1 **Cash water expenditures are associated with household water insecurity, food insecurity,**

2 **and perceived stress in study sites across 20 low- and middle-income countries**

3

4 **Abstract**

5 Billions of people globally, living with various degrees of water insecurity, obtain their household

6 and drinking water from diverse sources that can absorb a disproportionate amount of a

7 household's income. In theory, there are income and expenditure thresholds required for a

8 household to effectively mitigate water insecure conditions, but there is little empirical research

9 about these mechanisms in low- and middle-income settings. This study used data from 3,655

10 households from 23 water-insecure sites in 20 countries to explore the relationship between cash

11 water expenditures (measured as a Z-score, percent of income, and Z-score of percent of income)

12 and a household water insecurity score, and whether income moderated that relationship. We

13 also assessed whether water expenditures moderated the relationships between water insecurity

14 and both food insecurity and perceived stress. Using tobit mixed effects regression models, we

15 observed a positive association between multiple measures of water expenditures and a

16 household water insecurity score, controlling for demographic characteristics and accounting for

17 clustering within neighborhoods and study sites. The positive relationships between water

18 expenditures and water insecurity persisted even when adjusted for income, while income was

19 independently negatively associated with water insecurity. Water expenditures were also

20 positively associated with food insecurity and perceived stress. These results underscore the

21 complex relationships between water insecurity, food insecurity, and perceived stress and

22 suggest that water infrastructure interventions that increase water costs to households without

23 anti-poverty and income generation interventions will likely exacerbate experiences of household

24 water insecurity, especially for the lowest-income households.

25

26

29

30 **Highlights** (85 char including spaces for Elsevier journals)

31 • We assessed relationships between water expenditures, income, and water insecurity.

32 • Higher household expenditures were associated with greater water insecurity.

33 • Higher expenditures were also associated with food insecurity and perceived stress.

34 • We observed no income threshold for households overcoming water insecurity.

35 • Water projects that increase household costs should be paired with anti-poverty

36 measures.

37

38

Introduction

Water affordability is critical for achieving global household water security. Starting in 2005, the Millennium Development Goals, and then after 2015 the Sustainable Development Goals (SDGs), have guided the development of water and sanitation services in low- and middle-income settings. SDG Target 6.1 is "to achieve universal and equitable access to safe and affordable drinking water for all," while 6.2 focuses on access to sanitation. The inclusion of the notion of 'equity' implies a concern with the enduring problem of differential water access by social or economic class. In other words, SDG Targets 6.1 and 6.2 can be interpreted as a call for water, sanitation, and hygiene (WASH) programs to recognize differential willingness and ability to expend cash resources for WASH services. This is in line with the SDGs' emphasis on a more holistic understanding of water accessibility and quality (Smiley 2017).

Yet, the policy literature on WASH provision in low- and middle-income countries is strongly influenced by the notion that charging for water services is the best way to ensure that such services are appropriately allocated and financed (Anderson and Snyder, 1997, Grafton, Ward et al. 2011). Typically it is argued that charging more for water, and gearing consumption to price, will remove inefficiencies built into existing models of public service provision and provide the necessary capital for maintenance and service expansion (Anderson and Snyder 1997; Grafton et al. 2011). But there is mounting evidence that market-driven water services are not universally associated with better water services provision (Bel and Warner 2008; Rusca and Schwartz 2018; Staddon 2010). The efficiency and financial performance of public and private utilities around the world is highly variable, reflecting the different demands and operating context of each (Kirkpatrick, Parker, and Zhang 2006; Van den Berg and Danilenko 2017). Globally, utilities face demands for new (or renewed) infrastructure and new water quality and regulatory requirements with varied levels of monitoring and enforcement (Kirkpatrick, Parker, and Zhang 2006). Beyond this, scholars have repeatedly shown that market-driven water services programs often bring negative unintended consequences (Bakker 2010; McDonald 2014). Yet some

65   politicians and scholars continue to advocate for market-based policies without rigorous analyses

66   of the complex relations between reported water expenditures and relative levels of household

67   water insecurity.

68   Much of the world's poor acquire water from diverse sources, which are sometimes cost-

69   free (e.g., surface water) or community-owned (e.g., community kiosks), but are more commonly

70   part of market-driven water systems, whether governed by the municipality or small-scale water

71   entrepreneurs. People who are disconnected from municipal water systems tend to pay the most

72   for water (Allen and Bell 2011, p.1). This general finding has been demonstrated around the world,

73   including India, Nepal, Kenya and Colombia (Katuwal and Bohara 2011; Cook, Kimuyu, and

74   Whittington 2016; Zérah 2000). These studies tend to find that, for poorer households, the cash

75   element of water services costs can absorb up to 15% of total household cash income. These

76   financial costs are well above international benchmarks for water affordability of 3-5% of

77   household income/expenditure recommended by the World Bank, and 5% by the Asian

78   Development Bank (ADB) (Fankhauser and Tepic 2007). They also exclude the full range of

79   opportunity costs and other sacrifices routinely made for water acquisition, including for example

80   foregone school and employment time for women and girls (e.g., Zérah 2000). Many households

81   lacking reliable access to clean water may have to buy water and invest in additional coping

82   strategies including buying water storage containers, all of which increase household water

83   expenditures (Coulibaly, Jakus, and Keith 2014; Pattanayak et al. 2005). In India, Amit and

84   Sasidharan (2019) found that as household income increased, the proportion of income spent on

85   additional coping strategies decreased even while investments in pumping and high-volume water

86   treatment increased. Based on these findings, an income threshold may exist that, once

87   exceeded, allows households to implement coping strategies (e.g., additional storage or

88   disinfection technology) that substantively reduce water insecurity.

