**Abstract:** There is no consensus about how terrestrial biodiversity was assembled through deep time, and in particular whether it has risen exponentially over the Phanerozoic. Using a database of 60,859 fossil occurrences, we show that the spatial extent of the worldwide terrestrial tetrapod fossil record itself expands exponentially through the Phanerozoic. Changes in spatial sampling explain up to 67% of the change in known fossil species counts and, because these changes are decoupled from variation in habitable land area that existed through time, this therefore represents a real and profound sampling bias that cannot be explained as redundancy. To address this bias, we estimate terrestrial tetrapod diversity for palaeogeographic regions of approximately equal size. We find that regional-scale diversity was constrained over timespans of tens to hundreds of millions of years, and similar patterns are recovered for major subgroups, such as dinosaurs, mammals, and squamates. Although Cretaceous/Paleogene mass extinction catalysed an abrupt two- to three-fold increase in regional diversity 66 million years ago, no further increases occurred, and recent levels of regional diversity do not exceed those of the Paleogene. These results parallel those recovered in analyses of local community-level richness. Taken together, our findings strongly contradict past studies that suggested unbounded diversity increases at local and regional scales over the last 100 million years.

## 1. Introduction

Life on land today is spectacularly diverse, accounting for 75–85% of all species [1,2]. Understanding how terrestrial diversity was assembled through deep time is crucial for settling fundamental debates about the diversification process, such as whether it is constrained by ecological limits [3,4]. However, there is no consensus about the long-term

42 trajectory of terrestrial diversity – in particular, whether or not exponential increases through  
43 the Phanerozoic have led to diversity being higher today at local, regional, and global scales  
44 than at any point in the geological past [3,5-11].

45 Tetrapods today comprise >30,000 extant species and include many of the most iconic and  
46 intensely studied groups of animals. Curves of global Phanerozoic tetrapod palaeodiversity  
47 have been widely used as exemplars of terrestrial diversification [3,7,9]. In particular, they  
48 have been used to argue for an ‘expansionist’ model of diversification, characterised by  
49 unconstrained and apparently exponential increases in diversity at a variety of spatial scales,  
50 perhaps even driving a tenfold rise in species richness during the last 100 million years [7,8].  
51 Within this paradigm, mass extinctions act only as short-term setbacks within a trend of ever-  
52 increasing diversity. This expansionist interpretation of terrestrial diversity through deep time  
53 has been cited as evidence that contradicts a role for ecological limits in constraining  
54 diversification [3], and to propose fundamentally different diversification processes in the  
55 marine and terrestrial realms [8].

56 However, the only diversity curves spanning the entire Phanerozoic evolutionary history of  
57 tetrapods are based on first and last appearance data for families, drawn from compilations  
58 that are now decades old [5,9]. Families are defined inconsistently [12,13], and may not  
59 reflect patterns of diversity at the species level. Moreover, these curves do not account for  
60 pervasive and long-established spatial and temporal sampling biases [14-16], since they pre-  
61 date the widespread use of sampling standardisation methods.

62 Most problematically of all, ‘global’ palaeodiversity curves based on the worldwide fossil  
63 record are not truly global, because the spatial extent of the fossil record varies substantially  
64 through intervals of geological time [10,11]. In reality, the ‘global’ fossil record comprises a  
65 heterogeneous set of regional assemblages, with palaeogeographic regions that vary markedly  
66 in number, identity, and extent (both within and between continental regions) through  
67 intervals of geological time. Critically, the palaeogeographic spread (=spatial extent) of the  
68 terrestrial fossil record itself grows exponentially through the Phanerozoic (Figs 1B and Fig.  
69 2; see also Figs S1 and S2), and is decoupled from the actual terrestrial area that existed  
70 through time (see Results). Such changes in the geographic extent of the sampled fossil  
71 record will substantially bias patterns of diversity through time, even when using sampling-  
72 standardised richness estimators [17].

73 Patterns inconsistent with expansionism are recovered by analyses applying rigorous  
74 sampling standardisation to estimate regional diversity of more restricted groups of tetrapods  
75 [6,18-20], or over shorter intervals of time (the Mesozoic–early Paleogene; [10,11]).  
76 Analyses of Phanerozoic tetrapod diversity at the local-community scale [21] also contradict  
77 the expansionist model of diversification. However, it remains unclear how terrestrial  
78 tetrapod diversity at regional spatial scales changed through the entirety of the Phanerozoic,  
79 especially from the Paleogene to the present, when the most substantial increases in face-  
80 value ‘global’ curves are observed.

81 Here, we present the first regional-scale diversity patterns for terrestrial tetrapods that cover  
82 their entire Phanerozoic evolutionary history, while adequately correcting for key biases. In  
83 doing so, we interpret the structure of the fossil record as an array of well-sampled  
84 palaeogeographic regions that contain useful information about regional palaeodiversity, but  
85 which are only indirectly informative about true global palaeodiversity. To achieve this, we  
86 extend and substantially improve our recently-developed approach for addressing large-scale  
87 spatial sampling biases [11]. We conduct our analyses at the species level, and compare our  
88 results to different models the diversification process. Our results demonstrate that diversity  
89 curves based on face-value counts of taxa from the ‘global’ fossil record primarily reflect

90 major increases in the geographic spread of fossil localities towards the present day. After  
91 controlling for these biases, we find no evidence for expansionist diversification in regional  
92 assemblages. The similarity of this regional pattern to patterns of local richness [21] suggests  
93 that beta diversity is unlikely to have changed substantially over the Phanerozoic, although  
94 further work is needed to confirm this. These results imply that the global diversity present in  
95 terrestrial ecosystems today may be similar to that of the early Cenozoic.

96

## 97 **2. Methods**

98 *Overview of analytical procedure.* We estimated diversity and other variables for  
99 palaeogeographic regions with approximately equal sizes. To achieve this, our analysis  
100 implemented the following steps (each described in more detail below):

- 101 1. We downloaded occurrence data for Phanerozoic non-flying tetrapods and key  
102 subgroups from the Paleobiology Database (Fig. 3A; Figs S1), removed unsuitable  
103 records, and binned the remaining records within equal-length time intervals.
- 104 2. We used a spatial subsampling algorithm (described below) to identify all nested  
105 subsets of adjacent fossil localities (=subsampled palaeogeographic regions) for each  
106 time interval, using the set of palaeocoordinates for all collections yielding non-flying  
107 terrestrial tetrapods (Fig. 3C).
- 108 3. We computed variables of interest (diversity, spatial metrics, etc.) for each  
109 subsampled palaeogeographic region.
- 110 4. We standardised the spatial extent of sampling in the fossil record by identifying  
111 subsampled palaeogeographic regions that simultaneously met a set of criteria related  
112 to spatial extent (summed MST length) and other spatial and sampling-related metrics  
113 (see below). This was performed at several distinct spatial scales.
- 114 5. We identified clusters of overlapping palaeogeographic regions (Fig. 3D; see below).  
115 This is necessary because palaeogeographic regions identified via the exhaustive  
116 search algorithm implemented in Step 2 may share many of the same underlying  
117 fossil localities.
- 118 6. All variables computed for palaeogeographic regions were summarised for each  
119 spatial cluster by computing medians and interquartile ranges.

120 *Dataset.* We downloaded fossil occurrence data for Phanerozoic Tetrapodomorpha from the  
121 Paleobiology Database [22] on 27 February 2019. We also downloaded occurrences for key  
122 tetrapod subgroups (Dinosauromorpha, Probainognathia, Squamata, Pseudosuchia,  
123 Testudinata, and Lissamphibia), and used the ‘occurrence\_no’ fields from these downloads to  
124 filter records from the main occurrence dataset. All occurrence datasets were downloaded  
125 using the Paleobiology Database API [23], using function calls executed within the analysis  
126 R scripts (URLs used to perform these data downloads, together with all analysis scripts, are  
127 available on Dryad [XXX]).

128 We removed unsuitable records from the occurrence dataset largely following the procedures  
129 outlined in Close et al. [11]. Contrary to that study, however, we did not exclude collections  
130 from deposits that were unlithified or partially-lithified and sieved (this is because  
131 lithification biases more severely affect the face-value estimates of local richness analysed  
132 Close et al. [11]). The patterns we document here are therefore conservative with respect to  
133 lithification biases, which manifest primarily from the Late Cretaceous onwards and become  
134 more profound towards the present. Flying tetrapods (Aves, Pterosauromorpha, and  
135 Chiroptera) were excluded because their fossil record is inadequate in most intervals and  
136 regions, and Lagerstätten-dominated. After cleaning, the dataset comprised 17,323

137 collections (broadly equivalent to fossil localities; see discussion in [21] for more detail),  
138 yielding 60,859 occurrences of 14,023 non-flying, non-marine tetrapod species.

139 Following previous studies (e.g. [11]), we used composite time bins of approximately equal  
140 length (~10 myr; Table S1). Occurrences were assigned to a bin if that bin contained over  
141 50% of the geologic time range associated with that occurrence (defined by the early and late  
142 bounds recorded by the 'min\_ma' and 'max\_ma' fields in the Paleobiology Database, in Ma).  
143 A total of 4,056 occurrences were dropped because they did not meet these binning criteria  
144 (72,413 before and 68,357 after).

145 *Identifying subsampled palaeogeographic regions.* To control for the pervasive spatial  
146 sampling biases affecting the terrestrial fossil record, we estimated diversity and other key  
147 variables for approximately equally-sized palaeogeographic regions, which we defined by  
148 drawing spatial subsamples of adjacent fossil localities (on a per-interval basis). To define  
149 these palaeogeographic regions, we used a spatial subsampling algorithm that identifies all  
150 nested sets of adjacent spatial points [24]. Spatial points were defined by binning the  
151 palaeocoordinates for all collections in our cleaned occurrence dataset into equal-size  
152 hexagonal/pentagonal grid cells with 100 km spacings (Fig. 3A–B), using the R package  
153 dggridR [25]. Spatial points used in our spatial subsampling algorithm are therefore 100 km  
154 grid cells containing at least one fossil occurrence.

155 The spatial subsampling algorithm works by: 1) selecting a random spatial point as a starting  
156 location; 2) identifying the closest spatial point, choosing at random if there are two or more  
157 equidistant points; 3) saving these two points as a palaeogeographic region; 4) identifying the  
158 closest point to those two points; 5) saving this set as a palaeogeographic region, and 6)  
159 continuing this procedure until all spatial points have been added. The algorithm is then  
160 repeated for every possible starting location, and any duplicate palaeogeographic regions are  
161 discarded. Distances were calculated from midpoints of 100 km dggridR cells. This  
162 procedure results in a database of palaeogeographic regions (sets of directly-adjacent or  
163 nearest-neighbour fossil localities) covering all possible sizes (Fig. 3C).

164 Palaeogeographic regions were identified using the set of fossil localities for the most  
165 inclusive taxon set that we analysed (i.e. non-flying, non-marine tetrapods). Diversity  
166 estimates for individual tetrapod subclades were also derived from these same  
167 palaeogeographic regions, because these represent areas in which tetrapod subclades could  
168 potentially be sampled.

169 Each palaeogeographic region was then characterised by computing a wide range of different  
170 metadata (e.g. variables relating to diversity, spatial factors, or sampling metrics). Spatially-  
171 standardised sets of palaeogeographic regions were obtained by simultaneously applying sets  
172 of filtering criteria (e.g. relating to spatial extent, numbers of occupied grid cells, etc.; see  
173 below).

174 *Variables calculated for subsampled palaeogeographic regions.* We calculated a wide variety  
175 of metadata for each palaeogeographic region. Spatial variables include counts of occupied  
176 equal-area grid cells (i.e. cells yielding fossil occurrences) spanning a range of sizes (100,  
177 200, 500, 1,000 and 5,000 km spacings, calculated using the R package dggridR [25]); our  
178 primary measure of palaeogeographic spread, minimum-spanning tree (MST) length (= the  
179 minimum total length of all the segments connecting spatial points in a region [26]; see Close  
180 et al. [11] for justification); the distance of the longest branch in each MST (used to identify  
181 spatial regions with widely-separated clusters of localities). Sampling variables include  
182 counts of literature references reporting the fossil occurrences in each spatial region (used as

183 a proxy for research effort) and measures of sample coverage (Good's  $u$  [27] and the multiton  
184 ratio [28]).

