\Sigma}_{\mathbf{V}_i}$, $2 - p/2$,
450 is always larger than 1, which means that large singular values get magnified and small singular
451 values become even smaller. In this way, the gaps between singular values are emphasized and to
452 some extent contribute to the low rank properties of the basis vectors. Similar derivations hold for
453 FLSQR. Hence, methods analogous to LR-FLSQR and LR-FGMRES are obtained, and are dubbed
454 FGMRES-NNR p (v) and FLSQR-NNR p (v), respectively.

455 **4. Implementation details.** All the methods considered in this paper are iterative, and
456 therefore at least one suitable stopping criterion should be set for the iterations. When considering
457 hybrid formulations (like the ones in Algorithms 3.2 and 3.3), one could simultaneously set a good
458 value for the regularization parameter $\hat{\lambda}_j$ at the j th iteration, as well as properly stop the iterations.
459 Strategies for achieving this are already available in the literature (see [6, 8]).

460 Assuming that a good estimate for the norm of the noise $\boldsymbol{\eta}$ affecting the right-hand-side of (1.1)
461 is available, i.e., $\varepsilon \simeq \|\boldsymbol{\eta}\|_2$, one can consider the discrepancy principle and stop the iterative scheme
462 at the first iteration j such that

$$463 \quad (4.1) \quad \|\mathbf{b} - \mathbf{A}\mathbf{x}_j\|_2 \leq \theta\varepsilon, \quad \text{where } \theta > 1, \theta \simeq 1 \text{ is a safety threshold.}$$

464 Applying the discrepancy principle to LR-FGMRES (Algorithm 2.1) and LR-FLSQR (Algorithm
465 2.2) is particularly convenient, as the norm of the residual on the left-hand side of (4.1) can be
466 monitored using projected quantities, i.e.,

$$467 \quad \|\|\mathbf{b}\|_2 \mathbf{e}_1 - \mathbf{H}_j \mathbf{y}_j\|_2 \quad \text{for LR-FGMRES} \quad \text{and} \quad \|\|\mathbf{b}\|_2 \mathbf{e}_1 - \mathbf{M}_j \mathbf{y}_j\|_2 \quad \text{for LR-FLSQR,}$$

468 where decompositions (2.7) and (2.8), respectively, and the properties of the matrices appearing
469 therein, have been exploited. When running hybrid methods (see Algorithms 3.2 and 3.3), we
470 employ the so-called ‘‘secant method’’, which updates the regularization parameter for the projected
471 problem in such a way that stopping by the discrepancy principle is ensured. We highlight again
472 that the quantities needed to implement the ‘‘secant method’’ (namely, the norm of the residual and
473 the discrepancy associated to (3.6) at each iteration) can be conveniently monitored using projected
474 quantities: this is obvious for IRN-LSQR-NNR p and FLSQR-NNR p , as only right-‘‘preconditioning’’
475 is employed; it is less obvious for IRN-GMRES-NNR p and FGMRES-NNR p , but since the left-
476 ‘‘preconditioner’’ is orthogonal, one can still write

$$477 \quad \|\mathbf{b} - \mathbf{A}\mathbf{x}_j\|_2 = \|\mathbf{S}_k \mathbf{b} - \mathbf{S}_k \mathbf{A} \mathbf{S}_k^T (\mathbf{W}_p^\gamma)_k^{-1} \hat{\mathbf{x}}_j\|_2 = \|\|\mathbf{b}\|_2 \mathbf{e}_1 - \mathbf{H}_j \mathbf{y}_j\|_2.$$

478 Note that all the methods in Algorithm 3.2 and 3.3 can also run with $\hat{\lambda} = 0$, and still achieve
479 low-rank approximate solutions: this is because the approximation subspace for the solution in-
480 corporates regularizing ‘‘preconditioning’’ (see [12, 14] for details on this approach in the case of
481 smoothing ‘‘preconditioning’’ with finite-difference approximations of derivatives operators). Fi-
482 nally, when dealing with the inner-outer iteration scheme of Algorithm 3.2, in addition to a pa-
483 rameter choice strategy and stopping criterion for the hybrid projected problems (3.9) and (3.14),

484 one should also consider a stopping criterion for the outer iterations. We propose to do this by
 485 monitoring the norm of the difference of the singular values (normalized by the largest singular
 486 value so that $\sigma_1(\Sigma_{\mathbf{X}_{k+1}}) = \sigma_1(\Sigma_{\mathbf{X}_k}) = 1$) of two approximations of the solution of (1.3) obtained
 487 at two consecutive outer iterations of Algorithm 3.2, i.e., we stop as soon as

$$488 \quad (4.2) \quad \|\text{diag}(\Sigma_{\mathbf{X}_{k+1}}) - \text{diag}(\Sigma_{\mathbf{X}_k})\|_2 < \tau_\sigma, \quad k = 1, 2, \dots,$$

489 where $\text{vec}^{-1}(\mathbf{x}_i) = \mathbf{X}_i = \mathbf{U}_{\mathbf{X}_i} \Sigma_{\mathbf{X}_i} \mathbf{V}_{\mathbf{X}_i}^T$ ($i = k, k + 1$), and $\tau_\sigma > 0$ is a user-specified threshold. If
 490 no significant changes happen in the rank and singular values of two consecutive approximations of
 491 the solution, then (4.2) is satisfied.