89   The question is then: how can we meaningfully assess what that income threshold might

90   be in a way that is relevant to understanding how it affects household well-being? Our assumption

4

91 in this paper is that the household coping costs of meeting water expenditures can negatively

92 affect households in many ways, as demonstrated for other necessities such as energy or food

93 (Månsson, Johansson, and Nilsson 2014; Russell et al. 2018). Drawing on literature from

94 biocultural anthropology (Workman and Ureksoy 2017; Hadley and Crooks 2012; Wutich and

95 Brewis 2014), we use measures of reported water insecurity and two additional generalized

96 markers of negative effects: perceived stress and reported household food insecurity. Both are

97 considered to be tied intimately to human suffering, including suffering around water, albeit in

98 slightly different ways. Perceived stress is an outcome measure used to understand how different

99 situations affect our feelings and our perceived stress (Cohen, Kamarck, and Mermelstein 1983),

100 and has been associated with multiple forms of material poverty (Bisung and Elliott 2017). Food

101 insecurity is itself very stressful as a form of material poverty, both in terms of the actual threat of

102 hunger and in terms of the meanings and feelings it evokes (Weaver and Hadley 2009; Weaver

103 and Trainer 2017).

104   Water insecurity scholars have begun to recognize water's potential contribution to

105 elevated reports of perceived stress (Bisung and Elliott 2017). Research on perceived stress

106 encompasses a range of assessments of social stress (e.g., evoked distress, perceived stress,

107 symptoms of anxiety/depression). Water-related stress has also been shown to be associated

108 with limited water access (Brewis, Choudhary, and Wutich 2019), experiences of water insecurity

109 (Stevenson et al. 2016), shameful or conflictual water collection dynamics (Sultana 2011),

110 unpredictable and unjust water systems (Wutich and Ragsdale 2008), and social inequality in

111 water systems (Ennis-McMillan 2001). As such, perceived stress measures can provide a

112 valuable global summary assessment of the socioeconomic, cultural, and mental health toll of

113 water insecurity.

114   More recently, food insecurity has emerged as an area of intensive focus in water

115 insecurity scholarship, with efforts to better understand interconnections in the water-food nexus

116 (Wutich and Brewis 2014; Brewis et al. 2020). Water insecurity affects food insecurity through

5

117　multiple pathways, including the lack of water for growing food, the inability to prepare cooked

118　foods, and the high cost of buying water and food (Brewis et al. 2020; Collins et al. 2019). Food

119　insecurity is thus a measure that helps capture the physical health effects of water insecurity,

120　including those related to hunger and malnutrition. There is a substantial literature demonstrating

121　that food insecurity is associated with higher levels of stress markers including depression and

122　anxiety (Hadley and Patil 2006), perceived stress (Martin et al. 2016), and emotional expressions

123　of distress (Pike and Patil 2006). It may be that much of this is explained by food insecurity's

124　association with water insecurity, but very few studies have explored this relationship (Brewis et

125　al. 2020; Wutich and Brewis 2014).

126　　　This study leverages a data set managed by the Household Water Insecurity Experiences

127　(HWISE) Research Coordination Network that was compiled in 2017 and 2018 from 29 sites in

128　24 low- and middle-income countries around the world (Young, Collins, et al. 2019). We use this

129　unique comparative dataset to explore the complexities attending the relationship between

130　household financial (i.e., cash) water expenditures and well-being operationalized by a household

131　experience-based water insecurity score. This analysis builds on the household water affordability

132　literature above by statistically testing whether higher household water expenditures ~~exacerbate~~

133　<u>are associated with</u> water insecurity. In our first set of questions (Figure 1A), we aimed to answer

134　the following questions:

135　　1.　Are higher household water expenditures associated with a higher degree of water

136　　　　insecurity?

137　　2.　Is the relationship linear or is there a threshold beyond which the effect of higher water

138　　　　expenditures on water insecurity wanes or disappears entirely?

139　　3.　Does water insecurity decline at some level of income, regardless of expenditures, i.e.,

140　　　　can a household financially "earn its way out" of water insecurity?

141   Next, we evaluated the relationship between household expenditures and indicators of well-being

142   posited to be related to water insecurity, i.e. food insecurity and perceived stress, with two

143   additional questions (Figure 1B):

144   4. Do water expenditures mediate or moderate the association between water insecurity and

145   food insecurity?

146   5. Do water expenditures mediate or moderate the association between water insecurity and

147   perceived stress?

148   We report on our analyses of these research questions and discuss the implications for water

149   pricing schemes, achieving SDG 6 water targets, and future water insecurity research. Our results

150   advance understanding of the complex relationships between water insecurity, food insecurity,

151   and perceived stress, with both empirical and theoretical implications for household water

152   expenditures.

153   [FIGURE 1 ABOUT HERE]

154

155   **Methods**

156   *Sample*

157   Our data are drawn from the Household Water Insecurity Experiences (HWISE) data set compiled

158   in 2017 and 2018. The parent study involved over 7,000 participants at 29 water-stressed sites in

159   24 countries (for details on each site's sampling strategy, see Young, Collins, et al. 2019). Study

160   sites were located in sub-Saharan Africa, South America, Central America, the Middle East,

161   Oceania, and Asia, each with a target sample of 250 households from urban, peri-urban, and rural

162   settings. At all sites, informed consent was obtained prior to data collection by a trained

163   enumerator with IRB oversight (from a variety of institutions). Consent and data collection were

164   administered in the relevant local language. The survey was conducted with one eligible adult per

165   household who self-identified as knowledgeable about the household's water situation. Not all

166 households reported water expenditure data, and we excluded households from analysis if

167 reported water expenditures were greater than three standard deviations from the respective site

168 mean (i.e., unverifiable as either outliers or errors) and any other cases where key variables were

169 missing. Because not all sites completed all modules, our final analysis included 3,655

170 households from 23 sites in 20 countries (see Table 1).