185 We estimated species richness within palaeogeographic regions using four very different  
186 methods: face-value counts of species within regions (= raw or uncorrected richness; i.e. not  
187 sampling standardised), Shareholder Quorum Subsampling (SQS [26,29,30], also known as  
188 coverage-based rarefaction [31]); and the asymptotic extrapolators 'squares' [32] and Chao 2  
189 [33].

190 We focus primarily on patterns estimated using SQS, which provides an objective,  
191 frequency-dependent measure of diversity that is insensitive to variation in sampling [31].  
192 Standardising to equal sample coverage may increase the signal of evenness at lower quorum  
193 levels [17]. Nonparametric asymptotic richness extrapolators, on the other hand, are less  
194 sensitive to evenness, but are downward biased when sample sizes are insufficient for  
195 estimates to have asymptoted [17]. We therefore present estimates using both approaches.  
196 Face-value counts of species within palaeogeographic regions, meanwhile, facilitate direct  
197 comparison with existing face-value 'global' curves.

198 We implemented SQS using the analytical solutions in the R package iNEXT [34]), which  
199 allows seamless integration of interpolated (=subsampled), observed and extrapolated  
200 coverage-standardised species richness estimates. We used quorum levels of 0.4, 0.6 and 0.8.

201 *Grid-cell rarefaction algorithm.* To additionally control for variation in the 'packing density'  
202 or spatial coverage of fossil localities within equal-sized palaeogeographic regions, we used a  
203 grid-cell rarefaction (GCR) procedure prior to calculating our focal measure of diversity,  
204 SQS (other estimators were not subject to this procedure due to heavy computational  
205 demands). When using GCR, SQS was estimated for each palaeogeographic region at a range  
206 of subsampled grid-cell quotas (we present GCR results using quotas of 3, 5 and 8 occupied  
207 200 km equal-area grid-cells with per 1,000 km of MST length, calculated using 50  
208 subsampling trials). SQS richness was also estimated without GCR (GCR = 'off'). To  
209 compare different richness estimators on an equal footing, our focal results do not use SQS  
210 with grid-cell rarefaction.

211 *Standardising spatial sampling.* To standardise spatial sampling, we identified subsampled  
212 palaeogeographic regions that simultaneously met the following criteria:

- 213 1. Seven distinct spatial scales, comprising minimum-spanning tree (MST) lengths of  
214 1,000 km, 1,500 km, 2,000 km, 2,500 km, 3,000 km, 3,500 km and 4,000 km ( $\pm 10\%$ ;  
215 Fig. 3C and S3). We quantified palaeogeographic spread using MSTs for reasons  
216 outlined by Close et al. [11]);
- 217 2. MSTs for which the length of the longest branch was no more than 40% of the total  
218 MST size (in order to exclude clusters of localities separated by large gaps);
- 219 3. At least 20 literature references, to ensure a minimum level of study;
- 220 4. A multiton ratio [28] of at least 0.25, to exclude palaeogeographic regions with very  
221 poor sample completeness (sometimes estimates of Good's  $u$  may spuriously appear  
222 high for small sample sizes, and the multiton ratio offers a more conservative and  
223 partially-independent measure of sample completeness).

224 We also excluded palaeogeographic regions that crossed geographic barriers, based on the  
225 combined presence of countries or continental regions at particular points in time (South  
226 America and Africa after 120 Ma; Australia and New Zealand after 70 Ma; Europe and  
227 Africa after 66 Ma).

228 *Spatial clustering algorithm.* Because our spatial subsampling algorithm finds all nested sets  
229 of adjacent spatial points, the full set of palaeogeographic regions will invariably include  
230 some regions that share underlying spatial points to a greater or lesser degree (ranging from  
231 no overlap to almost complete overlap). To address potential issues with non-independence  
232 between data points inflating apparent sample size, we identified clusters of similar  
233 palaeogeographic regions based on the fraction of spatial points they shared (samples were  
234 added to a spatial cluster if they shared >25% of the spatial points with another sample in the  
235 cluster; Figs 3D and S4). Key variables such as diversity and spatial or sampling metrics  
236 were then summarised for each cluster of palaeogeographic regions by computing median  
237 values and interquartile ranges.

238 *Model Comparisons.* We used linear model comparisons to examine whether patterns of  
239 spatially-standardised diversity are more consistent with diversification that is unconstrained  
240 ('expansionist', with steady increases through time) or constrained (i.e. with long-lived  
241 diversity equilibria, separated by phase-shifts). Our linear models included combinations of  
242 three explanatory variables: (1) absolute time, representing continuous per-lineage  
243 diversification; (2) an intercept, representing a null model in which diversity is static through  
244 time; and (3) a diversification-phase variable in which the intercept and/or slope are allowed  
245 to differ before and after the Cretaceous/Paleogene (K/Pg) mass extinction (66 Ma). Phase  
246 was included both as a covariate (allowing the intercept to vary independently between  
247 phases) and an interaction term (allowing the intercept and slope to vary between phases; see  
248 Table 1 for full list of models). These models were compared against an intercept-only null  
249 model. Richness estimates were log-transformed. Models were ranked using Akaike  
250 Information Criteria with the adjustment for small sample sizes (AICc) [35].

251 *Interactive data explorer.* Patterns of spatially-standardised diversity and other variables can  
252 be explored interactively using a Shiny web application, available as a gist on GitHub. The  
253 application can be run within RStudio by executing the following command:

254 `shiny::runGist('https://gist.github.com/rclose/URL-to-come-after-acceptance')`

255 **[Note to reviewers: to make access to the interactive Shiny application easier during peer-**  
256 **review, we have make it available as an online web application accessible at**  
257 **<https://factsaboutgiraffes.shinyapps.io/test-plot/>. The free tier for shinyapps.io permits 25**  
258 **hours of use per month, which should suffice for review purposes. However, it would**  
259 **probably not be enough for post-publication usage, so we will use the Gist described above**  
260 **instead.]**

261 The interactive data explorer allows exploration of spatially-standardised diversity results for  
262 all taxon sets, richness and other variables. Clicking on a data point plots the underlying data  
263 on a palaeomap and displays tables of the underlying occurrence data in that  
264 palaeogeographic region.

### 265 **3. Results**

266 The palaeogeographic spread (=spatial extent) of the terrestrial fossil record grows  
267 exponentially through the Phanerozoic (Figs 1B and Fig. 2; see also Figs S1 and S2), and is  
268 decoupled from the actual terrestrial area that existed through time. Although the  
269 palaeogeographic spread of the sampled fossil record increases fourfold through the  
270 Cenozoic, increases in actual terrestrial area over the same interval are much smaller (~15%;  
271 [36]; Fig. 1B; Fig. S5). Changes (i.e., first differences) in the palaeogeographic extent of the  
272 'global' fossil record of terrestrial tetrapods explain approximately 24–67% of changes in  
273 face-value species counts, and 31–34% of the changes in subsampled richness estimates,

274 depending on the measure of palaeogeographic spread used (Figs 1C–D and S6). By contrast,  
275 changes in the palaeogeographic spread of the fossil record are not significantly correlated  
276 with changes in continental area (Figs 1E–F and S7). The strong correlations observed  
277 between diversity and spatial sampling therefore represent real and profound sampling biases  
278 [10,11,17,21] that cannot be explained by ‘redundancy’ or ‘common cause’ effects [37,38].

279 The non-marine sedimentary rock record also decays exponentially with increasing age due  
280 to the progressive loss of sediments to erosion and burial, and is therefore likely to exert  
281 some influence on the palaeogeographic spread of fossil localities through time [16,39,40].  
282 Surprisingly, though, we find that neither changes in ‘global’ diversity nor the  
283 palaeogeographic spread of the fossil record are significantly correlated with changes in  
284 extent of non-marine sediments (Fig. S8). This indicates that the rock record is not the  
285 primary factor controlling spatial sampling in the terrestrial fossil record, and further justifies  
286 our direct use of the palaeogeographic distribution of the tetrapod fossil record to estimate  
287 spatially-standardised diversity patterns. Generalised least-squares models (GLS) of ‘global’  
288 diversity, as a function of the palaeogeographic spread of the worldwide fossil record,  
289 continental area and non-marine sediment extent (modelling temporal autocorrelation using a  
290 first-order autoregressive structure), recover a strong, statistically significant explanatory role  
291 only for palaeogeographic spread (Table 2).

292 Because pervasive spatial bias prevents us from estimating meaningful time series of global  
293 diversity through the Phanerozoic, we recommend that studies must instead focus on  
294 estimating regional-scale diversity for well-sampled palaeogeographic regions. The patterns  
295 of spatially-standardised regional richness that we recover are broadly consistent across  
296 spatial scales and for different richness estimators (Fig. 4). Surprisingly, results are highly  
297 congruent even when using face-value counts of species from spatially-standardised regions  
298 (in other words, when spatial sampling is standardised, but sampling intensity is not; Fig. 4).  
299 This suggests that variation in the spatial scope of the terrestrial fossil record has a more  
300 pronounced effect on apparent species richness than does variation in intensity or  
301 completeness of sampling within those regions.

302 Although data are insufficient to estimate regional diversity for much of the Paleozoic, levels  
303 during the latest Permian (~255 Ma) appear to have been similar to those of the Early  
304 Triassic (~250 Ma; Fig. 4). Similar regional diversity estimates are maintained up until the  
305 latest Cretaceous (~70 Ma), spanning a total interval exceeding 180 million years. Linear  
306 regressions of diversity on time for this extended interval return non-significant slopes,  
307 indicating a long-term static pattern of standing regional diversity (Fig. S9). This is true  
308 despite substantial faunal turnover throughout, including the Permian/Triassic (P/T) mass  
309 extinction (252 Ma), and the initial origins of groups that are speciose today during the  
310 Jurassic and Cretaceous [41].

311 Nevertheless, there are two clear intervals when regional-scale tetrapod diversity apparently  
312 increased substantially. All tetrapods share a single ancestor species that lived no later than  
313 the Late Devonian [42]. Although the data are insufficient to obtain diversity estimates  
314 during the Carboniferous, early increases in terrestrial tetrapod diversity must therefore have  
315 occurred within the Carboniferous to mid-Permian. A large apparent increase in maximum  
316 regional diversity also occurred later, in the aftermath of the K/Pg mass extinction [10,11,21].  
317 This primarily results from the fossil record of mammals, which shows an abrupt three- to  
318 fourfold increase in regional diversity (Fig. 5). There is no evidence in our data for  
319 substantial increases in maximum regional diversity through the remainder of the Cenozoic,  
320 either in tetrapods as a whole, or in major subclades (Figs 4 and 5). In fact, linear regressions  
321 of regional diversity on time for the Cenozoic recover significant trends towards lower

322 richness through time, driven by lower diversity in bins Ng3 and Ng4 (approximately the last  
323 10 million years; Fig. S9).

324 Model selection using information criteria demonstrates that the best explanations of regional  
325 diversity include the passage of time and a phase-shift across the K/Pg boundary. Across all  
326 spatial standardisation criteria, the model including time and phase as an interaction term  
327 receives greatest support (Table 1). This is because there is a shift to a higher regional  
328 diversity equilibrium across the K/Pg boundary, but this is followed by a significant decrease  
329 in regional diversity towards the present (Table S2; Fig. S9). For other richness estimators,  
330 see Supplementary Results.

331 Grid-cell rarefaction results highlight that the density of spatial coverage inside standardised  
332 palaeogeographic regions increases towards the present: when higher quotas of occupied grid  
333 cells are imposed, many more data points are excluded from the Paleozoic–Mesozoic than  
334 from the Cenozoic (Fig. S10).