492 We conclude this section with a few remarks about the computational cost of the proposed
 493 methods. Note that, if $\mathbf{A} \in \mathbb{R}^{N \times N}$, IRN-GMRES-NNR p is intrinsically cheaper than IRN-LSQR-
 494 NNR p (since, at each iteration, the former requires only one matrix-vector product with \mathbf{A} , while
 495 the latter requires one matrix-vector product with \mathbf{A} and one with \mathbf{A}^T). However, methods based
 496 on the Arnoldi algorithm are typically less successful than methods based on the GKB algorithm
 497 for regularization; see [15]. Other key operations for implementing our proposed methods are the
 498 computation of the SVDs of relevant quantities, and/or the application of the “preconditioners” in
 499 (3.18). Namely, each iteration of LR-FGMRES, LR-FLSQR, FLSQR-NNR p , and FGMRES-NNR p
 500 requires the computation of the SVD of an $n \times n$ matrix, which amounts to $\mathcal{O}(n^3) = \mathcal{O}(N^{3/2})$
 501 floating point operations. When considering IRN-LSQR-NNR p and IRN-GMRES-NNR p , only the
 502 SVD of the approximate solution should be computed once at each outer iteration. However,
 503 each inner iteration of IRN-LSQR-NNR p and IRN-GMRES-NNR p , as well as each iteration of
 504 FLSQR-NNR p and FGMRES-NNR p , requires the computation of matrix-vector products of the
 505 form $\mathbf{S}_k^T (\mathbf{W}_p^\gamma)_k^{-1} \mathbf{v}_i$: this can be achieved within a two-step process, where first the rescaling $\tilde{\mathbf{v}}_i =$
 506 $(\mathbf{W}_p^\gamma)_k^{-1} \mathbf{v}_i$ is applied with $\mathcal{O}(N) = \mathcal{O}(n^2)$ floating-point operations, and then $\mathbf{S}_k^T \tilde{\mathbf{v}}_i = (\mathbf{V}_{\mathbf{X}_k} \otimes$
 507 $\mathbf{U}_{\mathbf{X}_k}) \tilde{\mathbf{v}}_i$ is computed. While a straightforward implementation of the latter would require $\mathcal{O}(N^2) =$
 508 $\mathcal{O}(n^4)$ floating-point operations, exploiting Kronecker product properties can bring down the cost of
 509 this operation to $\mathcal{O}(n^3) = \mathcal{O}(N^{3/2})$, by computing $\mathbf{S}_k^T \tilde{\mathbf{v}}_i = \text{vec}(\mathbf{U}_{\mathbf{X}_k}^T \text{vec}^{-1}(\mathbf{v}_i) \mathbf{V}_{\mathbf{X}_k})$. We emphasize
 510 that the incorporation of the flexible “preconditioners” does not increase the order of computational
 511 complexity and is very practical, since operations are done on matrices of size $n \times n$ (n is the
 512 dimension of the image). In particular, the full SVD’s of $n \times n$ matrices can be computed easily
 513 with MATLAB’s built-in `svd` function (this is what we used in our numerical experiments); one
 514 can also use Lanczos bidiagonalization [20] or randomized SVD [11] to compute the approximate
 515 leading singular values and vectors.

516 **5. Experimental Results.** In this section, we present results of numerical experiments on
 517 several image processing problems to demonstrate the performance of the new IRN-GMRES-NNR p ,
 518 IRN-LSQR-NNR p , FGMRES-NNR p , and FLSQR-NNR p methods. Variants of FGMRES-NNR p
 519 and FLSQR-NNR p (marked with “(v)”) are also tested. To shorten the acronyms, we omit p when
 520 $p = 1$, which means IRN-GMRES-NNR denotes IRN-GMRES-NNR p when $p = 1$, etc. Examples
 521 are generated using *IR Tools* [6].

522 In general, we compare the performances of the proposed methods to standard Krylov subspace
 523 methods GMRES and LSQR, also used in a hybrid fashion. We also test against the low-rank
 524 projection methods described in Section 2 and the singular value thresholding (SVT) algorithm [3],
 525 which was originally proposed for low-rank matrix completion problems, and can be extended to
 526 problems with linear constraints of the form

$$527 \quad (5.1) \quad \min_{\mathbf{x}} \tau \|\text{vec}^{-1}(\mathbf{x})\|_* + \frac{1}{2} \|\text{vec}^{-1}(\mathbf{x})\|_F^2 \quad \text{subject to} \quad \mathbf{A}\mathbf{x} = \mathbf{b}, \quad \text{where} \quad \text{vec}^{-1}(\mathbf{x}) = \mathbf{X}.$$

528 The k th iteration of the SVT algorithm for (5.1) reads

$$529 \quad (5.2) \quad \begin{cases} \mathbf{X}_k = \mathcal{D}_\tau(\mathbf{A}^T \mathbf{y}_{k-1}) \\ \mathbf{y}_k = \mathbf{y}_{k-1} + \delta_k(\mathbf{b} - \mathbf{A}\mathbf{x}_k) \end{cases},$$