171   Because this sample represents roughly half of all households in the HWISE data set, we

172 analyzed select demographic differences between included cases and those excluded due to

173 missing covariate data (see Supplementary Files, Table S1). In most cases, detected differences

174 were attributable to the exclusion of entire sites such as Morogoro, Tanzania; Acatenango,

175 Guatemala; and Upolu, Samoa. Though interpretation of our results is limited to water insecure

176 communities with profiles similar to our included sites, this is not unduly restrictive.

177

178 *Water insecurity scores*

179 Our water insecurity scores were constructed using items from the same water insecurity

180 experiences module that was the basis for the HWISE Scale (2019; Young, Boateng, et al. 2019).

181 The cross-culturally validated HWISE Scale is composed of 12 items; 11 items were collected in

182 all study sites, but the twelfth ("feelings of shame about the water situation") was only collected in

183 the second sampling wave. In order to take advantage of data from all sites, we use an 11-item

184 version of the scale that excludes the "shame" question. The 11-item water insecurity score

185 accounts for 99.3% of the variation in HWISE Scale scores with minimal additional error.

186   The 11 items compiled into our water insecurity score queried the number of times in the

187 prior four weeks that the household had experienced problems related to *water availability* (supply

188 interrupted, no water availability at all), *quantity* (not enough to wash clothes, having to change

189 foods eaten, not having as much to drink as liked, going to sleep thirsty), *hygiene* (inadequate

190 water for bathing, inadequate water for handwashing), and *psychosocial dimensions* (worrying

191 about having enough water, having one's day interrupted because of water problems, feeling

192 upset/angry about the water situation). Likert-type responses were individually scored from 0 to 3

193 as: 0 = never, 1 = rarely (1-2 times in the previous four weeks), 2 = sometimes (3-10 times),

194 3 = often (11-20 times) or always (>20 times). We generated a score for each household by

195 summing values across the 11 items, resulting in a range of 0-33, where higher scores indicate

196 greater water insecurity.

197

198 *Water expenditures and self-reported monthly income*

199 We generated three relative measures of cash water expenditures (i.e., physical currency or

200 electronic payments) using two survey questions that asked, "In the past 4 weeks, approximately

201 how much money did you spend on getting water for your household?" and "What is the primary

202 monthly income for your household?" First, we calculated expenditures as the site-specific *Z*-

203 score of absolute monthly spending (in USD, converted at the time that data collection was

204 completed at each site). Self-reported monthly income was also collected in local currency and

205 converted to USD. Then, we calculated expenditures as the percent of monthly household income

206 (in USD). Lastly, we generated site-specific *Z*-scores for the percent of income, yielding three

207 currency-less measures of household water expenditures. We initially explored the unadjusted,

208 absolute USD expenditures by site to understand the underlying variance in magnitude across

209 sites. Because these values were not adjusted for purchasing power and are likely a proxy for the

210 absolute differences in disposable income between lower- and middle-income nations, we do not

211 analyze these any further.

212   We considered alternative measures of expenditures, such as standardization by

213 purchasing power parity (PPP). But this was not possible because most study sites did not capture

214 information about water volumes fetched or purchased, or unit costs for the many water sources

215 used by participating households. Because local water pricing in water-stressed communities can

216 be dynamic and is shaped by many factors such as weather, service outages, and politics (e.g.,

217 Bakker 2003), PPP standardization is not more likely to offer stable short-term measures of water

218   expenditures across sites, consistent with ongoing debates about PPP among economists (Taylor

219   and Taylor 2004).

220

221   *Food insecurity*

222   The level of reported household food insecurity was collected using the 9-item Household Food

223   Access Insecurity Scale (HFIAS) (Coates, Swindale, and Bilinsky 2007). The items in this index

224   were phrased similarly to the water insecurity items, i.e. Likert-type responses with a 4-week recall

225   period. Scores ranged from 0 to 27 with higher values indicating higher food insecurity.

226

227   *Perceived stress*

228   Perceived stress was collected in the survey using the short version of the Perceived Stress Scale

229   (PSS) comprised of four items measured on a five-point Likert-type scale that are each scored

230   from 0 to 4 (Cohen, Kamarck, and Mermelstein 1983):

231   (1) "In the last month, how often have you felt that you were unable to control the important

232   things in your life?"

233   (2) "In the last month, how often have you felt confident about your ability to handle your

234   personal problems?"

235   (3) "In the last month, how often have you felt that things were going your way?"

236   (4) "In the last month, how often have you felt difficulties were piling up so high that you could

237   not overcome them?"

238   PSS scores are obtained by reversing response scores (e.g., 0 = 4, 1 = 3, 2 = 2, 3 = 1 & 4 = 0) to

239   the two positively stated items (items 2 and 3) and then summing across all four items (range 0–

240   16) so that higher values indicate higher perceived stress.

241

242   *Statistical analyses*

243   We first examined the variation in each site's mean household water expenditures, and assessed

244   the relationship between mean expenditures and a site's mean water insecurity score using

245   Pearson's correlations. We then examined Spearman's rank correlations between each of our

246   three measures of water expenditures and the frequency of selected survey items that were

247   candidate covariates (e.g., a reported lack of money to buy water, and reports that water issues

248   prevented households from earning money) to understand bivariate relationships (and potential

249   collinearity) between the expenditure measures and covariates that may shape household water

250   insecurity.