335

#### 336 4. Discussion

337 Although long under-appreciated, variable spatial sampling represents a fundamental fossil  
338 record bias, and one that must be accounted for. Our results show that previous  
339 interpretations of exponential increases in tetrapod diversity through the Phanerozoic are an  
340 artefact of the increasing spatial extent of the ‘global’ fossil record (Fig. 1A–B). Between one  
341 and two thirds of the changes through time seen in ‘global’ diversity curves can be explained  
342 by changes in the palaeogeographic extent of sampled fossil localities (Figs 1B, D and S6),  
343 and this covariation is not explained by changes in the actual amount of habitable land area  
344 (Fig. S7E–H) or the extent of non-marine sediments (Fig. S8F–J). Although changes in  
345 continental area and the extent of non-marine sediments through time likely do exert some  
346 influence on the worldwide palaeogeographic spread of the terrestrial fossil record  
347 (particularly the extent of non-marine sediments, which decreases exponentially with  
348 increasing age [40]), other factors appear to be at least as important.

349 Estimating truly representative ‘global’ diversity curves for terrestrial tetrapods is, therefore,  
350 almost certainly not possible based on our current knowledge of the fossil record, and  
351 diversity analyses must focus on local and regional scales. We present the first spatially-  
352 standardised regional richness estimates spanning the entire evolutionary history of tetrapods.  
353 By estimating diversity for comparably-sized palaeogeographic regions through time, we  
354 recover fundamentally different patterns of diversity change to those found by previous  
355 studies of face-value ‘global’ trends [5,9], even when we consider only face-value species  
356 counts that do not control for variation in sampling intensity (Fig. 4). Most notably, variation  
357 in regional diversity within individual time bins is usually on par with variation through time,  
358 leading to patterns that are constrained over timescales of up to ~180 million years. We find  
359 no support for large sustained increases over the last 100 million years.

360 We do, however, observe an abrupt increase in regional-scale terrestrial tetrapod diversity  
361 during the earliest Cenozoic, consistent with recent work at local to continental spatial scales  
362 [10,11,21]. The precise reasons for this step-change are currently uncertain. It may support a  
363 fundamental role for the K/Pg mass extinction in disrupting and reorganising terrestrial  
364 ecosystems, consistent with a role for ecological limits in regulating diversification [4].  
365 Mammals certainly experienced a large increase in richness in the early Cenozoic. However,  
366 the relative contribution of mammals to overall tetrapod diversity patterns – and thus the  
367 magnitude of the increase itself – is likely exaggerated, due to their high preservation  
368 potential and the ease of diagnosing species from isolated teeth: in the Cenozoic fossil record,

369 mammal diversity is more than twice that of squamates (Fig. 5), yet the reverse is true for  
370 extant species richness. In contrast, the P/T extinction, the largest in Earth history, does not at  
371 present appear to have played a similar role in elevating long-term diversity (although sparse  
372 Paleozoic data limits interpretations). The reasons for the differing long-term impacts of the  
373 P/T and K/Pg extinctions on standing terrestrial diversity are unclear, but may reflect  
374 differences in the timescales over which the two events took place, or variation in the biology  
375 and preservation potential of the groups that flourished in the aftermath of each event.

376 Meanwhile, we find no evidence for effects on regional diversity of other events in  
377 evolutionary history of terrestrial tetrapods that have been hypothesised to have catalysed  
378 diversity increases, including the initial expansion of angiosperms during the middle and Late  
379 Cretaceous [7], and the breakup of the supercontinent Pangea [43]. This does not rule out a  
380 role for events in plant evolution as drivers of tetrapod diversification. Instead, it is possible  
381 that floral state-changes across the K/Pg boundary (e.g. increases in seed sizes [44]) might  
382 have been more important for mammalian species richness than events within the Cretaceous  
383 itself, a hypothesis that requires further investigation. Neither do our analyses of regional  
384 diversity rule out some increase in global richness due to continental fragmentation (although  
385 we have shown that global diversity cannot currently be estimated). Modelling of species-  
386 area relationships suggests that this effect could have approximately doubled global terrestrial  
387 tetrapod biodiversity between the Triassic and Late Cretaceous, during the main interval of  
388 Pangean fragmentation [43]. Pangean fragmentation was largely complete by the end of the  
389 Cretaceous, and it seems unlikely that the comparatively minor continental rearrangements  
390 that occurred during the Cenozoic could have driven the proposed ten-fold increase in global  
391 diversity recovered by influential previous work [5,9].

392 Our results are consistent with a growing body of evidence from the fossil record for  
393 constrained diversification within the terrestrial realm [6,10,11,18,21,32,45,46]. Moreover,  
394 the regional-scale patterns we document for Phanerozoic tetrapods are highly congruent with  
395 those observed at smaller spatial scales, such as for local richness [21], which also show  
396 minimal increases from the late Paleozoic–Mesozoic, a step-change across the K/Pg  
397 boundary, and no increase through the Cenozoic. The similarity between patterns of diversity  
398 at local (alpha) and regional (gamma) scales suggests an absence of systematic long-term  
399 trends in tetrapod beta diversity within regions through the Phanerozoic, although studies of  
400 the long-term patterns of beta diversity are needed to confirm this. Although limitations of  
401 the fossil record prohibit us from analysing regional-scale flying tetrapod diversity here,  
402 within-community patterns suggest these groups (birds, bats, pterosaurs) were also subject to  
403 long-term constraints [21]. These patterns suggest that the early diversification of birds  
404 resulted in the stepwise addition of substantial species richness to terrestrial ecosystems [10],  
405 with limited subsequent increases [21] that mirror the patterns of tetrapod richness  
406 documented here.

407 The diversity patterns we present are for regional spatial scales, and thus not directly  
408 comparable with global patterns. Furthermore, our results suggest that truly global estimates  
409 of tetrapod diversity through geological time are inaccessible based on our current knowledge  
410 of the fossil record. Nevertheless, barring substantial and as-yet-unquantified increases in  
411 global-scale faunal provinciality (i.e. between continental regions), previous findings of  
412 sustained, expansionist increases in ‘global’ standing diversity over the last 100 million years  
413 [5,7,9] are most likely artefactual, resulting from a failure to account for exponential  
414 increases in the spatial extent of terrestrial sampling over the same interval. Our results  
415 provide further evidence to overturn the previous paradigm of unconstrained, expansionist  
416 diversification, instead indicating long periods of relative stasis, disrupted by rare,  
417 geologically-rapid rises in maximum standing diversity.

418

419 **Acknowledgments:** We thank all contributors to the Paleobiology Database. This is  
 420 Paleobiology Database official publication XXX. We thank Mike Benton and two  
 421 anonymous reviewers for helpful review comments.

422 **Funding:** This research was funded by the European Union's Horizon 2020 research and  
 423 innovation program under grant agreement 637483 (ERC Starting Grant TERRA to RJB).  
 424 PDM was supported by a Royal Society University Research Fellowship (UF160216).

425 **Author contributions:** RJB and RAC conceived the study. JA, MTC, MDU, PDM, RJB,  
 426 RBB, TJC and EMD contributed to the data set. RAC designed and conducted the analyses,  
 427 and made the figures. RBB and RJB provided methodological input. RJB and RAC wrote  
 428 the manuscript. All authors provided critical feedback on the text.

550

551 **Fig. 1.** Spatial bias and the global fossil record of Phanerozoic terrestrial tetrapods. (A) Face-  
 552 value (red) and sampling-standardised (SQS [29,31] using quorum = 0.6; blue) ‘global’  
 553 species richness of Phanerozoic terrestrial tetrapods. (B) Spatial sampling (occupied equal-  
 554 area grid cells with 500 km spacings, green) and habitable area (terrestrial area as a  
 555 percentage of Earth’s surface [36], purple). Counts of occupied grid cells increase steeply  
 556 through the Cenozoic, and accelerate towards the present. (C, D) Relationships between  
 557 changes in (B) face-value and (D) sampling-standardised species richness (using SQS,  
 558 quorum = 0.6) and changes in counts of occupied grid cells per equal-length bin (all variables  
 559 log-transformed). (E, F) Relationships between (E) changes in face-value and (F) sampling-  
 560 standardised species richness (using SQS, quorum = 0.6) and changes in continental area  
 561 through time. Datapoints for C1 and C2 removed as outliers.

14

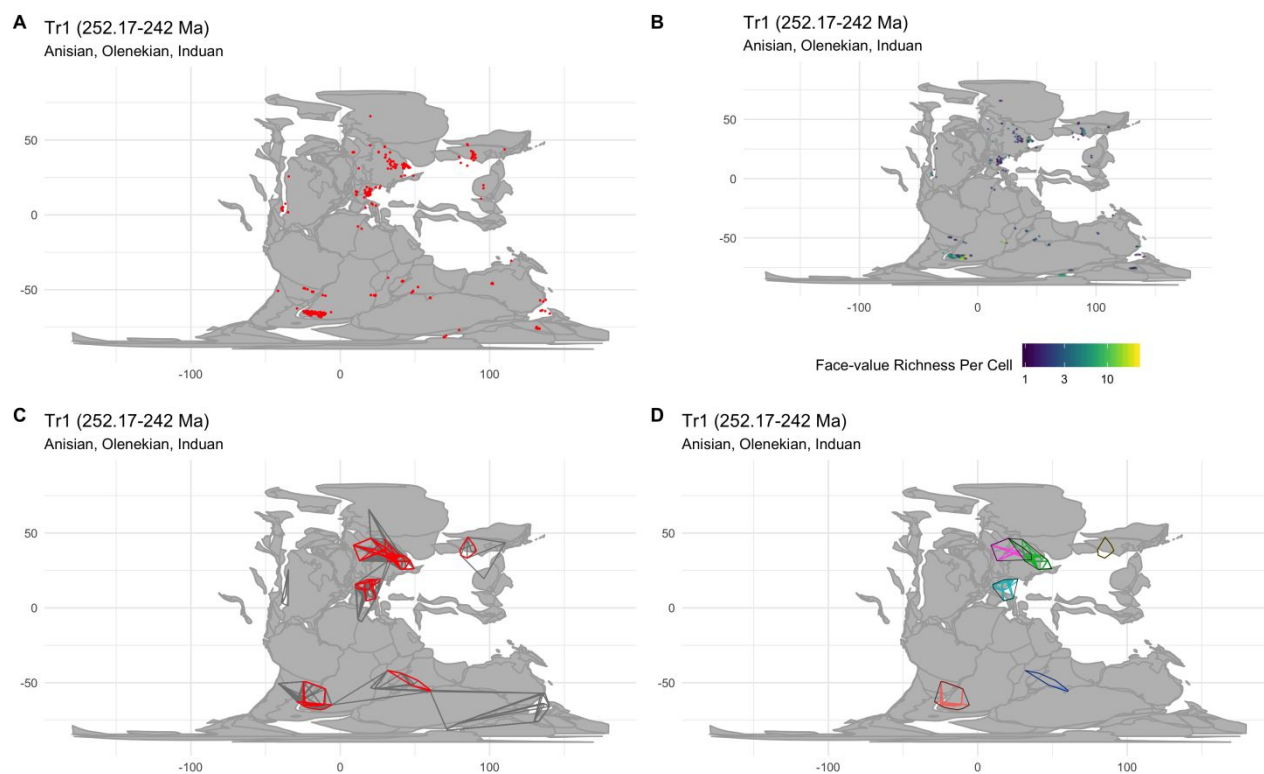

562

563 **Fig. 2.** Spatial sampling in the Phanerozoic record of terrestrial tetrapods. Per-bin counts of  
 564 equal-area grid cells with 200 km spacings, broken down by (A) hemisphere, (B) absolute  
 565 palaeolatitude zone (low = 0–30°, mid = 30–60°, high = 60–90°), and (C) continental region.  
 566 Spatial sampling rises steeply through the Phanerozoic, and is especially limited outside of  
 567 North America, Europe and Asia, in the southern hemisphere, and at low and high  
 568 palaeolatitudes.