530 where δ_k is a step size and \mathcal{D}_τ is the *singular value shrinkage operator*, defined as

$$531 \quad \mathcal{D}_\tau(\mathbf{X}) = \mathbf{U}_\mathbf{X} \mathcal{D}_\tau(\boldsymbol{\Sigma}_\mathbf{X}) \mathbf{V}_\mathbf{X}^T, \quad \mathcal{D}_\tau(\boldsymbol{\Sigma}_\mathbf{X}) = \max\{\boldsymbol{\Sigma}_\mathbf{X} - \tau \mathbf{I}, \mathbf{0}\},$$

532 where $\mathbf{X} = \mathbf{U}_\mathbf{X} \boldsymbol{\Sigma}_\mathbf{X} \mathbf{V}_\mathbf{X}^T$ is the SVD of \mathbf{X} , $\mathbf{0}$ is a matrix of zeros, and the maximum is taken
533 component-wise. Although (5.1) is not the same problem as (1.2), they are similar in that both
534 penalize the nuclear norm of $\text{vec}^{-1}(\mathbf{x})$ and they respect the constraint $\mathbf{A}\mathbf{x} = \mathbf{b}$.

535 The Schatten- p function is introduced in Section 3.1 as a smooth approximation for $\|\cdot\|_{*,p}$. The
536 smooth approximation allows for further derivations including computation of optimality conditions,
537 where the ‘‘smoothing coefficient’’ γ is crucial. However, γ is not so crucial numerically, and we
538 can set it to 0 without affecting the results (compared to using a very small γ). However, to be
539 consistent with Algorithms 3.2 and 3.3, in our experiments, we have set the initial value of γ to
540 10^{-10} , and every time we need to decrease γ , we divide the current γ value by 2.

541 Regarding the comparisons with the low-rank projection methods presented in Section 2, there
542 are no **universal** and theoretically informed ways of choosing the truncation ranks for the solutions
543 and for the basis vectors of the solution subspace. Hence, for all test problems, we experiment
544 on a reasonable number of trials, each with different truncation rank choices, and select the best
545 performing rank out of all ranks tested. For simplicity, we consider the same truncation rank for
546 basis vectors and solutions ($\tau_{\kappa_B} = \tau_\kappa$). We follow the same process to choose the number of restarts
547 and the number of iterations for each restart for RS-LR-GMRES, as well as the shrinkage threshold
548 τ in SVT; strategies to select the step size for SVT are described in [3].

549 *Example 1: Binary Star.* We consider an image deblurring problem involving a binary star test
550 image of size 256×256 : this test image has rank 2. The true image is displayed in the leftmost
551 frame of Figure 2. A standard Gaussian blur is applied to the test image, and Gaussian white
552 noise of level $\|\boldsymbol{\eta}\|_2 / \|\mathbf{b}^{\text{ex}}\|_2 = 10^{-3}$ is added. The blurred and noisy image is shown in Figure 2,
553 second frame from the left. Due to the **presence** of noise, the blurred image has full rank. For this
554 example, the blurring operator \mathbf{A} is square of size 65536×65536 , hence GMRES-related methods
555 are used for comparison, namely: GMRES, IRN-GMRES-NNR, FGMRES-NNR, LR-FGMRES and
556 RS-LR-GMRES (i.e., we only consider the case $p = 1$ here). SVT is also taken into consideration.
557 The truncation rank for LR-FGMRES and RS-LR-GMRES is set to 30 for both basis vectors and
558 approximate solutions (i.e., $\tau_{\kappa_B} = \tau_\kappa = 30$). RS-LR-GMRES is restarted every 40 iterations. The
559 step size for SVT is set to be $\delta_k = \delta = 2$ and the singular value shrinkage threshold τ is 1. Note
560 that, although the true solution has only rank 2, setting truncation rank to 2 for low rank methods
561 produces solutions of worse quality (compared to setting the rank to 30). This might be because
562 of the inherent ill-posedness of the problem, which makes it harder to obtain solutions with desired
563 properties (e.g., with rank 2): indeed, if we do truncate to rank 2, a lot of information about the
564 solution might be lost.

565 Figure 1 displays the histories of relative errors $\|\mathbf{x}^{\text{ex}} - \mathbf{x}_m\|_2 / \|\mathbf{x}^{\text{ex}}\|_2$ for the first 200 iterations
566 (i.e., $m = 1, \dots, 200$) of these methods. For IRN-GMRES-NNR, 4 outer cycles were run, each with
567 a maximum of 50 iterations: a new outer cycle is initiated as soon as the discrepancy principle is
568 satisfied in the inner cycle. No additional regularization is used (i.e., $\hat{\lambda} = 0$ for all methods).

Fig. 1: *Example 1*. Relative errors vs. number of iterations for GMRES-based methods and SVT.

569 We can observe from Figure 1 that when the truncation ranks are chosen reasonably, LR-
 570 FGMRES and RS-LR-GMRES both produce a less pronounced semi-convergence behavior than
 571 GMRES, with LR-FGMRES attaining a smaller relative error than RS-LR-GMRES. FGMRES-
 572 NNR, on the other hand, shows slower semi-convergence than GMRES, but it also converges to
 573 a slightly better relative error. IRN-GMRES-NNR behaves especially well in this case, with sig-
 574 nificantly reduced relative errors even at the end of the second outer cycle. The “jumps” at the
 575 beginning of each outer IRN-GMRES-NNR iteration are due to the strategy used for restarts (the
 576 older basis vectors are cleared at each restart).

