ABSTRACT

The main objective of this study is to develop an accurate design method for computing inlet hydrographs of surface runoff, with average recurrence intervals of 10, 25, and 50 years, from typical urban highway by flood routing technique.

Hydrologic data such as the rainfall intensity, runoff flow rate, air temperature, wind velocity, and soil moisture content were collected during rainfall seasons in 1972 and 1973 on two urban highway watersheds in the Salt Lake City area, Utah. These data were used in the verification of a mathematical model simulating the surface runoff from such highway watersheds. The difficulties and inherent problems associated with field data collection from urban highway cross-section are discussed and possible remedies recommended. Hyetographs and the corresponding hydrographs of major storms which occurred in 1972 and 1973 at both sites are presented. Watershed infiltration capacities of sideslopes at both sites are empirically evaluated.

Fletcher, J. E., and C. L. Chen, Urban Storm Runoff Inlet Hydrograph Study: Vol. 3. Hydrologic Data for Two Urban Highway Watersheds in the Salt Lake City Area, Utah. Final Report, PRWG106-3, Utah Water Research Laboratory, Utah State University, Logan, Utah 84322, May 1975.

Key Words: Air temperature, Data collection, Field data, Highway, Hydrographs, Hyetographs, Rainfall, Retention, Soil moisture, Storms, Runoff, Watershed, Wind

PREFACE

The work described in this report was performed under contract DOT-FH-11-7806, entitled "Urban Storm Runoff Inlet Hydrograph Study" between the Federal Highway Administration and Utah State University. This research contract was aimed at the development of an accurate design method for computing inlet hydrographs of surface runoff under intense rainstorms on urban highways. One of the major tasks in this research project was the collection of hydrologic data from typical urban highway cross-sections. The field data including precipitation and runoff were used in the verification of a mathematical model of surface runoff which was formulated in the analytical phase of the project. The work reported herein was part of the field phase of the project.

This report is a summary of the hydrologic data collected during rainfall seasons in 1972 and 1973 on two urban highway cross-sections in the Salt Lake City area, Utah.

The research was conducted under the general supervision of Dr. Cheng-lung Chen, Professor of Civil and Environmental Engineering at Utah State University. The field phase of the research was primarily performed by Joel E. Fletcher, Professor of Hydrology at Utah State University. Gratitude is due many students who helped collect and reduce field data in the course of the investigation.

The contract was monitored by Dr. D. C. Woo, Contract Manager, Environmental Design and Control Division, Federal Highway Administration. The authors are indebted to him for his ideas to initiate this study and overall research plan, detailed discussions of research conduct of all phases, and critical reviews and comments of the results during the course of the work.

This volume is third in a series. The others in the series are:

INTRODUCTION

Collection of field data such as precipitation and runoff for the verification of a mathematical model simulating the rainfall-runoff process is not an easy task, especially on an urban interstate highway where factors related to the human activities such as the amount of passing traffic reduce the reliability of data. For example, the splash from heavy traffic during a storm not only accounts for a significant portion of the precipitation lost but also interrupts the natural rainfall-runoff process. In addition, all the equipment to be installed would be subjected to potential dangers—accident and vandalism, because the highway nowadays becomes a center of the human activities. Despite these anticipated difficulties and other related problems, the equipment was installed and data collected for two rainfall seasons in 1972 and 1973. (Data were still being taken in 1974 at the time this report was written.) Field data collected include rainfall intensities, runoff flow rates, temperatures, wind velocities, and soil moisture

contents at two highway cross-sections in the Salt Lake City area, Utah. Data for each rainfall event in final, usable form are presented in this report.

The project was initiated in June 1971, requiring the balance of the first rainfall season for the selection of test sites as well as procurement and installation of field equipment. Thus, to date only two seasons of field data could be collected and reduced. As will be shown later in this report, the year 1972 happened to be a season with infrequent storms. Several major storms occurred in 1973, however. Hyetographs and the corresponding hydrographs of the major storms will be presented to characterize, if possible, the typical rainfall-runoff process on the urban highway cross-sections. No attempt was made herein to further analyze the hyetographs and hydrographs at the inlet, but such a study will be made in connection with other phases of the project.

FIELD INSTALLATIONS OF EQUIPMENT

In view of the difficulties in obtaining reliable field data, the senior author visited a few major cities such as Baltimore, Philadelphia, and Chicago where similar data were or have been collected for many years. Precaution was thus taken to avoid unnecessary interruption of field measurements due to the improper design of installed equipment, such as a discharge-measuring flume. The main problem encountered in Baltimore, according to Schaake (1971, personal contact), was the plugging of the stilling well intake by debris. However, no debris on the Baltimore watersheds was large enough to plug the throats of the Parshall flume installed.