251   Although the site samples all employed random selection at the household level, several

252   sites also first stratified by survey clusters (e.g., population strata, neighborhoods, or

253   villages/towns). We fitted three-level tobit mixed-effects random intercept regression models

254   using the metobit command in Stata v16.0 (College Station, TX), to account for clustering of

255   participants within each site (n = 23), and survey clusters within sites (n = 66) as random effects.

256   Tobit regression modifies the likelihood function to account for censoring of scaled dependent

257   variables like our water insecurity, food insecurity, and perceived stress scores (Austin, Escobar,

258   and Kopec 2000). We specified all lower limit censoring at zero and the upper limits to the

259   maximum values for each score separately. All statistical analyses were performed in Stata and

260   interpreted with a statistical significance threshold of $\alpha \leq 0.05$.

261   To answer question 1 about the relationship between water expenditures and water

262   insecurity, we fit separate, multilevel tobit regression models using the water insecurity score as

263   the dependent measure. Each model included one of our three independent expenditure variables

264   of interest (absolute USD Z-score, % income, and % income Z-score) and a vector of level-1 fixed

265   effects known to shape water insecurity or expenditures. These include the respondent's age and

266   gender, particularly younger females (O'Reilly et al. 2009); the number of children in the

267   household, which increases water demand (Arbués, García-Valiñas, and Martínez-Espiñeira

268   2003); whether the main drinking water supply was a vended source (e.g., tanker truck, bottled

269   water, small vendor), which increases the unit cost of water (Katko 1991); and the total amount

270   of drinking and other household water stored in the household at the time of interview. The

271   amounts of stored water help us indirectly control for seasonality and wealth effects, as water-

272   stressed households store more water during drier weather and when they have the financial

273   means to afford more or larger storage containers (Tucker et al. 2014). We introduced a single

274   binary covariate denoting rural vs. non-rural geographic location at the site level, and no additional

275   covariates at the cluster level. We hypothesized that higher expenditure levels of any kind would

276   be associated with a higher water insecurity score.

277   To answer question 2, we evaluated the linearity assumption in this modeling technique

278   using residual plots. Next, to evaluate question 3, we tested whether expenditures mediated the

279   relationship between income and water insecurity by exploring how the presence and absence of

280   the expenditures term affected the adjusted model coefficient for income. We then performed

281   moderation analysis by including an interaction term between income and expenditures in the

282   models with each of our three expenditure measures. In these interaction models, we

283   hypothesized that households with the highest income and expenditures would be associated

284   with lower water insecurity scores.

285   To answer questions 4 and 5 about water expenditures' respective relationships with food

286   insecurity and perceived stress, we fitted separate sets of models using a similar specification

287   described for question 1. We used the water insecurity score as an independent variable, and

288   food insecurity or perceived stress scores as the outcomes of interest. In our mediation analysis,

289   we first fitted adjusted models of food insecurity and perceived stress with the water insecurity

290   score (our exposure of interest) and demographic covariates, and then separately introduced

291   each of the three water expenditure measures to see if they substantively affected the adjusted

292   model coefficient of the water insecurity score in magnitude or direction. In the moderation

293   analysis, each set of three models of food insecurity and perceived stress included an interaction

294   term between the water insecurity scores and expenditures (for each of the three expenditure

295   measures), adjusted for demographic covariates.

296

297   **Results**

298   *Descriptive statistics*

299   Table 1 presents the sample sizes for each site along with the respective mean and standard

300   deviations for absolute monthly water expenditures in USD, and for water expenditures expressed

301   at a percent of monthly income. There was considerable variation in absolute monthly

302   expenditures (mean = $8.60, standard deviation [SD] = $19.44) ranging from USD $0.04 in

303   Chiquimula, Guatemala, to USD $60.92 in Beirut, Lebanon. The mean percent of income spent

304   on water was 5.2% (SD = 8.0), just above international benchmarks for water affordability set by

305   the World Bank and Asian Development Bank (Fankhauser and Tepic 2007), and ranged from

306   near-zero in Chiquimula, Guatemala, and 0.1% in Bahir Dar, Ethiopia, and Pune, India, to 13.7%

307   in Punjab, Pakistan. We found similarly wide variation in the site-specific bivariate correlation

308   coefficients between the two expenditure measures and the water insecurity score. Absolute USD

309   water expenditures were significantly positively associated with the water insecurity score in nine

310   sites with correlation coefficients ranging from 0.10–0.42 (Table 1). Only Beirut yielded a

311   significant negative relationship (-0.13, P = 0.004).

312   Percent-of-income expenditures were significantly positively associated with water

313   insecurity score in seven sites, with correlation coefficients ranging from 0.14–0.31 (Table 1).

314   Beirut flipped from having water insecurity be negatively associated with expenditures to being

315   positive (0.27, P < 0.001), and the correlations for several other sites changed in magnitude.

316   There were no statistically significant negative associations. It is clear that the measure of

317   expressing expenditures mattered, and that the unadjusted absolute USD measure may

318   ultimately be a weak proxy for national income differences, with residents of middle-income

319   nations generally able to spend relatively more on water in absolute terms than residents from

320   lower-income nations. The remainder of our analyses use only the standardized water

321   expenditures indicators.