577 Figure 2 displays the exact and the corrupted images, as well as the best reconstructions
 578 computed by LR-FGMRES and IRN-GMRES-NNR: these are obtained at the 47th and the 189th
 579 (total) iteration of LR-FGMRES and IRN-GMRES-NNR, respectively. By looking at relative errors
 580 in Figure 1, we see that LR-FGMRES is the second best out of all methods, and yet the quality of
 581 the solution is inferior compared to IRN-GMRES-NNR. Compared to the LR-FGMRES solution,
 582 the IRN-GMRES-NNR one is a more truthful reconstruction of the exact image: it not only has
 583 less artifacts immediately around the stars, but also has less background noise, in the sense that
 584 the pixel intensities in the background are closer to the true ones (as it can be seen by looking
 at the background color). More details can be spotted if we zoom into the central part (51×51

Fig. 2: *Example 1*. Exact and corrupted test images, together with the best reconstructions obtained by the LR-FGMRES and the IRN-GMRES-NNR methods.

585

586 pixels) of the computed images, as shown in Figure 3: here the best LR-FGMRES reconstruction,
 587 as well as the IRN-GMRES-NNR reconstructions at the end of the 2nd, 3rd and 4th inner cycles
 588 are displayed. It is clear that the IRN reconstructions are improving over each outer cycle, and
 589 that even the solution at the end of the 2nd cycle is significantly better than the LR-FGMRES
 590 solution, which means that not all four outer iterations need to be run to achieve solutions of
 superior qualities (even if more outer iterations allow further improvement in the solution). Figure

Fig. 3: *Example 1.* Zoom-ins of the LR-FGMRES best solution, and the IRN-GMRES-NNR solutions at the end of each inner cycle.

591
 592 4 displays surfaces plots of the central part (51×51 pixels) of the test problem data, as well as the
 593 best reconstructed images (for RS-LR-GMRES and FGMRES-NNR these are obtained at the 165th
 594 and the 63th (total) iterations, respectively). It can be seen that for all the solutions shown here, the
 595 reconstructed central two stars approximately have the same intensity, although they are somewhat
 596 less intense than in the exact image. These surface plots also confirm our earlier observation that
 597 IRN-GMRES-NNR does an exceptional job removing background noise. In addition, FGMRES-
 598 NNR also gives a good background reconstruction. Finally, Figure 5 displays the singular values
 599 of the best solutions obtained adopting different GMRES-based solvers, as well as the evolution of
 600 the singular values of the solution at the end of each inner IRN-GMRES-NNR cycle (matching the
 601 reconstructions displayed in Figure 3). The singular values are “normalized” (i.e., divided by the
 602 largest one), and the graphs are cropped to focus on the relevant values. Looking at the displayed
 603 values, we can conclude that the solutions computed by all the low-rank solvers have indeed some
 604 low-rank properties, with very quickly-decaying large singular values followed by slowly-decaying
 605 smaller singular values. Compared to GMRES, the new FGMRES-NNR and IRN-GMRES-NNR
 606 methods give solutions that have a more pronounced low rank, as shown by the large gaps between
 607 the smaller singular values of the solutions computed by these methods. Regarding IRN-GMRES-
 608 NNR, the evolution of the singular values stabilizes as we move toward later outer iterations, which
 609 validates the stopping criterion proposed in Section 4.

610 *Example 2: Limited angle parallel-ray tomography.* We consider a computed tomography (CT)
 611 test problem, modeling an undersampled X-ray scan with parallel beam geometry. This is a so
 612 called “limited angle” CT reconstruction problem, where the viewing angles for the object span
 613 less than 180 degrees. A smooth and rank-4 phantom is considered, as shown in the leftmost frame
 614 of Figure 7 (note that the yellow straight lines in the northwestern corner do not belong to the
 615 phantom; they are shown for later purposes). Gaussian white noise of level 10^{-2} is added to the
 616 data. The coefficient matrix \mathbf{A} has size 32942×65536 . Because of this, among the new solvers,
 617 only LR-FLSQR, FLSQR-NNR p , FLSQR-NNR $p(v)$, and IRN-LSQR-NNR p will be tested, against