569

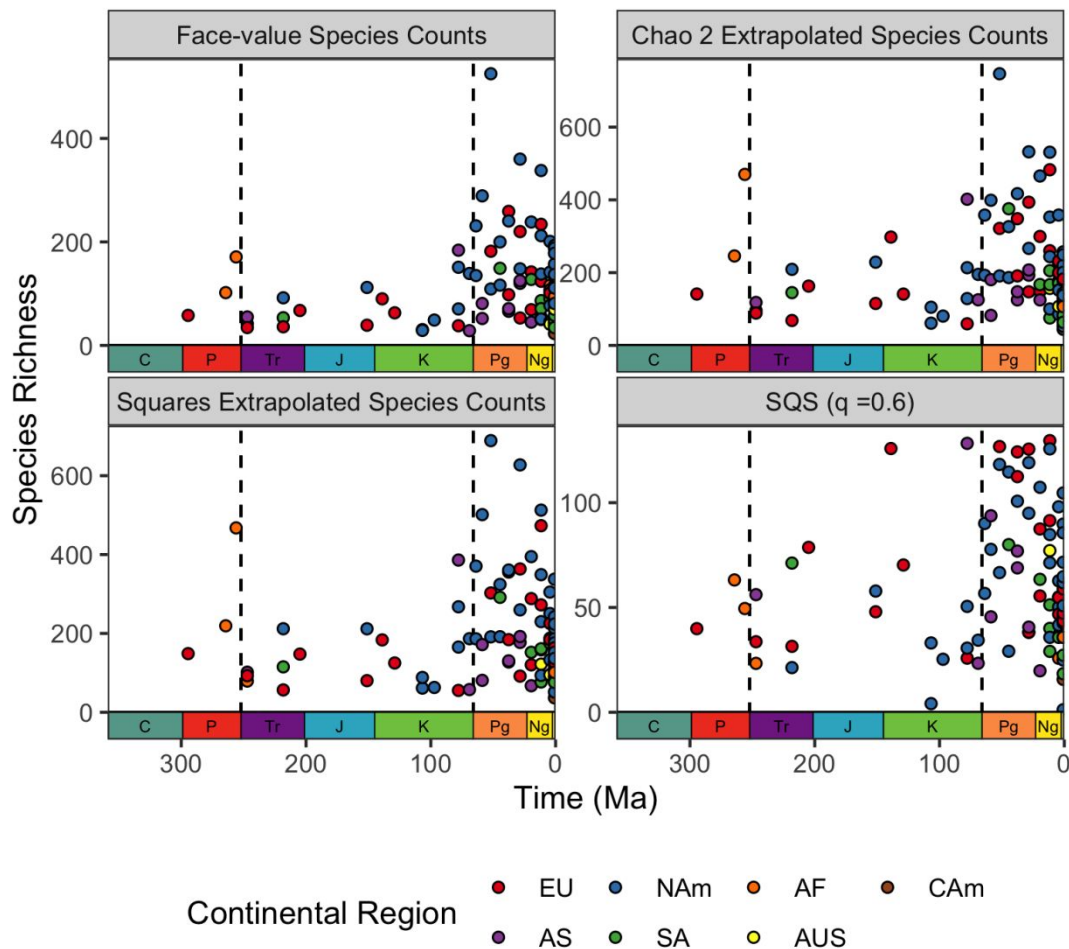

570

571 **Fig. 3.** Key steps in the spatial standardisation procedure used in this study, showing samples  
 572 for the early–middle Triassic (Tr1 time bin). (A) Palaeocoordinates of fossil localities. (B)  
 573 Fossil localities binned within 100 km equal-size hexagonal/pentagonal grid cells (using  
 574 `dggridR`). (C) Palaeogeographic regions delineated using convex hulls, with samples meeting  
 575 spatial standardisation criteria for 2000 km MST distance highlighted in red. (D) Clusters of  
 576 highly similar palaeogeographic regions.

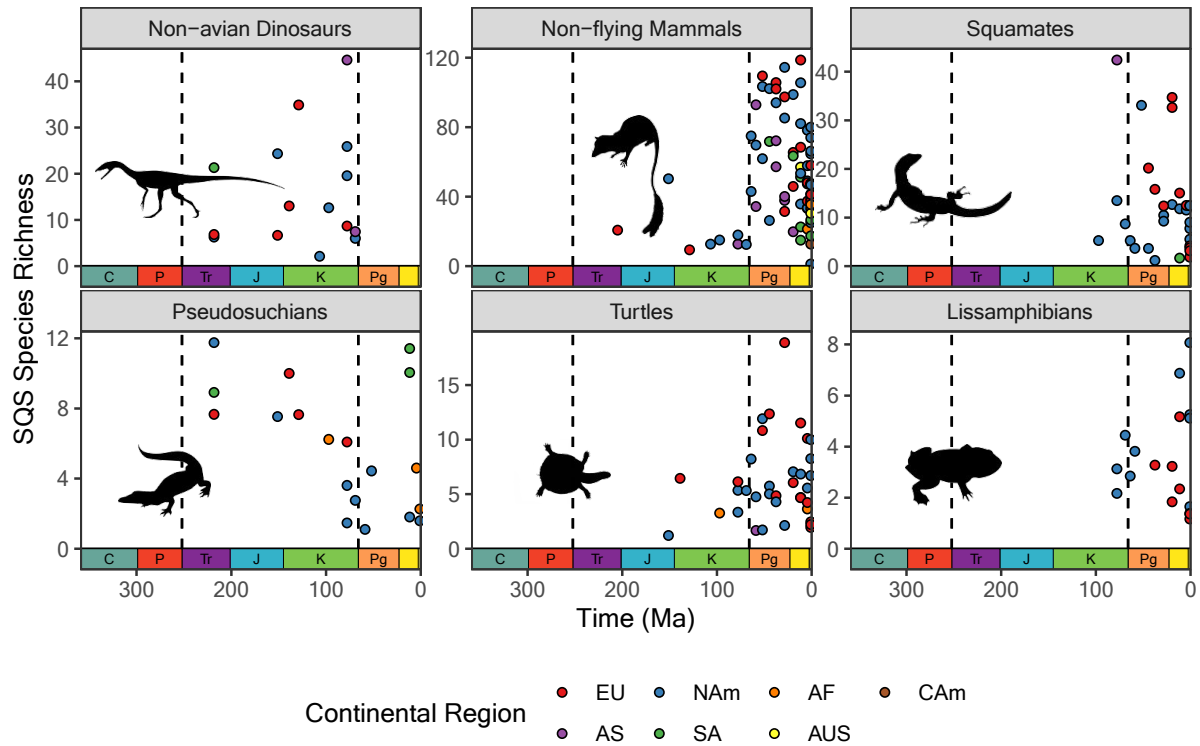

577

578

579 **Fig. 4.** Patterns of spatially-standardised regional-scale species richness of non-flying  
 580 terrestrial tetrapods through the Phanerozoic, for regions 2000 km in size (minimum-  
 581 spanning tree [MST] distance). Patterns depicted using face-value (but spatially standardised)  
 582 species counts, squares [32] and Chao 2 extrapolated richness [33], and SQS [29,31] (using  
 583 quorum = 0.6). Grid-cell rarefaction algorithm not used (GCR = off). Colours correspond to  
 584 dominant continental regions of palaeogeographic regions. Data points represent median  
 585 richness estimates for clustered palaeogeographic regions.

586

587

588 **Fig. 5.** Patterns of spatially-standardised regional-scale species richness for major subclades  
 589 of non-flying terrestrial tetrapods (non-avian dinosaurs, non-flying mammals, squamates,  
 590 pseudosuchians, turtles and lissamphibians), for regions 2000 km in size (minimum-spanning  
 591 tree [MST] distance). Species richness estimates extrapolated using SQS (quorum = 0.6,  
 592 GCR = off). Colours represent dominant continental regions of palaeogeographic regions.

| Intercept Only                     | 1  | -66.3  | 137  | 20.30      | 3.83e-05 | 1.000              | 25200.00       |

604 **Table 2.** Coefficients for variables included in generalised least-squares models of ‘global’  
 605 species richness (face-value and sampling standardised, using SQS at a quorum of 0.6) as a  
 606 function of the palaeogeographic spread of the fossil record (counts of occupied equal-area  
 607 grid cells with 500 km spacings), continental area and non-marine sediment extent (counts of  
 608 columns in Macrostrat database). Temporally-correlated errors modelled using a first-order  
 609 autoregressive structure. Palaeogeographic spread and non-marine sediment extent variables  
 610 log-transformed to achieve normality. When all three explanatory variables are included in a  
 611 linear model, only palaeogeographic spread (MST distance) is a significant (at  $p \leq 0.01$ ) and  
 612 strong explanation of variation in ‘global’ species richness.

| term                                      | estimate | std.error | statistic | p.value |