322   [TABLE 1 ABOUT HERE]

323

324   *Correlation analysis*

325   Table 2 presents the Spearman's rank correlations among the three water expenditures measures

326   and the frequency of households reporting "water problems prevented earning money," and

327   "lacked money to purchase water." As expected, all of the water expenditure-related variables

328   were significantly correlated with each other, with the highest correlation observed between

329   absolute USD *Z*-score and percent of income *Z*-score (*rho* = 0.65, *P* < 0.001). The strongest

330   correlation between any of these expenditure variables and *frequency of water problems*

331   *preventing earning money* was for percent of monthly income spent on water (*rho* = 0.25, *P* <

332   0.001). The strongest correlation between the expenditure variables and *frequency of lacked*

333   *money to purchase water*, was also observed for percent of monthly income spent on water (*rho*

334   = 0.32, *P* < 0.001). These significant associations, while relatively weak compared with the

335   expenditure measures themselves, demonstrate an initial statistically significant relationship

336   between water expenditures and two fundamental aspects of water insecurity: interference with

337   livelihoods, and financial barriers (Wutich et al. 2017).

338   [TABLE 2 ABOUT HERE]

339

340   *Regression modeling: water insecurity*

341   Our first set of regression models assessed whether household water expenditures were

342   associated with water insecurity scores (question 1), and the linearity of any observed effects

343   (question 2). We found consistent, positive associations between expenditures and water

344   insecurity (Table 3, Models 1–3). Higher water expenditures were associated with higher water

345   insecurity scores after adjusting for select household demographics and water storage practices,

346   but with varying effect sizes for absolute USD (Z-score: β = 0.88, standard error [SE] = 0.18, $P <$

347   0.001), % income (β = 0.13, SE = 0.02, $P <$ 0.001), and % income Z-score (β = 1.70, SE = 0.18,

348      $P <$ 0.001). The expenditure measures based on Z-scores have larger coefficients because a 1-

349   unit increase in Z-score is a much larger shift up the expenditure distribution curve than a 1

350   percentage point increase in percent-income. Therefore, the Z-score measure has a larger effect

351   on the water insecurity score than the percent-income measure.

352   Among the covariates, the number of children in the household ($0.27 \leq \beta \leq 0.29$, SE =

353   0.07, $P <$ 0.001 in all models) and living in a rural context ($2.09 \leq \beta \leq 2.45$, SE = 0.71, $P <$ 0.003

354   in all models) were significantly positively associated with a higher water insecurity score, while

355   age was negatively associated with the water insecurity score and approached statistical

356   significance (β = -0.02, SE = 0.01, $0.028 \leq P \leq 0.055$).

357   We then examined the residuals for the regression models of water insecurity scores in

358   Table 3. The randomly dispersed, non-skewed pattern of the residuals, with few potential outliers,

359   indicates that a linear fit was generally appropriate (see Supplemental Files, Figure S1). Model 1

360   produced the most centered residual cloud and Model 2 produced a longer tail to the right, but

361   the plots in Figure S1 suggest homoscedasticity of residuals (i.e., that they are independent and

362   identically distributed). In other words, there was no evidence of a threshold at which higher

363   expenditures were associated with a lower water insecurity score.

364   [TABLE 3 ABOUT HERE]

365   For our mediation analysis, we added income to each of the three models of water

366   insecurity scores in Table 3 and looked at the difference in the regression coefficient for income

367   with, and without, each respective water expenditure measure in the model (question 3). There

368   was virtually no difference, and thus no evidence that water expenditures mediated the

369   relationship between income and water insecurity score, so we proceeded with the moderation

370   analysis.

371   Next, we assessed whether income moderated the relationship between water

372   expenditures and water insecurity (also question 3) by adding an interaction term for income and

373   expenditures to the models in Table 3. We observed statistically significantly positive associations

374   between all water expenditure measures and the water insecurity score, again with stronger

375   associations for the expenditure measures standardized as absolute USD Z-score (β = 1.19, SE

376   = 0.20, P < 0.001) and percent income Z-score (β = 1.36, SE = 0.21, P < 0.001). We

377   simultaneously observed consistently strong negative associations between income and the

378   water insecurity score (-3.46 ≤ β ≤ -2.35, 0.39 ≤ SE ≤ 0.60, P < 0.001 in all models). In other

379   words, after adjusting for covariates, each additional $1,000 of household income is associated

380   with a water insecurity score that is 2.4–3.5 points lower, depending on how we define

381   expenditures (Table 4, Models 4–6).

382   The number of children in the household and rural context also remained statistically

383   significantly positively associated with the water insecurity score in all models, and age was

384   marginally negatively associated (Table 3). The interaction between water expenditures and

385   income was not significant in any models, suggesting that income and water expenditures are

386   independently associated with the water insecurity score. The interpretation of this interaction

387   term is complicated because its frequency distribution is severely right-skewed; most surveyed

388   households had very low income regardless of the water insecurity score. Households with high

389   income and low water insecurity scores—despite being infrequent—can appear in the same part

390   of the interaction term's frequency distribution as households with low income and high water

391   insecurity, which is clearly a different household context.

392   Nevertheless, water expenditures and income were both strongly related to water

393   insecurity with opposite effects, but independently so, and with varying strength depending on

394   how one measures expenditures. Finally, the coefficients for the cluster and site random effects

395   were consistently larger than those of any household-level fixed effects throughout Models 1–6,

396   suggesting that location contributes substantially to the variation in water insecurity score,

397   consistent with the bivariate results in Table 1.