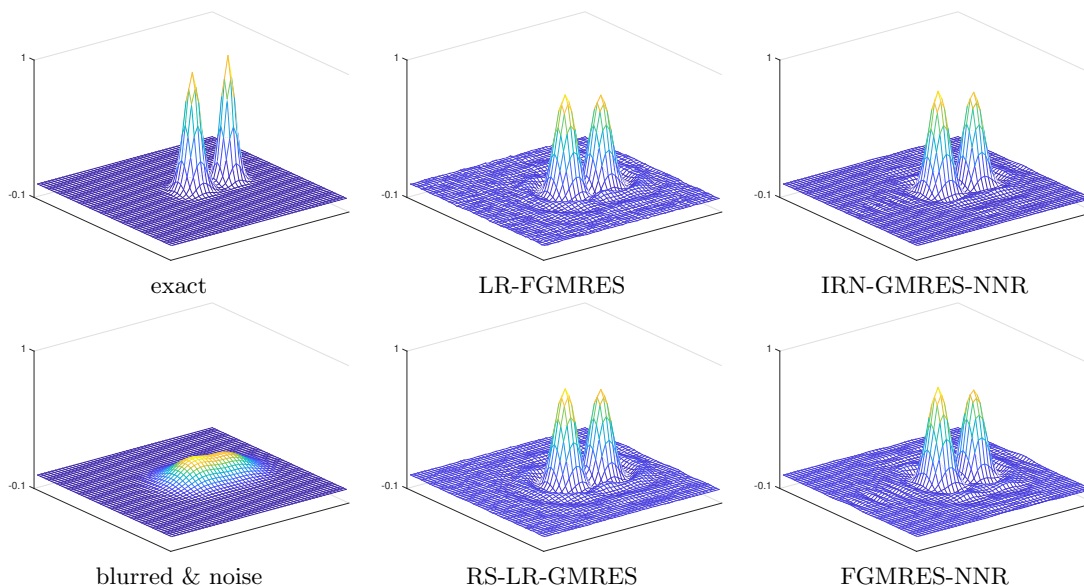

Fig. 4: *Example 1*. Zoomed-in surfaces of the exact solution and the available data, as well as the best reconstructions obtained by the new GMRES-based methods.

Fig. 5: *Example 1*. Left frame: normalized singular values of the best solutions computed by each GMRES-based method. Right frame: evolution of the singular values of the solutions computed by IRN-GMRES-NNR at each outer iteration. Singular values less than 10^{-3} are omitted.

618 their standard counterpart LSQR. Recall that FLSQR-NNR $p(v)$ is the FLSQR-NNR p variant that
 619 defines the preconditioners using the basis vectors of the solution subspace. The hybrid strategy
 620 is not used here, meaning that we set $\hat{\lambda} = 0$ for all methods. For this test problem, we consider
 621 both the values $p = 1$ and $p = 0.75$ (recall that, when $p = 1$, we omit p from the notation). The
 622 results obtained running the available low-rank solvers SVT and RS-LR-GMRES are shown, too.
 623 Note that RS-LR-GMRES only works for square matrices \mathbf{A} , hence this solver is tested on the
 624 normal equations $\mathbf{A}^T \mathbf{A} \mathbf{x} = \mathbf{A}^T \mathbf{b}$, which is not the problem solved by the other methods (therefore

625 this comparison may not be completely fair). Parameters for SVT are chosen to be: step size
 626 $\delta_k = \delta = 8 \times 10^{-5}$ and threshold $\tau = 100$. RS-LR-GMRES is set to restart every 20 iterations.
 627 The truncation rank is 10 for both basis vectors and solutions, and for both the LR-FLSQR and
 628 the RS-LR-GMRES methods. The maximum number of iterations is 100 for all methods.

629 Figure 6 displays the history of the relative errors for LSQR, LR-LSQR, FLSQR-NNR p ,
 630 FLSQR-NNR $p(v)$, and IRN-LSQR-NNR p , for $p = 1$ and $p = 0.75$. Figure 7 displays the ex-
 631 act phantom together with the best reconstructions obtained by LSQR, FLSQR-NNR $p(v)$, and
 632 IRN-LSQR-NNR. Figure 8 displays surface plots of the northwestern corner of the exact and re-
 633 constructed phantoms (64×64 pixels, as highlighted in the leftmost frame of Figure 7).

634 Looking at relative errors in Figure 6, it is obvious that the winners are the FLSQR-NNR $p(v)$
 635 methods, with both $p = 1$ and $p = 0.75$: they give the lowest relative errors, and the fastest semi-
 636 convergences. For this test problem, using a value of $p < 1$ lowers the relative error of FLSQR-
 637 NNR $p(v)$; however, the same does not hold for IRN-LSQR-NNR p . Therefore we can conclude that
 638 the the choice of p is problem and solver dependent, and using $p < 1$ does not necessarily improve
 639 the quality of the solution. We regard $p = 1$ as a safe choice for this parameter. Although both
 640 the FLSQR-NNR $p(v)$ methods with $p = 1$ and $p = 0.75$ perform well, the latter is able to further
 641 reduce the noise in the reconstructed solution, especially on the boundary.

Fig. 6: *Example 2*. Relative errors vs. number of iterations for different solvers. Upper frame: some of the new solvers are compared to the already available solvers. Lower frame: comparisons of different instances of the new solvers (here $p = 0.75$).

Fig. 7: *Example 2*. Exact phantom and best reconstructions obtained by different solvers.