613

## 614 **Supplementary Information**

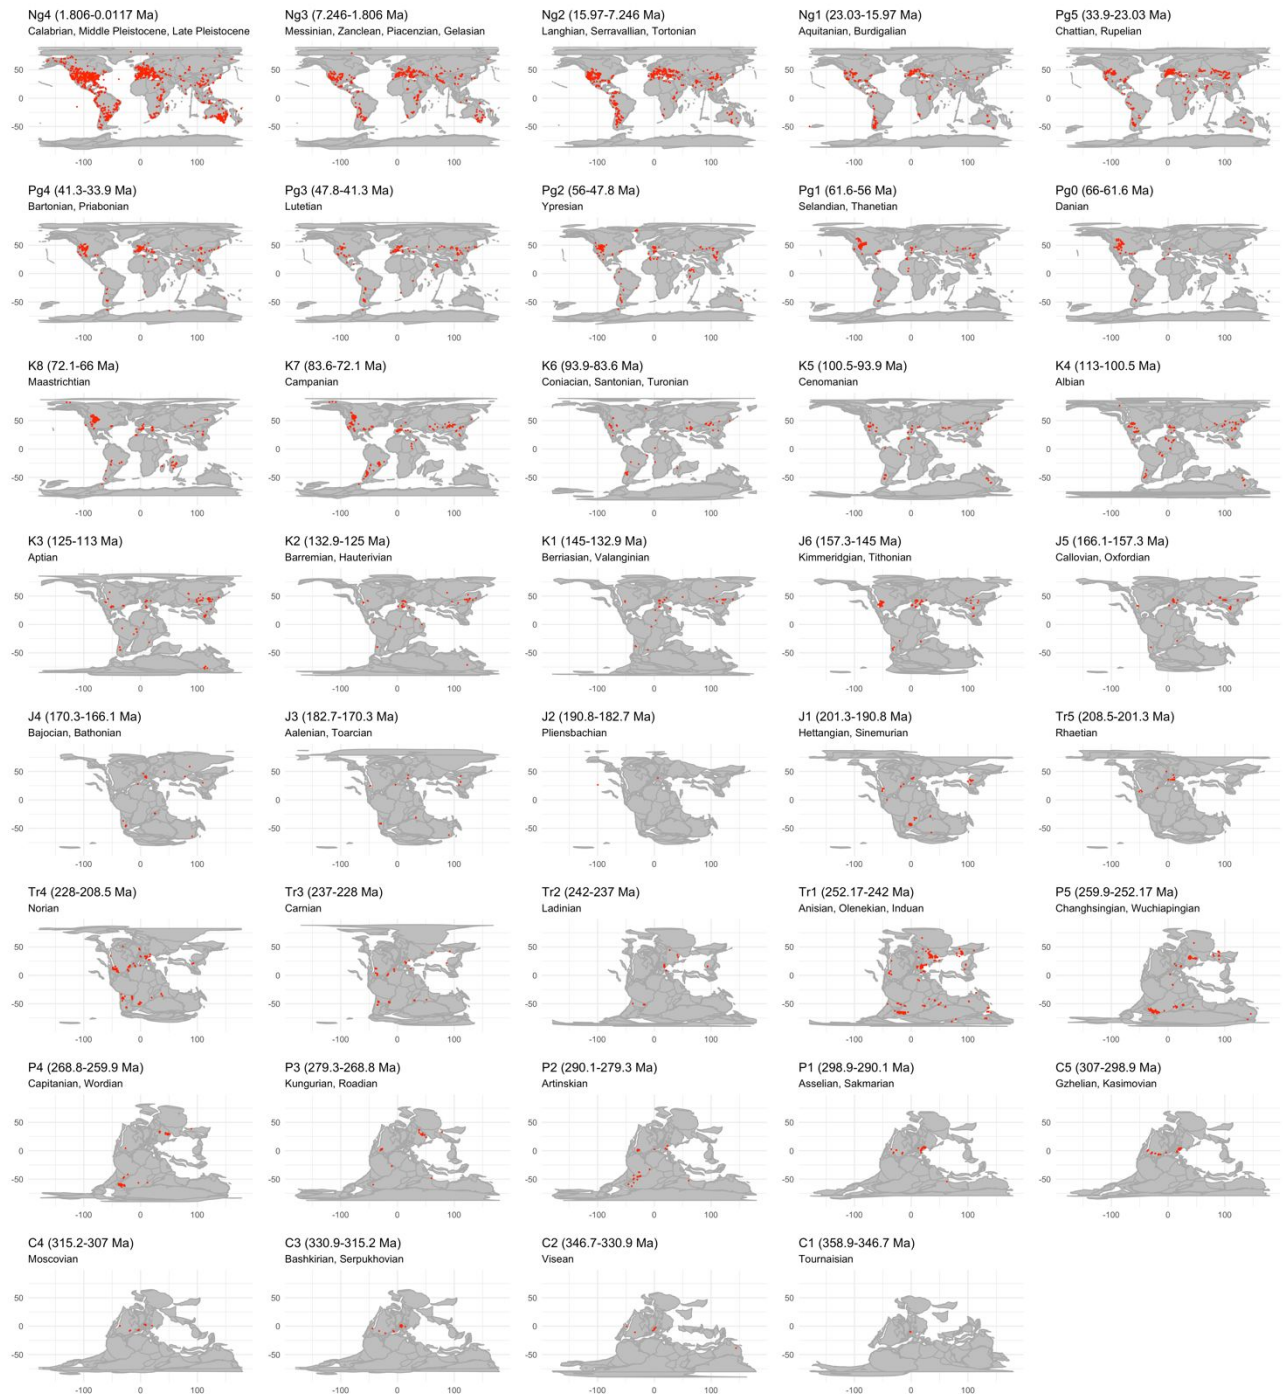

### 615 **Supplementary Methods**

616 *Note on spatial subsampling procedure.* We use the spatial distribution of fossil localities  
617 with well-defined palaeocoordinates to quantify the palaeogeographic extent of the known  
618 fossil record for each interval. The strength of the correlation between geographic spread and  
619 estimated richness is very great (Figs 1 and S6), and is unlikely to be the result of errors.  
620 Minor errors would primarily arise from recording modern-day geographic coordinates  
621 inaccurately in the Paleobiology Database, and from tectonic rotations used to recover  
622 palaeocoordinates. However, for most of the standardised palaeogeographic regions that we  
623 analyse (i.e., subsamples of fossil localities with approximately equal geographic extents), the  
624 localities come from regions of the globe that are linked on a single tectonic plate that moves  
625 as a rigid unit. Therefore, the error associated with these estimates are, for our purposes,  
626 negligible.

### 627 **Supplementary Results**

628 *Model-fitting with additional richness estimators.* Model-selection and fitting results for other  
629 richness estimators are given in Tables S3–S4 (SQS with GCR), S5–S6 (face-value species  
630 counts), S7–S8 (squares) and S9–S10 (Chao 2). Results are highly congruent for all richness  
631 estimators, with the “Time \* Pre/Post-K/Pg phase” model receiving highest support. In all  
632 models that include phase and time as an interaction term, this is due to a significant decrease  
633 in richness through the Cenozoic (Tables S6, S8 and S10; Fig. S9).

634

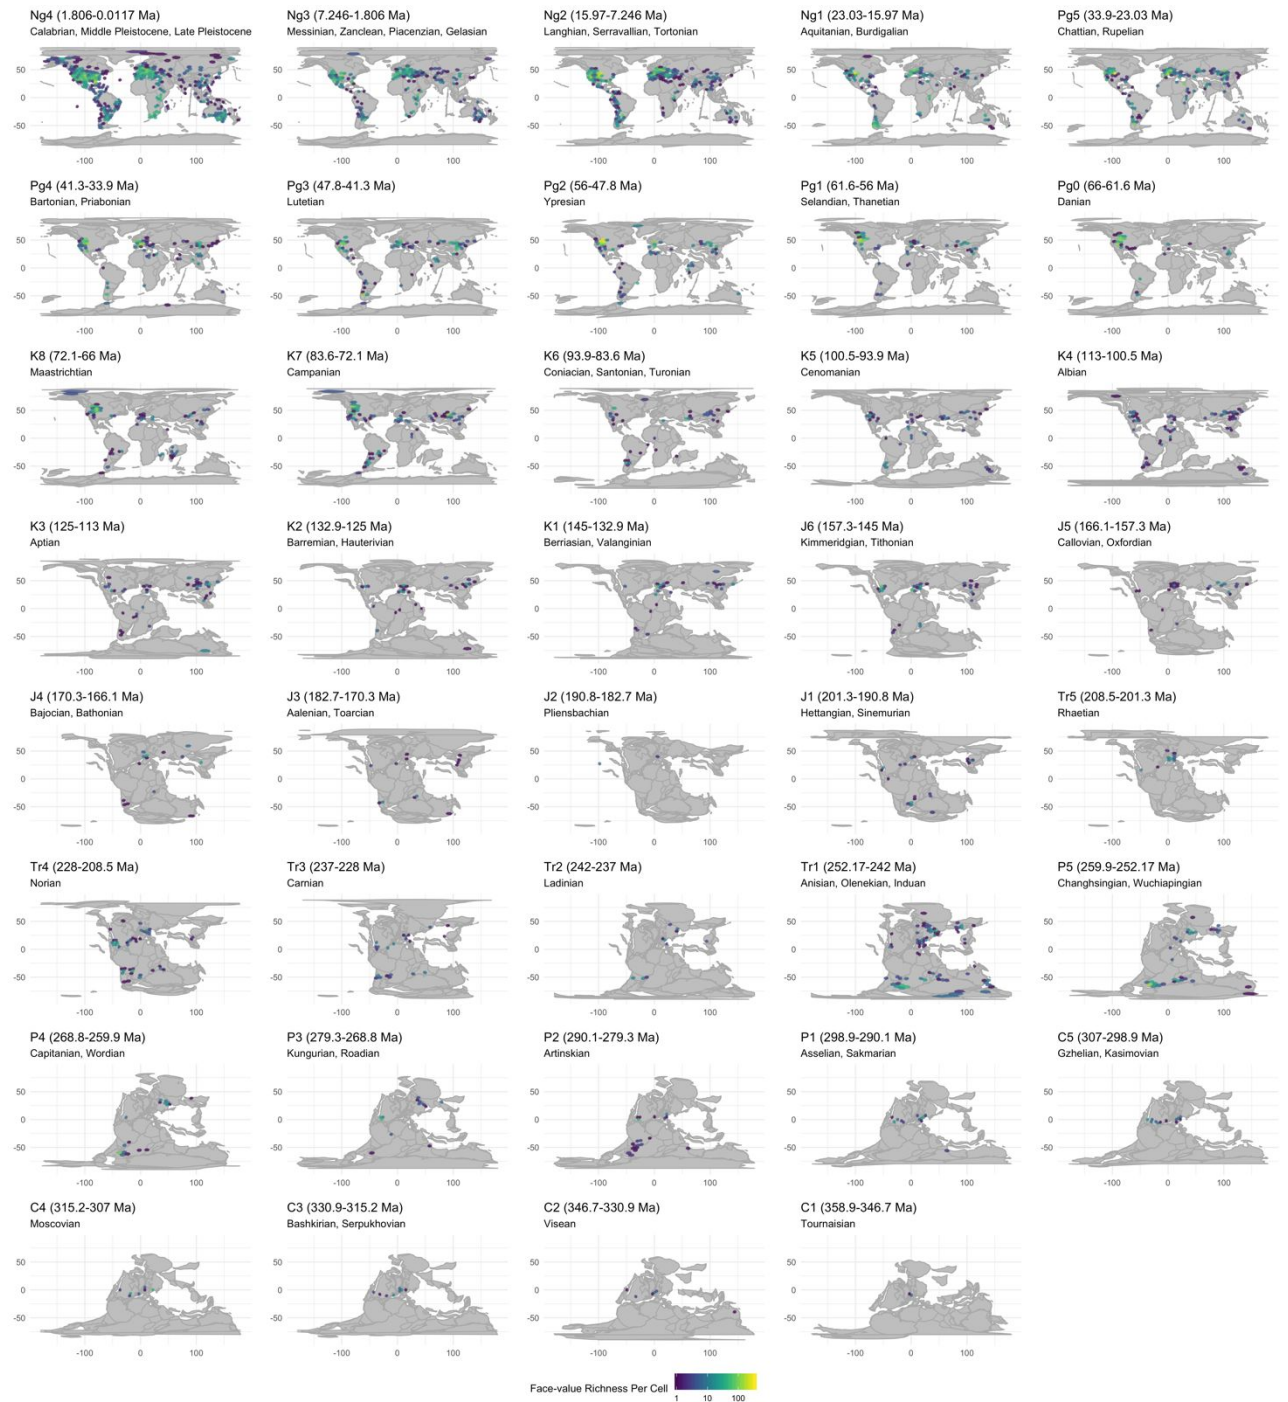

635

636 **Fig. S1.** Distribution of non-flying tetrapod fossil localities through the Phanerozoic, using  
 637 equal-length time bins.