398   [TABLE 4 ABOUT HERE]

399

400   *Regression modeling: food insecurity*

401   To explore whether water expenditures mediated or moderated the association between water

402   insecurity and food insecurity (question 4), we fit separate models with each of our three

403   expenditure measures using the Household Food Insecurity Access Scale (HFIAS) as the

404   outcome of interest (Table 5). We began with our mediation analysis to test the differences in the

405   regression coefficients for the water insecurity score with, and without, each respective

406   expenditure measure in the model. There was no evidence that water expenditures mediated the

407   relationship between water insecurity score and HFIAS, so we proceeded with the moderation

408   analysis.

409   Across all models, higher water insecurity scores were significantly positively associated

410   with higher food insecurity scores; a 1-point increase in water insecurity was consistently

411   associated with approximately a half-point increase in food insecurity. The percent-income (β =

412   0.05, SE = 0.02, P = 0.017) and percent-income Z-score (β = 1.23, SE = 0.27, P < 0.001)

413   measures of water expenditures (Models 8 and 9) were significantly positively associated with

414   food insecurity, again with the Z-score measure yielding greater magnitude. This is consistent

415   with the positive relationships between expenditures and water insecurity, and water insecurity

416   and food insecurity. Higher water expenditures expressed as the absolute USD Z-score were not

417   associated with lower food insecurity (β = -0.42, SE = 0.24, P = 0.078).

418   The interaction term between water insecurity and expenditures was only significantly

419   negatively associated with food insecurity for absolute USD Z-score (Model 7: β = -0.05, SE =

420   0.02, P = 0.013). Given the tiny effect sizes and the lack of any significant results for the interaction

421   terms based on either of the percent-income-based expenditure measures, there was little

422   evidence that expenditures moderated the relationship between water and food insecurity.

423   We found age, number of children in the household, and rural context to all be significantly

424   and positively associated with food insecurity across all models (with the exception that rural

425   context only approaches significance in Model 7: β = 1.23, SE = 0.64, P = 0.055). Interestingly,

426   using a primary water source that is purchased/vended was consistently, significantly associated

427   with a lower food insecurity score (-2.53 ≤ β ≤ -2.03, SE = 0.37, P < 0.001 in all models), perhaps

428   indicating some relationship between ability to pay for food and water respectively after adjusting

429   for a household's degree of water insecurity, or perhaps being a proxy for income, i.e. households

430   that can afford vended water can also afford food security.

431   [TABLE 5 ABOUT HERE]

432

433   *Regression modeling: perceived stress*

434   We applied the same approach we used with food security to evaluate the relationship between

435   water insecurity and perceived stress, using the PSS score as the outcome of interest (question

436   5). Again, we began with mediation analysis and explored the differences in the regression

437   coefficient for the PSS score with, and without, each respective expenditure measure in the

438   model. There was no evidence that water expenditures mediated the relationship between water

439   insecurity score and PSS, so we proceeded with the moderation analysis.

440   In all three models, higher water insecurity scores were significantly associated with higher

441   PSS scores (Table 6, Models 10–12). Every measure of water expenditure was also significantly

442   associated with perceived stress, although the directions of the relationships varied. Absolute

443   USD Z-score (Model 10: β = -0.19, SE = 0.09, P = 0.028) was negatively associated with

444   perceived stress, whereas percent-income (Model 11: β = 0.02, SE = 0.01, P = 0.034) and

445   percent-income Z-score (Model 12: β = 0.34, SE = 0.10, P = 0.001) yielded positive associations.

446   This may signal that perceived stress is tied to perceptions of water costs. Households may not

447   associate a larger dollar amount of water costs, relative to their neighbors, as stressful alone.

448   Rather, when these water costs are placed in the context of the overall household budget as a

449   percentage, households are better able to contextualize relative water costs. The interaction term

450   for water insecurity and expenditures was not significant in any of the models, indicating that these

451   factors are independently associated with perceived stress. The associations between other

452   household characteristics and perceived stress were relatively muted, compared with the earlier

453   analyses of water and food insecurity, and generally non-significant with a few relationships

454   approaching the α < 0.05 significance threshold. For example, the number of children was

455   significantly associated with perceived stress in Model 10 using absolute USD Z-score ($β$ = 0.05,

456   SE = 0.03, P = 0.047), yet only approached statistical significance in Models 11 and 12 despite

457   similar effect sizes. Likewise, having a primary water source that is purchased or vended was

458   significantly associated with lower perceived stress in Model 11 using percent-income ($β$ = -0.36,

459   SE = 0.14, P = 0.009) and Model 12 using percent-income Z-score ($β$ = -0.38, SE = 0.14, P =

460   0.006), yet, only marginally significant in Model 10. The coefficients for the cluster- and site-level

461   random effects were also consistently smaller than those in the models of the water insecurity

462   and food insecurity scores, indicating that geography may have less influence on perceived stress

463   than for other constructs.

464   [TABLE 6 ABOUT HERE]

465

466   **Discussion and Conclusion**

467   This study leveraged data from a larger parent study of water insecurity experiences in low- and

468   middle-income countries to explore relationships between household water expenditures, water

469   insecurity, food insecurity, and perceived stress. These data revealed a linear, positive

470   association between relative measures of household water expenditures and a household water

471   insecurity score, after adjusting for household demographic characteristics. For example, when

472   measuring expenditures as percent of income, spending 10 percent more of the household's

19

income on water was associated with a 1.2-point increase in the household water insecurity score after adjusting for household characteristics such as income, which drives the water insecurity score in the opposite direction. This is notable given the diverse drivers and experiences of household-level water insecurity.