The gaging problems encountered in Chicago were also due to debris plugging the 1/4 or 1/8 inch intake pipe to the stilling wells in the flumes (Kiefer, 1971, personal contact). The plugging showed its effects on both reduced depth in the stilling wells as well as on time lags in the hydrographs measured by the flumes. A slot or a series of small holes for the intake rather than a 1/4 or 1/8 inch pipe was devised in this project to solve such intake problems.

Field inspection of the runoff gaging sites indicated that a measuring device such as the cut-throat flume developed by Skogerboe et al. (1971) would be most advantageous since it passes debris and sediment and only requires a minimum head loss in the measurement.

Selection of Test Sites

In order to attain the primary objective of field data collection, namely, the verification of the mathematical model by use of field data, several factors were considered in the selection of test sites. It was determined that first the sites should have standard urban highway cross-sections which offer various aspects of the runoff process including a unique simple pattern of overland flow to either or both sides and/or gutter flow. Second, the geometry of the drainage area should be simple and the ground surface (paved or grassed) should be even and homogeneous so that there would be no problem in describing them mathematically. Finally, the precipitation expectancies at the sites should be so high that major storms with substantial intensities are expected to occur many times during a rainfall season.

Conferences were held with Utah Highway Department engineers to select test sites in the Salt Lake City area. A number of sites which have cross-sections similar to those specified by the Federal Highway Administration were considered and inspected before the selection. Three cross-sections, as shown in Figure 1, were chosen for collection of hydrologic data including rainfall intensity and runoff discharge.

A cross-section similar to Figure 1(a), which represents a single drainage area for runoff from a combined roadway (impervious) and sideslope (paved or grassed), was found near Gentile Street on I-15 at Layton, a suburb of Salt Lake City. This site will be hereafter called the Layton site. Two typical cross-sections were found on I-215 near Parleys Canyon and 33rd South Street in Salt Lake City. The first of these as shown in Figure 1(b), drains water from a sideslope to a gutter. The second, shown in Figure 1(c), drains water from a roadway having four traffic lanes to a curb and gutter. The former cross-section at Parleys Canyon hereafter will be referred to as Parleys site number 1 and the latter, Parleys site number 2. The locations of both sites with respect to Salt Lake City environments are shown in Figure 2. The installations of equipment on both sites are described below.

Layton Site

Layout

The equipment layout and the topography are shown in Figure 3. This test site has an area of 58,625 square feet (553 feet long and 106 feet wide) and has a single runoff gaging flume called WL-1. Precipitation is measured by six Belfort 5-780 weighing recording rain gages (L-1, L-2, L-3, L-4, L-5, and L-6) set at 24 hours per rotation, one Belfort 5-780 weighing recording rain gage (L-7) set at 196 hours per rotation, and six Truchek rain gages (SL-1, SL-2, SL-3, SL-4, SL-5, and SL-6). In addition to the precipitation gages, soil moisture is recorded at one location (LM), wind direction and speed (LW) at one location, and air temperature (LT) at one location.

The soil at this location is a compact, well aggregated clay loam covered with crested wheat