638

639

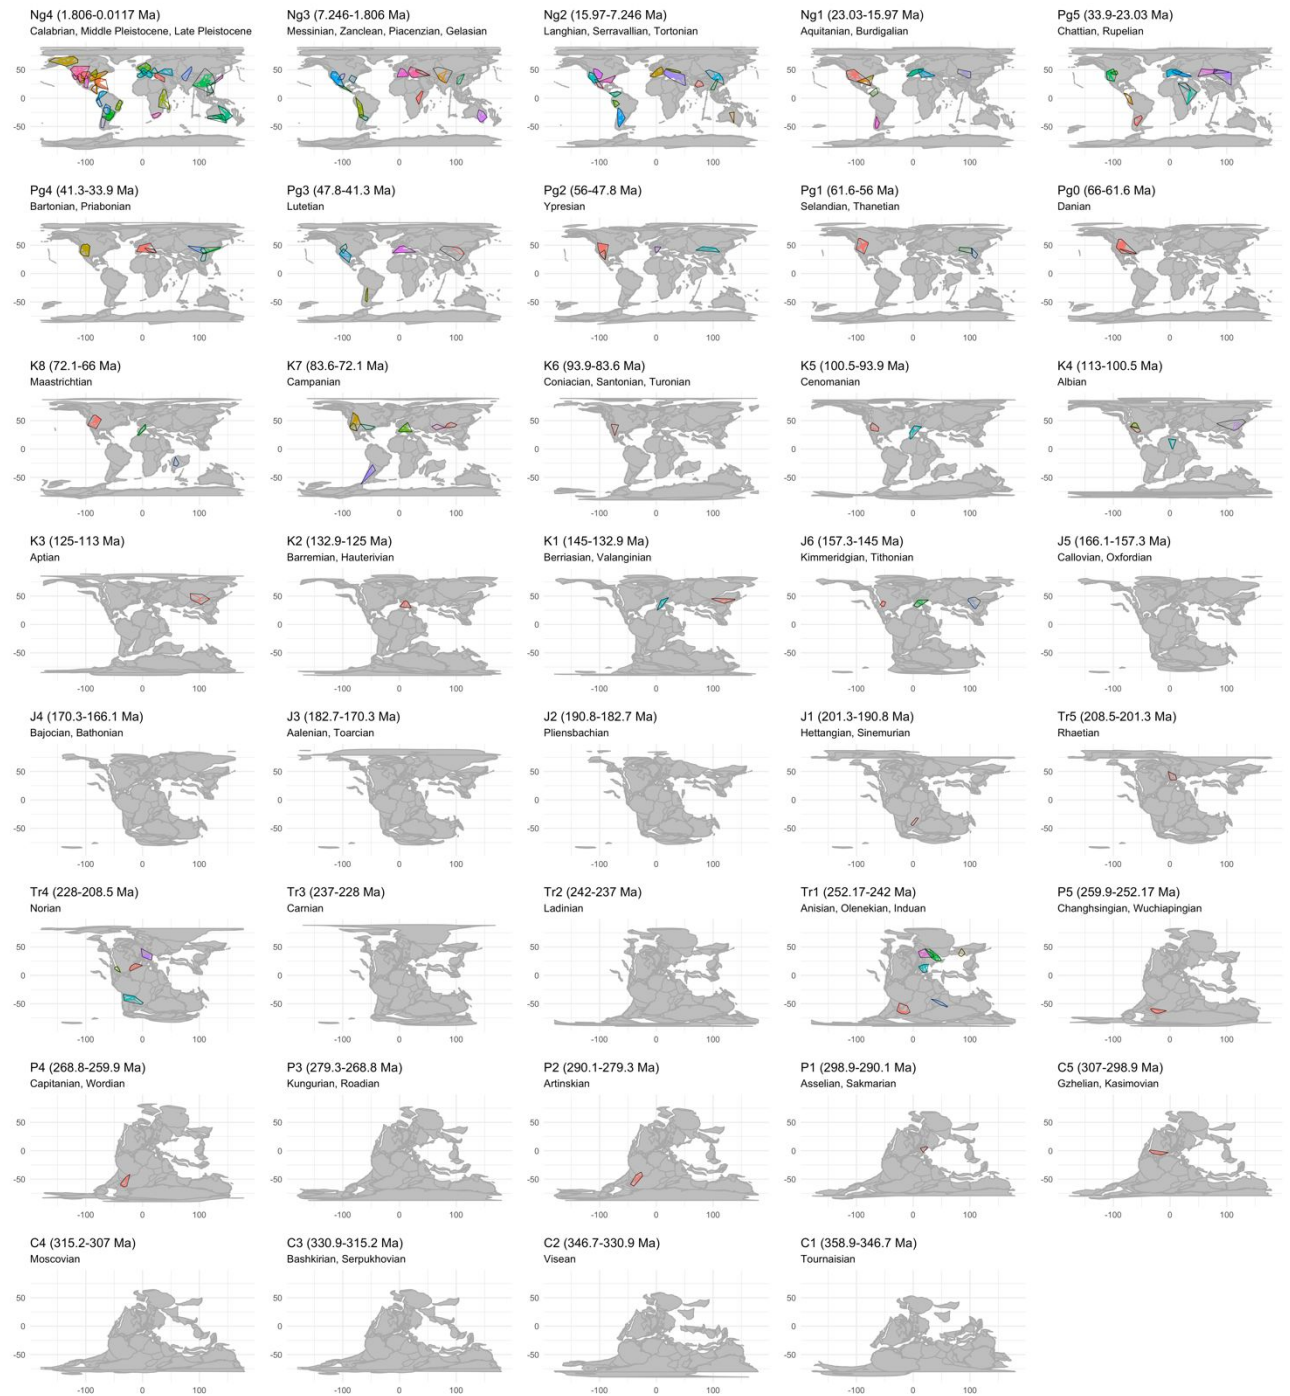

640 **Fig. S2.** Distribution of equal-sized hexagonal/pentagonal grid cells with 500 km spacings  
 641 (between cell midpoints) containing occurrences of non-flying tetrapod fossils through the  
 642 Phanerozoic, using equal-length time bins. Colours represent face-value species counts per  
 643 cell.

645

646 **Fig. S3.** Distribution of subsampled spatial regions sampling non-flying tetrapod fossils  
 647 through the Phanerozoic, using equal-length time bins. Spatial regions meeting spatial  
 648 standardisation criteria for 2000 km MST lengths (see Methods for full list of criteria) are in  
 649 red, and those not meeting these criteria are in grey.

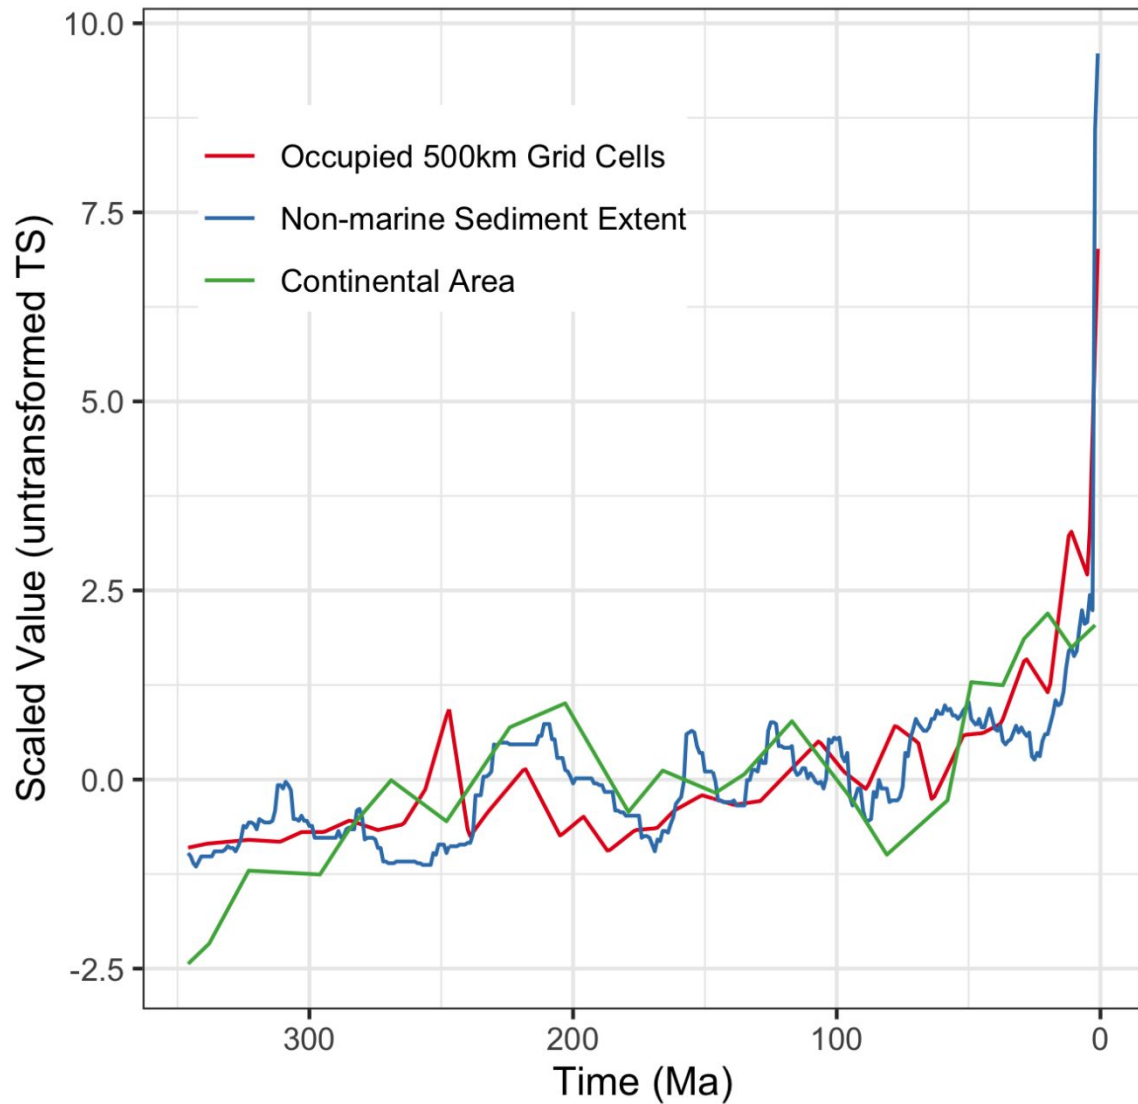

650

651

652 **Fig. S4.** Clusters of subsampled spatial regions (2000 km MST length) for non-flying  
 653 tetrapods through the Phanerozoic, using equal-length time bins. Colours differentiate  
 654 clusters.