The linear association between household water expenditures and our water insecurity score has important implications. It suggests that low-income households may face chronic water insecurity via cost recovery-driven water projects utilizing tariffs whose rate increases may exceed the rate of wage increases, and especially where communities are prone to water price shocks due to natural or human-triggered hazards. We recognize that most cost recovery pricing schemes target middle- and high-income households. But price increases can produce trickle-down price shocks for vended water sources frequented by low-income households, especially when small-scale water providers, such as kiosk water venders, tanker services, or packaged water, are left to market forces (Amankwaa et al. 2014). We hypothesized that there might be some income threshold beyond which households are able to essentially earn their way out of water insecurity, and we observed no evidence of this—though there were very few households that exhibited both high income and high expenditures, and all the models suggest that any threshold might vary across nations and socio-economic contexts. Higher-earning households in our sample did, on average, experience improved water security relative to lower-earning households after adjusting for water expenditures; this provides additional support for calls for better integration of WASH and anti-poverty initiatives (Lombard et al. 2012), with the caveat that pro-poor pricing systems can present financial trade-offs for water companies (Ruijs 2009).

Of note, there was no evidence of any interaction between expenditures and income, suggesting that water expenditures and income have independent effects on water insecurity. This is consistent with the many social mechanisms that can help higher-income households mitigate water insecurity without more direct spending on water services. For example, higher-income households often, on average, have access to different social networks and opportunities

20

499 that may yield access to free water through professional employment settings, access to other

500 "insider" water sources (legal or not), or higher value bartering relationships (i.e., having higher-

501 order assets or services that can be used to secure water). Both high- and low-income households

502 may also alleviate water insecurity by making investments with high upfront costs, such as paying

503 for a piped connection, private well, or storage and disinfection resources which result in lower

504 ongoing water expenditures.

505 Beyond water insecurity, our analysis also found that relative measures of household

506 water expenditures were associated with greater food insecurity and perceived stress. These are

507 relationships that we have not seen tested explicitly in prior studies. These findings provide further

508 support to recent theoretical developments that position food insecurity and stress-related illness

509 as core companion phenomena to household water insecurity (Brewis, Choudhary, and Wutich

510 2019; Brewis et al. 2020; Wutich and Brewis 2014; Stevenson et al. 2012; Stevenson et al. 2016).

511 Here, we briefly unpack each finding and its implications in greater detail.

512 Our data revealed a positive relationship between water insecurity and food insecurity,

513 consistent with a recent study that used the same data but conceptualized water insecurity using

514 a factor approach (Brewis et al. 2020). That study observed positive associations between water

515 insecurity scores and HFIAS, with consistent positive associations between all sub-domains of

516 water insecurity and food insecurity. These collective findings underscore the proposition that

517 water insecurity is a driver of food insecurity—with water expenditures perhaps moderating this

518 relationship—and suggest that a similarly integrated approach to mitigating water and food

519 insecurity is required. Our mixed results in assessing water expenditures as a moderating factor

520 are perhaps due to unknown income-related effects. Absolute expenditure measures were

521 negatively associated with HFIAS—implying that certain expenditure levels could mitigate food

522 insecurity, if not water insecurity—but relative measures using the percent of income spent on

523 water were positively associated with HFIAS. Future studies with a more economically diverse

524 household sample could help clarify these relationships.

525   Our data also revealed a positive relationship between water insecurity, water

526   expenditures and perceived stress, which corroborates prior findings about pathways between

527   water insecurity and adverse mental health outcomes (Wutich and Ragsdale 2008). Water

528   insecurity and water expenditures were independently associated with perceived stress,

529   suggesting different manifestations of cognitive load stemming from these phenomena. Future

530   research on water worry and/or stigma could help elucidate the mechanisms by which social,

531   biological, financial, and other dimensions of water insecurity produce stress and anxiety and

532   possible moderating effects of gender and/or age in this relationship.

533   Our findings highlight the need for more careful measurement of water expenditures.

534   Beyond the different measures used here to operationalize water expenditures, it is important to

535   acknowledge that, in many low- and middle-income settings, households have long 'paid' for

536   water in both cash and non-cash ways and there are often additional hidden costs of these water

537   procurement strategies (Pattanayak et al. 2005). Such payments can be complex and multi-

538   faceted, involving deployment of cash (to buy from a commercial vendor), time (to collect water

539   from a distant source) and other forms of non-monetary exchange (e.g., reciprocity - Stoler et al.

540   2019; Brewis et al. 2019; Pearson, Mayer, and Bradley 2015). These types of expenditures may

541   be utilized simultaneously or cyclically for different types of water, depending on the context

542   (Wutich et al. 2018), and all should be more rigorously measured in future studies. Because of

543   the way our methodology resolved costs, we did not include non-monetary costs (e.g., time,

544   foregone opportunities, etc.), nor do we account for water-related disability adjusted life-years,

545   i.e. the loss in life-years due to water insecurity.

546   One common method for attempting to evaluate the value of non-market goods, the

547   'coping cost' approach, attempts to account for the multiple costs that can accrue as households

548   pursue multiple tactics for securing household water. Such 'coping costs' can include goods or

549   actions for which there are verifiable market prices (exchange of goods and services for cash as

550   with tanker, bottled or sachet water purchase) and non-market prices estimated through methods

551 such as 'revealed price' (Freeman III, Herriges, and Kling 2014). But, as noted at the outset of

552 this paper, it is difficult to monetize coping costs. For example, what is the value of lost children's

553 labor or school time following diarrheal illness? One study, by Hutton, Haller and Bartram (2007)

554 adopts rules of thumb about factors of GNI per capita, though notes the lack of a strong empirical

555 basis. Monetizing the coping costs of stress would be even more formidable and would perhaps

556 miss the point that not all dimensions of well-being are, or should be, monetized. This suggests

557 avenues for future research that capture both the monetary costs of water for households (e.g.,

558 water expenditures) as well as the opportunity cost of obtaining water through non-cash means.