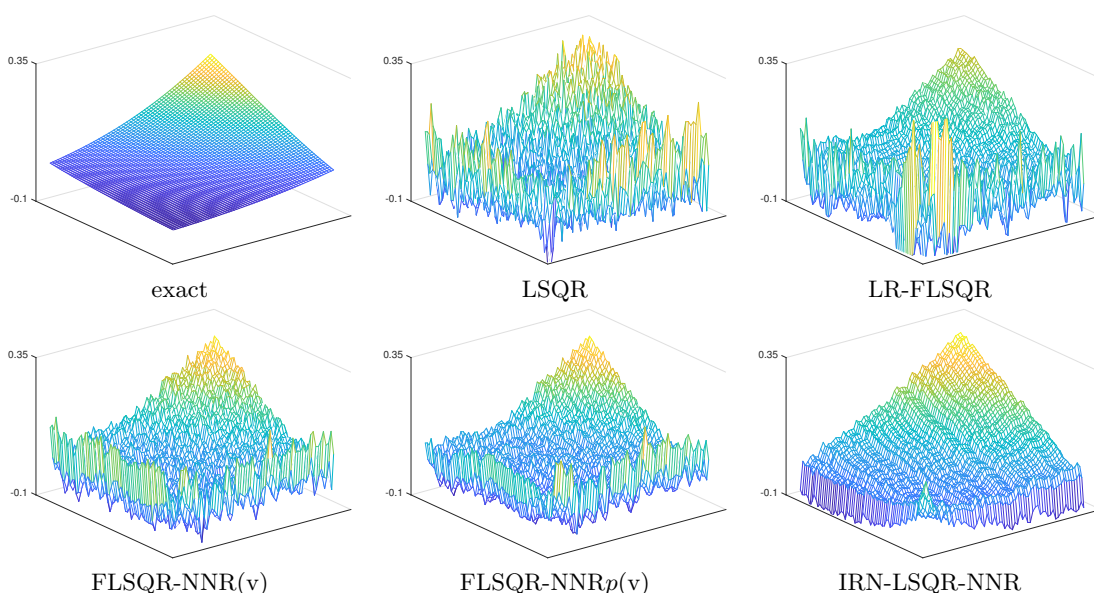

Fig. 8: *Example 2*. Surface plots of the northwestern corner of the exact phantom (highlighted in Figure 7) and the best reconstructed phantoms computed by different solvers.

642 Looking at all the displayed results, the advantages of our new FLSQR-NNR $p(v)$ and IRN-
 643 LSQR-NNR methods are evident. Namely, they produce smooth solutions that preserve the original
 644 concave shape of the exact phantom, and they retain similar intensities of pixels at the same loca-
 645 tions of the exact phantom (although the LR-FLSQR solution is smooth within the boundary, it fails
 646 to reconstruct intensity at the high point). Differences between FLSQR-NNR $p(v)$ and IRN-LSQR-
 647 NNR reconstructions are clear, too: while both are smooth, the IRN-LSQR-NNR reconstruction
 648 has a less concave shape compared to that of FLSQR-NNR $p(v)$, but a smoother boundary.

649 *Example 3: Inpainting.* We consider two different inpainting test problems. Inpainting is the
 650 process of restoring images that have missing or deteriorated parts. These images are likely to

651 have quite a few lost pixels, either in the form of salt and pepper noise, or missing patches with
 652 regular or irregular shapes. The two examples considered here are of different nature: the first one
 653 has less structured and more randomly distributed missing patches, while the second one has more
 654 structured and regularly shaped missing parts. The corrupted images (shown in top-middle frames
 655 of Figures 11 and 13) are constructed by first applying a blur operator, and then superimposing
 656 the undersampling pattern to the ideally exact images (shown in the top-left frames of Figures 11
 657 and 13). We follow this particular order of first blurring and then taking out pixels to simulate the
 658 real process of photo-taking. For both these test problems, white noise of level 10^{-2} is added to
 659 the data, and we consider purely iterative methods (i.e., $\hat{\lambda} = 0$). We always take $p = 1$, and we run
 660 100 iterations of all the methods.

661 Firstly, we consider a test problem where 58.2% of the pixels are missing (following some
 662 random and not very regular patterns). The exact image is commonly known as the **house** test
 663 image, whose rank is 243 and has a total number of 65536 (256×256) pixels; the corrupted image
 664 has the same size and number of pixels, but out of which only 27395 are non-zero. The singular
 665 values of the exact image is shown in Figure 9(a). Correspondingly, the forward operator \mathbf{A} is of
 666 size 27395×65536 , so we have an underdetermined linear system: \mathbf{A} is obtained by first applying
 667 a shaking blur, and by then undersampling the blurred image. This can be easily coded within the
 668 *IR Tools* framework.

669 Figure 10 displays the history of the relative errors for LSQR, LR-FLSQR (with truncation of
 670 the basis vectors for the solution, as well as the solution, to rank 20), FLSQR-NNR, FLSQR-NNR(v)
 671 and IRN-LSQR-NNR. Figure 11 displays the exact and corrupted images, together with the best
 672 reconstructions obtained by the methods listed above: these correspond to the 16th, 32nd, 67th,
 673 30th and 62nd iterations of LSQR, LR-FLSQR, FLSQR-NNR, FLSQR-NNR(v) and IRN-LSQR-
 674 NNR, respectively (i.e., these are the iterations where the minimum relative error is attained over
 675 the total 100 iterations).

Fig. 9: *Example 3*. Singular values of exact test images **house** and **peppers** scaled by the largest singular values respectively.

Fig. 10: *Example 3 (house)*. Relative errors vs. number of iterations for different solvers.

Fig. 11: *Example 3 (house)*. Exact and corrupted images; best reconstructions obtained by standard and new solvers.

676 Secondly, we consider a test problem similar to the previous one, i.e., we take an exact image
 677 commonly known as [the peppers test image](#), which has full rank (its singular values are shown
 678 in [Figure 9\(b\)](#)), and we obtain the forward operator \mathbf{A} by first applying a shaking blur, and
 679 by then undersampling the blurred image. Here the exact image has a total number of 65536
 680 (256×256) pixels, and only around 1.3% of pixels are missing and should be inpainted: differently
 681 from the previous problem, the missing pixels follow particular patterns (e.g., circles, squares, and
 682 rectangles), and this makes the inpainting task somewhat more challenging. Figure 12 displays the
 683 history of the relative errors for LSQR, LR-FLSQR (with truncation of the basis vectors for the

684 solution, as well as the solution, to rank 50), FLSQR-NNR, FLSQR-NNR(v) and IRN-LSQR-NNR.
 685 Figure 13 displays the exact and corrupted images, together with the best reconstructions obtained
 686 by the methods listed above: these correspond to the 11th, 18th, 60th, 33rd and 34th iterations of
 687 LSQR, LR-FLSQR, FLSQR-NNR, FLSQR-NNR(v) and IRN-LSQR-NNR, respectively (i.e., these
 688 are the iterations where the minimum relative error is attained over the total 100 iterations).