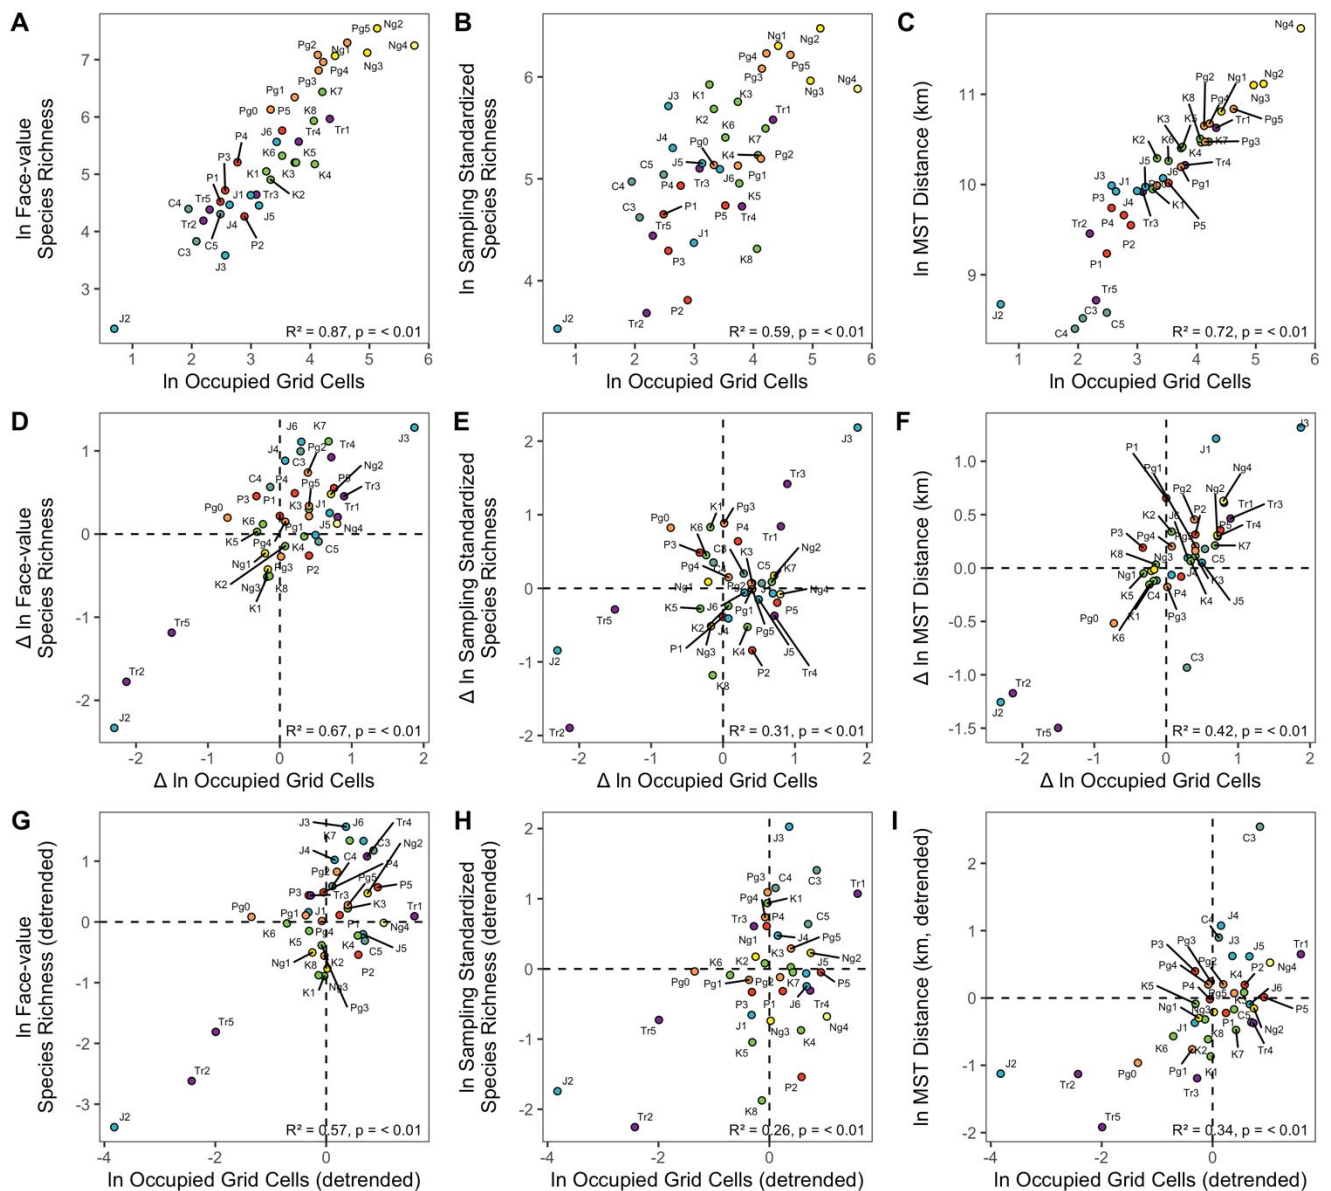

655

656

657 **Fig. S5.** Time series (scaled to unit variance and centred) for the palaeogeographic spread of  
 658 the worldwide non-flying terrestrial tetrapod fossil record (occupied equal-area grid cells  
 659 with 500 km spacings), and estimates of continental area (from Cao et al. [36]) and non-  
 660 marine sediment extent (derived from Macrostrat by [40]). Only non-marine sediment extent  
 661 mirrors palaeogeographic spread in rising sharply during the Neogene–Recent, and increases  
 662 in continental area over the same interval are much smaller.

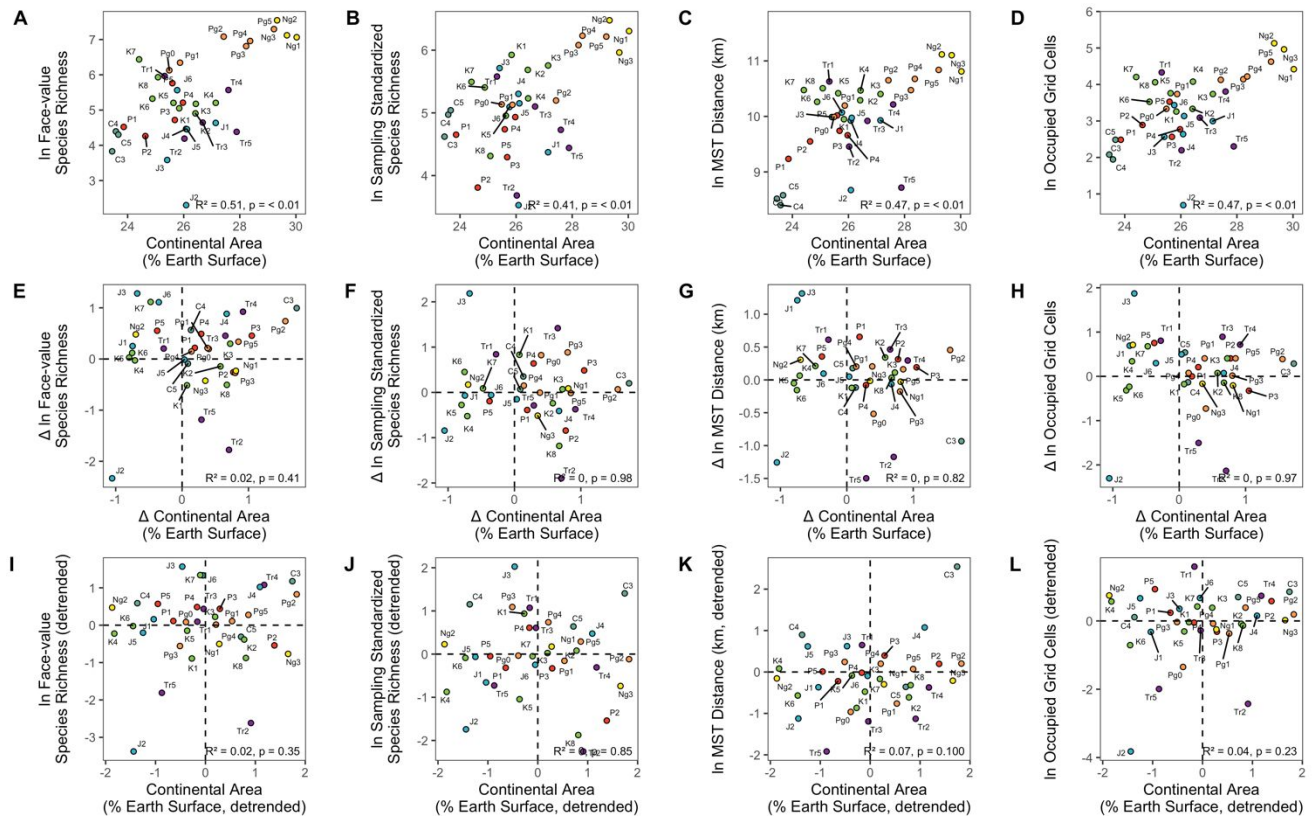

663

664

665 **Fig. S6.** Bivariate relationships between the palaeogeographic spread of the worldwide non-  
 666 marine, non-flying tetrapod fossil record, quantified using per-bin counts of occupied equal-  
 667 area grid cells with 500 km spacings ([36]) and other key variables. (A–B) Raw (i.e. not  
 668 detrended or differenced) relationships between time series occupied grid cell counts and  
 669 “global” tetrapod species richness estimates (face-value counts of species, and sampling  
 670 standardised SQS richness at quorum = 0.6). (D–E) Corresponding first-differenced  
 671 relationships. (G–H) Corresponding relationships for time series detrended with ARIMA  
 672 models (using the R function `auto.arima()` in the package `forecast` [47]). (C, F, I)  
 673 Relationships between palaeogeographic spread quantified using occupied grid cells, and  
 674 using MST length. All variables log-transformed. Datapoints for C1 and C2 removed as  
 675 outliers.

676

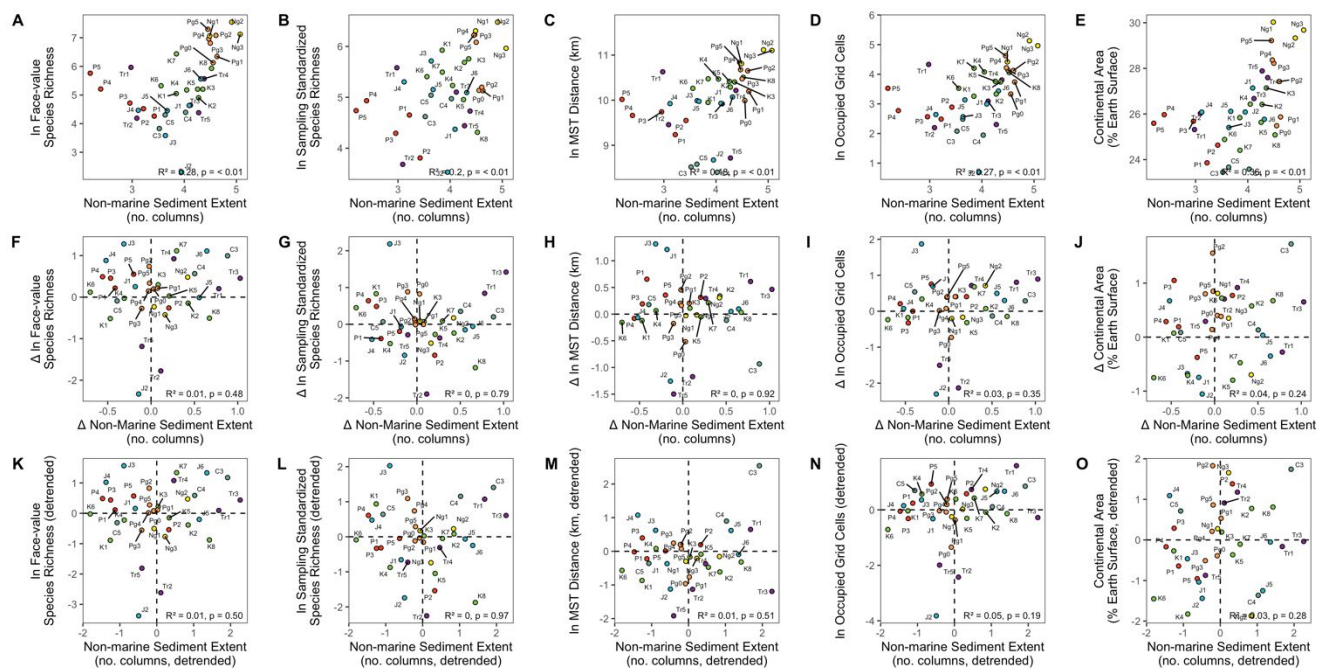

677

678 **Fig. S7.** Bivariate relationships between an estimate of continental area through the  
 679 Phanerozoic ([36]) and other key variables. (A–D) Raw (i.e. not detrended or differenced)  
 680 relationships between time series of continental area, “global” tetrapod species richness  
 681 estimates, and the palaeogeographic spread of their fossil record. (E–H) Corresponding first-  
 682 differenced relationships. (I–L) Corresponding relationships for time series detrended with  
 683 ARIMA models (using the R function `auto.arima()` in the package `forecast` [47]). Datapoints  
 684 for C1 and C2 removed as outliers. Although relationships using ‘raw’ time series are  
 685 significant, accounting for spurious time series effects renders them non-significant.