559 In sum, the quantification of water expenditures impacts analytical results; this should be taken

560 into account in future work on water costs and expenditures and water insecurity.

561   Our study findings must be interpreted with caution due to several limitations. This study

562 used cross-sectional data from 23 culturally-diverse study sites, known to struggle with water

563 insecurity, in 20 countries that are broadly theorized to be representative of water-scarce

564 communities around the world (Young, Collins, et al. 2019). We emphasize that the interpretation

565 of our results is limited to water insecure communities with socio-demographic profiles that

566 resemble our included sites, with attention to sites' respective sample sizes used for analyses in

567 this study. For example, other sites with high out-migration rates might yield different results if

568 residents commonly earn their way out of water insecurity by moving to more water-secure

569 neighborhoods. The data are also subject to seasonality bias (most sites were surveyed only

570 once, sometimes in the wet season and sometimes in the dry season), and are not representative

571 of any single country, thus limiting us from inferring any causal relationships between water

572 expenditures, water insecurity, food insecurity, and perceived stress – mutually-reinforcing

573 relationships that likely operate in both directions. The self-reported household water expenditure

574 figures also may suffer from systematic inaccuracies, as has been shown with household

575 estimates of water prices (Binet, Carlevaro, and Paul 2014). The variation in completeness of

576 surveys across study sites also biases the results toward sites with a larger sample size, despite

577   our efforts to control for this effect by using multilevel, mixed-effects regression modelling. Our

578   modeling approach also focused on individual differences and—aside from our rurality indicator—

579   did not include additional site- or cluster-level covariates, such as population and environment

580   characteristics, that are theorized to shape water insecurity, food insecurity, or perceived stress.

581   These types of processes could in turn interact with local household geographic patterns (e.g.,

582   income distributions), but our design did not assess local spatial effects.

583   Our analysis of the relationships between household expenditures on water and water

584   insecurity, food insecurity and perceived stress suggests that—at best—only a small number of

585   high-income households may be able to earn their way out of water insecurity, presumably by

586   activating a wider range of coping strategies. These results also demonstrate that higher water

587   expenditures are positively associated with food insecurity and perceived stress. One implication

588   of this is that development programs focused on livelihood enhancement need to incorporate the

589   costs of water services. Conversely it can be concluded that water programs focused on using

590   price to both finance and regulate service use may in some cases aggravate the problems they

591   are trying to address. Subsidies may not be the answer either, as a recent World Bank report

592   found that water subsidies, which tend to focus on networked services, disproportionately benefit

593   high-income households (Andres et al. 2019). Achieving the SDGs, especially SDG 6.1 ("to

594   achieve universal and equitable access to safe and affordable drinking water for all"), requires a

595   paradigm shift that considers access as a multi-faceted dimension of water security, including

596   relative water costs (Wutich, Budds et al. 2017).

597   ~~Traditional~~ Biophysical conceptualizations of water security are oriented around physical

598   access to water. But the results of this study highlight the ~~need to consider~~increasingly recognized

599   importance of integrating social and economic factors (Cook and Bakker 2012)~~,~~. such as having

600   the financial means to pay for water services~~.~~ once physical access via the requisite infrastructure

601   is made possible. Global water security will also require involvement of water service providers to

602   achieve a delicate balance in structuring tariffs for water services to cover the financial costs of

603   providing services while also ensuring physical and financial access to these services for

604   customers of all income levels.

605

842

843   Because this sample represents roughly half of all households in the HWISE data set, we

844   analyzed select demographic differences between included cases and those excluded due to

845   missing covariate data. We found respective differences in age (38.6 [SE= 0.23] vs. 40.2 [0.23], *t*

846   = 4.94, *P* < 0.001), number of children (2.2 [SE= 0.03] vs. 2.4 [0.03], *t* = 5.25, *P* < 0.001), amount

847   (in liters) of stored drinking water (168.6 [SE= 45.9] vs. 289.6 [37.6], *t* = 2.04, *P* = 0.042), whether

848   primary source is purchased/vended (23.7% [0.01] vs. 17.1% [0.01], *t* = -7.29, *P* < 0.001), and

849   rural context (33.9% [0.01] vs. 30.1% [0.01], *t* = -3.62, *P* < 0.001). In most cases, detected

850   differences were attributable to the exclusion of entire sites such as Morogoro, Tanzania;

851   Acuatengo, Guatemala; and Upolu, Samoa. These three sites accounted for over 600 households

852   with average respondent ages in the 40s, and with households categorized as 75-100% urban,

853   thus rendering our included sample slightly younger and more rural. The mean children per

854   household was skewed lower by the exclusion of the Morogoro site (300 households with mean

855   2.61), in addition to losing 189 households from San Borja, Bolivia (site mean 2.53), and nearly

856   200 households from Punjab, India (site mean 4.02). Finally, the exclusion of the Rajasthan, India,
857   site removed 248 households with mean stored drinking water of 2,289 (in 100-liter units, by far

858   the largest site mean for this measure) thus skewing the water storage mean, and Morogoro,

859   Punjab, and Upolu, all had near-zero rates of using purchased/vended water. Though

860   interpretation of our results is limited to water insecure communities with profiles similar to our

861   included sites, this is not unduly restrictive.