Fig. 12: *Example 3 (peppers)*. Relative errors vs. number of iterations for different solvers.

Fig. 13: *Example 3 (peppers)*. Exact and corrupted images; best reconstructions obtained by standard and new solvers.

689 It is evident that FLSQR-NNR(v) achieves reconstructions of superior quality, including clarity,
 690 brightness, and smoothness. Its ability to fill-in missing spots with pixels that are of similar intensity

691 to their surroundings is the best among all methods. The best reconstructions are computed by IRN-
 692 LSQR-NNR for the **house** test image, and by FLSQR-NNR for the **pepper** test image: in both cases,
 693 these methods are also good at removing noise and restoring missing pixels. However, for both test
 694 images, the reconstructions obtained by IRN-LSQR-NNR lack clarity compared to ones obtained
 695 by both FLSQR-NNR and FLSQR-NNR(v) methods; compared to the reconstructions obtained by
 696 LSQR and LR-FLSQR, they are anyway more desirable in terms of recovered brightness and fill-in of
 697 the missing pixels. *Moreover, we have seen in these two examples that our newly proposed methods*
 698 *perform very well not only for low rank, but also for full or nearly full rank image reconstruction,*
 699 *thanks to the regularizing properties of our newly derived “preconditioners” $(\mathbf{W}_p^\gamma)_k$ and \mathbf{S}_k .* Our
 700 *methods can also be extensively tested for higher noise levels (for example, 10^{-1}) and yield similar*
 701 *results. However, for space considerations we are not able to show all of them here.*

702 *A study of regularization parameters.* In the previous examples we have seen that the IRN-NNR
 703 methods and the flexible Krylov NNR methods perform exceptionally well on image deblurring,
 704 tomography, and inpainting problems, producing superior reconstructions compared to existing
 705 methods including SVT, RS-LR-GMRES and the low-rank flexible Krylov methods inspired by
 706 RS-LR-GMRES, even without the use of additional regularization. In this section, we explore
 707 the effect of additional regularization (i.e., we set $\hat{\lambda} \neq 0$) on the reconstructed images and the
 708 corresponding relative errors. In particular, additional regularization allows the new methods to be
 709 used in a hybrid fashion. We are going to observe that there is only little to negligible room for the
 710 methods to improve when they are used in a hybrid fashion *(as their performance is already very*
 711 *good with $\hat{\lambda} = 0$).*

712 We consider three different ways of choosing the regularization parameter $\hat{\lambda}$. (i) We take
 713 the “secant method” mentioned in Section 4, which updates the regularization parameter at each
 714 iteration using the discrepancy. (ii) We select the optimal regularization parameter which minimizes
 715 the 2-norm of the difference between the exact solution and the regularized solution at each iteration.
 716 Namely, when using standard GMRES and LSQR, at the m th iteration we seek to minimize *with*
 717 *respect to $\hat{\lambda}$*

$$718 \quad \|\mathbf{x}^{\text{ex}} - \mathbf{x}_{m,\hat{\lambda}}\| = \|\mathbf{V}_m^T \mathbf{x}^{\text{ex}} - \mathbf{V}_m^T \mathbf{x}_{m,\hat{\lambda}}\| = \|\mathbf{V}_m^T \mathbf{x}^{\text{ex}} - \mathbf{y}_{m,\hat{\lambda}}\|;$$

719 when using the IRN methods we should incorporate the appropriate preconditioners $(\mathbf{W}_p^\gamma)_k$ and
 720 \mathbf{S}_k and, for all the iterations in the inner iteration cycle corresponding to the k th outer iteration,
 721 we seek to minimize *with respect to $\hat{\lambda}$*

$$722 \quad \|\hat{\mathbf{x}}^{\text{ex}} - \mathbf{V}_m \mathbf{y}_{m,\hat{\lambda}}\| = \|\mathbf{V}_m^T \hat{\mathbf{x}}^{\text{ex}} - \mathbf{V}_m^T \mathbf{V}_m \mathbf{y}_{m,\hat{\lambda}}\| = \|\mathbf{V}_m^T \hat{\mathbf{x}}^{\text{ex}} - \mathbf{y}_{m,\hat{\lambda}}\|, \text{ where } \hat{\mathbf{x}}^{\text{ex}} = (\mathbf{W}_p^\gamma)_k \mathbf{S}_k \mathbf{x}^{\text{ex}}.$$

723 It is intrinsically difficult to implement this strategy for flexible Krylov subspace methods, because of
 724 the complexity of changing preconditioners at each iteration. (iii) We perform a manual exhaustive
 725 search. Namely, we first run the solvers multiple times using various regularization parameters $\hat{\lambda}$,
 726 starting with a larger range and narrowing down to a smaller range containing the best parameter;
 727 we then record the minimum relative errors among all iterations for all values of $\hat{\lambda}$, and select the
 728 corresponding $\hat{\lambda}$. This approach is the most expensive *one*, and differs from the previous one in that
 729 the (optimal) regularization parameter $\hat{\lambda}$ is fixed for all iterations. Of course, both the second and
 730 third approaches require the knowledge of the exact solution and we test them only to investigate
 731 the best possible performance of the hybrid approach.