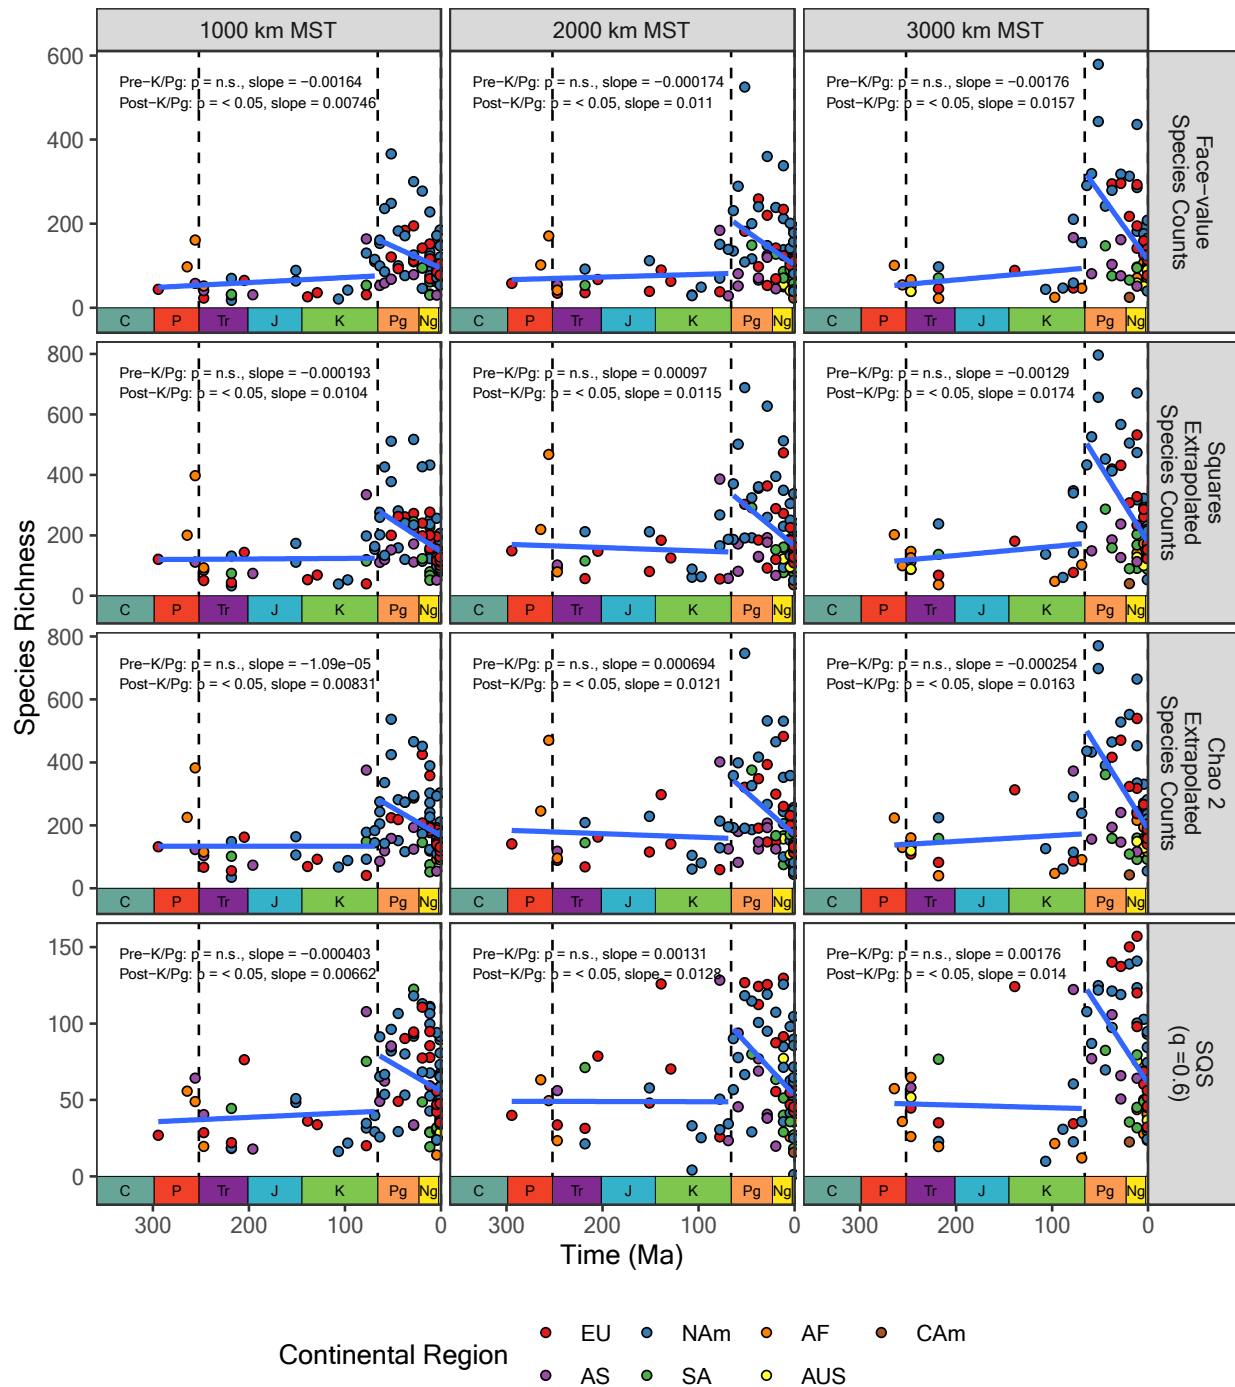

686

687

688

689 **Fig. S8.** Bivariate relationships between non-marine sediment extent (derived from the  
 690 Macrostrat database (<http://www.macrostrat.org>), via Peters and Husson [40]) and other key  
 691 variables. (A–E) Raw (i.e. not detrended or differenced) relationships between time series of  
 692 non-marine sediment extent and diversity, palaeogeographic spread and continental area. (F–  
 693 J) Corresponding first-differenced relationships. (K–O) Corresponding relationships for time  
 694 series detrended with ARIMA models (using the R function `auto.arima()` in the package  
 695 `forecast` [47]). Datapoints for C1 and C2 removed as outliers. Although relationships using  
 696 ‘raw’ time series are significant, accounting for spurious time series effects renders them  
 697 non-significant.

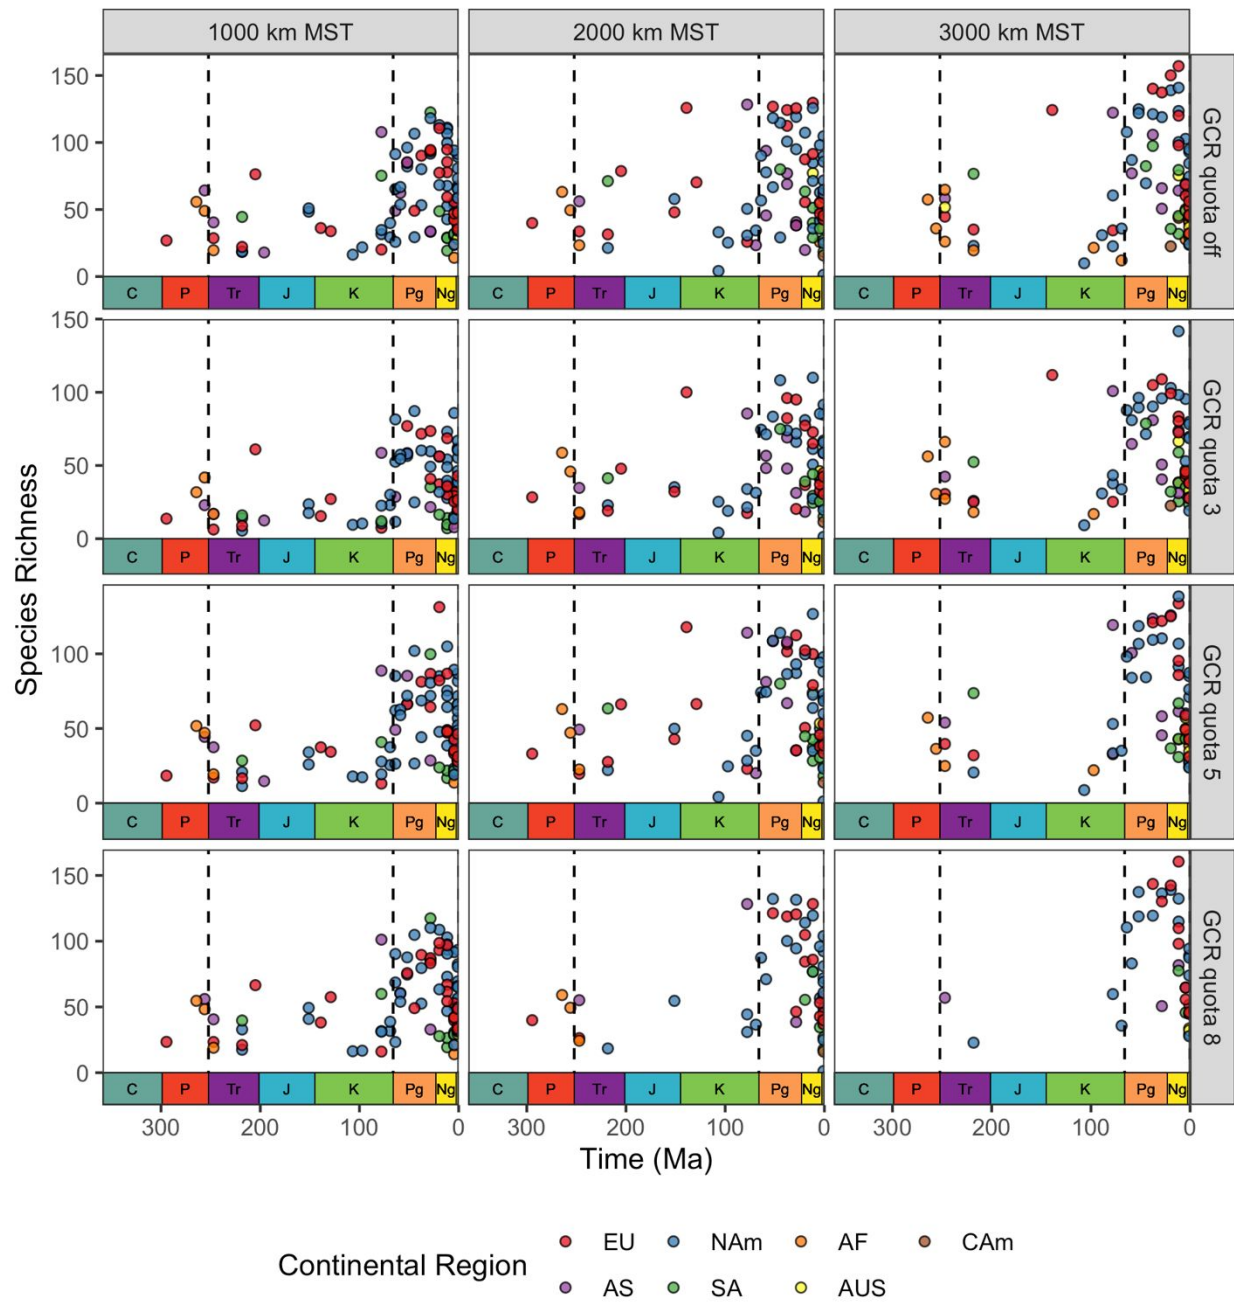

699

700 **Fig. S9.** Linear models of ln richness as a function of time within pre- and post-K/Pg  
 701 diversification phases, for face-value species counts (= raw or uncorrected richness; i.e., not  
 702 sampling-standardised), squares' extrapolated species richness and SQS richness (quorum =  
 703 0.6). No grid-cell rarefaction used (GCR = off). Shaded envelopes denote 95% confidence  
 704 intervals for regression slopes. Regressions for the pre-K/Pg phase are never significant, but  
 705 those for the post-K/Pg phase are sometimes significant, with a positive slope (indicating a  
 706 statistically significant decline in diversity towards the present).

707

708

709 **Fig. S10.** Effects of using a grid-cell rarefaction procedure (using quotas of 3, 5 and  
 710 occupied cells per 1000 km of summed MST distance) prior to computing SQS richness  
 711 estimates (quorum = 0.6) on spatially-standardised regions. GCR algorithm not used for  
 712 “GCR quota = off”. As the GCR quota is raised, increasingly fewer suitable regions are  
 713 available from pre-Cenozoic intervals.

714

715 **Supplementary Tables**716 **Table S1.**

717 Definitions of composite time bins of approximately equal length.

| bin        | stages  | LAD      | FAD     | midpoint  | duration |
|------------|---|----------|---------|-----------|----------|
| <b>Ng4</b> | Calabrian, Middle Pleistocene, Late Pleistocene | 0.0117   | 1.806   | 0.90885   | 1.7943   |

**Table S2.** Parameter estimates for coefficients in linear models fitted to spatially-standardised terrestrial tetrapod species richness data (SQS, quorum = 0.6; 1000–4000 km MST distance; GCR quota = off). All models fitted to each palaeogeographic spread level are shown, regardless of Akaike weight, and ordering does not reflect importance.

**Table S4.** Parameter estimates for coefficients in linear models fitted to spatially-standardised terrestrial tetrapod species richness data (SQS, quorum = 0.6; GCR quota = 5 occupied grid-cells/1000 km MST length). All models fitted to each palaeogeographic spread level are shown, regardless of Akaike weight, and ordering does not reflect importance.

**Table S6.** Parameter estimates for coefficients in linear models fitted to spatially-standardised terrestrial tetrapod species richness data (face-value species counts). All models fitted to each palaeogeographic spread level are shown, regardless of Akaike weight, and ordering does not reflect importance.