732 Table 1 compares the performances (in terms of minimum relative error achieved by each
 733 method) of standard Krylov methods (GMRES and LSQR) and their IRN-NNR and flexible NNR

734 (F-NNR) counterparts, with and without using a hybrid approach. In this way we can under-
 735 stand how the use of additional regularization affects each solver differently. The three parameter
 736 choice methods described above are dubbed “Secant (i)”, “Optimal (ii)” and “Fixed (iii)”, respec-
 737 tively. All the previous examples are considered here. GMRES and its counterparts IRN-GMRES-
 738 NNR, FGMRES-NNR are used for Example 1, while LSQR and its counterparts IRN-LSQR-NNR,
 739 FLSQR-NNR(v) are used for Examples 2 and 3.

		$\hat{\lambda} = 0$	$\hat{\lambda} \neq 0$	$\hat{\lambda} = 0$	$\hat{\lambda} \neq 0$	$\hat{\lambda} = 0$	$\hat{\lambda} \neq 0$	$\hat{\lambda} = 0$	$\hat{\lambda} \neq 0$

Table 1: Minimum relative errors without ($\hat{\lambda} = 0$) and with ($\hat{\lambda} \neq 0$) a hybrid approach. The mark “X” means that the optimal regularization parameter found by the “Fixed (iii)” method is 10^{-16} , hence there is no need for [additional](#) regularization.

Fig. 14: Reconstructions obtained by standard hybrid Krylov methods and by the new methods without using additional regularization. Left side: zoomed in surface plots of the reconstructions of *Example 1*; right side: reconstructions of *Example 3 (peppers)*.

740 It is easy to observe that the use of additional regularization is most effective for the standard
 741 GMRES solver, where the minimum relative error is reduced significantly. However, for the other
 742 solvers, the hybrid approach does not have a notable advantage over not using regularization. At
 743 times the “Fixed (iii)” parameter choice strategy delivers a regularization parameter of the order
 744 of 10^{-16} , which is numerically equivalent to not having regularization. This indicates that our
 745 new IRN-NNR and F-NNR methods are successful in computing good reconstructions and, even
 746 without additional regularization, they perform much better than standard Krylov methods used
 747 in a hybrid fashion (comparing IRN-GMRES-NNR to GMRES in Example 1, and FLSQR-NNR(v)
 748 to LSQR in the other examples). Figure 14 shows a couple of such comparisons.

749 **6. Conclusions.** This paper introduced new solvers, based on Krylov subspace methods, for
 750 the computation of approximate low-rank solutions to large-scale linear systems of equations. Our

751 main goal was to apply the new methods to regularize inverse problems arising in imaging applica-
 752 tions. The starting point of our derivations was an IRN approach to the NNR_p problem (1.3). In
 753 this way, the original problem (1.3) is reduced to the solution of a sequence of quadratic problems,
 754 where an appropriate smoothed linear transformation is introduced to approximate the nondif-
 755 ferentiable nuclear norm regularization term. Our new methods make smart use of Kronecker
 756 product properties to reformulate each quadratic problem in the IRN sequence as a Tikhonov-
 757 regularized problem in standard form. We use both Krylov methods with fixed “preconditioners”
 758 within an inner-outer iteration scheme (namely, IRN-LSQR- NNR_p and IRN-GMRES- NNR_p), and
 759 Krylov methods with flexible iteration-dependent “preconditioners” within a single iteration scheme
 760 (namely, FLSQR- NNR_p , FGMRES- NNR_p , LR-FGMRES, and LR-FLSQR). Some of these meth-
 761 ods (namely, IRN-LSQR- NNR_p , IRN-GMRES- NNR_p , FLSQR- NNR_p , and FGMRES- NNR_p) can
 762 be used in a hybrid framework, so that the Tikhonov regularization parameter can be efficiently,
 763 effectively, and adaptively chosen. These new solvers are shown to perform exceptionally well on
 764 the test problems described in Section 5, and they give reconstructions of significantly improved
 765 quality over existing methods.

766 Future work includes the extension of the present methods to handle cases where the solution
 767 of (1.1) is low-rank but rectangular, i.e., $\text{vec}^{-1}(\mathbf{x}) = \mathbf{X} \in \mathbb{R}^{m \times n}$ with $m \neq n$. Also, while a
 768 solid theoretical justification is provided for IRN-LSQR- NNR_p and IRN-GMRES- NNR_p , the same
 769 is not true for FGMRES- NNR_p and FLSQR- NNR_p : further analysis will be needed to deeply
 770 understand the regularization properties of these flexible solvers. Finally, the new IRN-LSQR-
 771 NNR_p and IRN-GMRES- NNR_p methods can be reformulated to work with well-posed problems
 772 and in the framework of matrix equations, possibly providing a valid and principled alternative to
 773 the current popular methods based on low-rank-projected and restarted Krylov solvers.