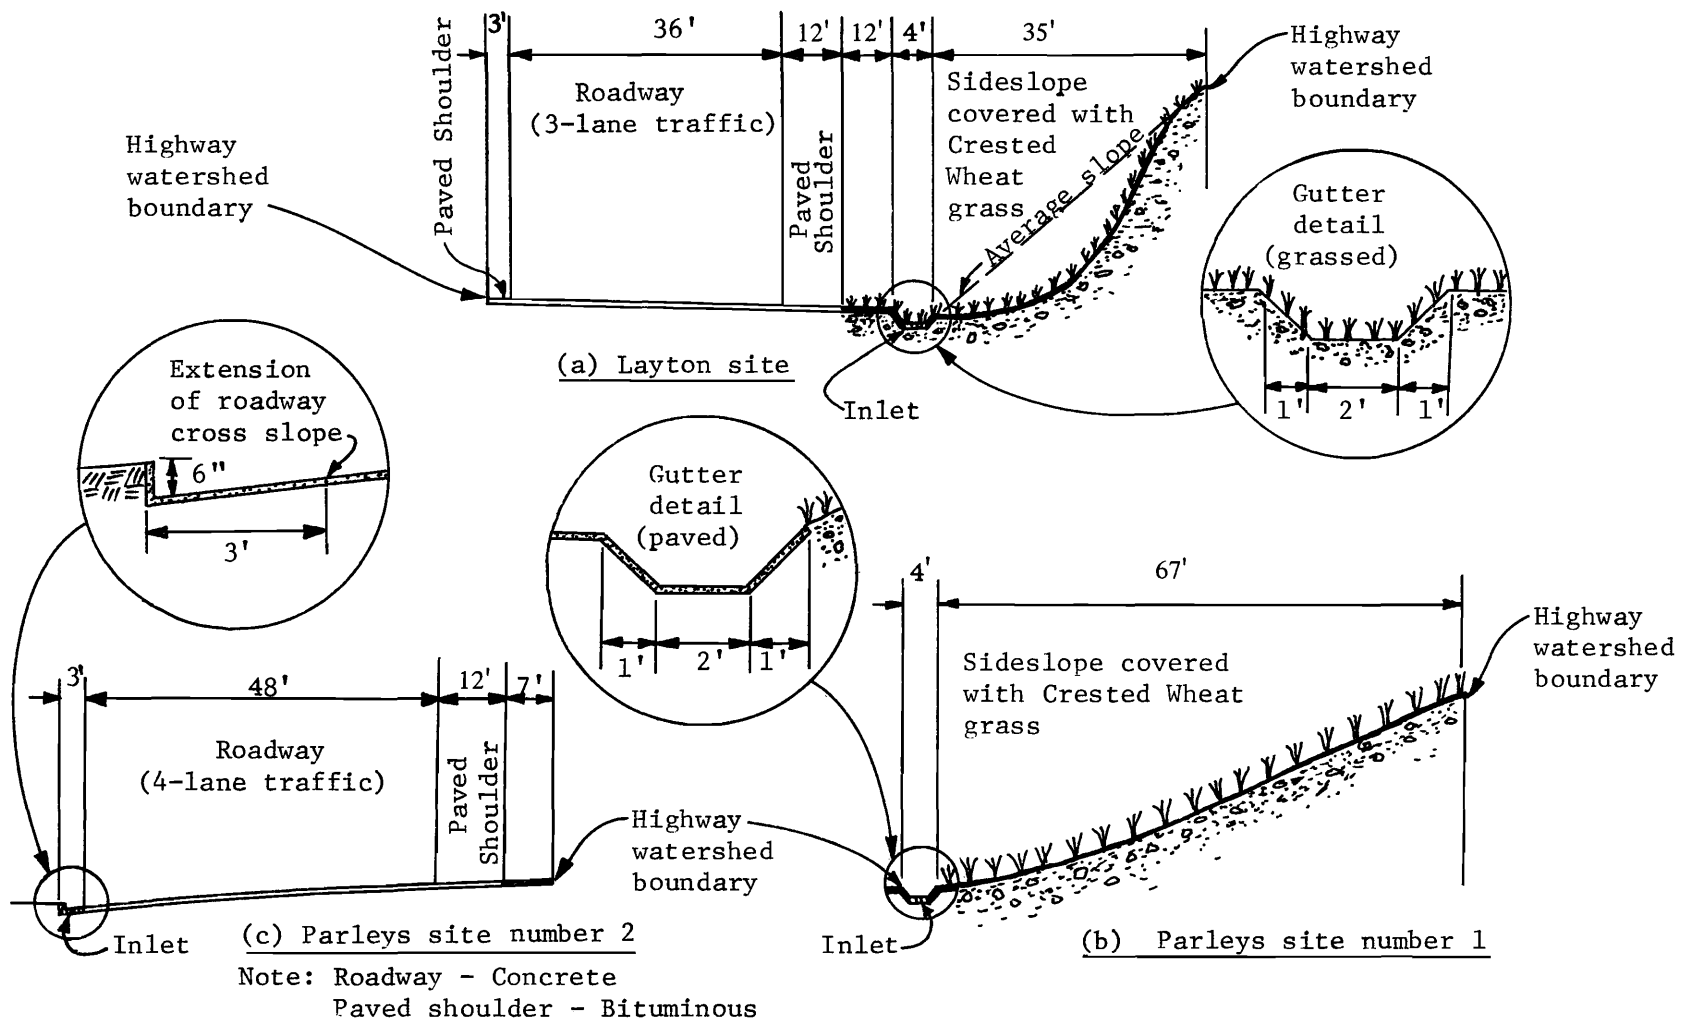

Figure 1. Typical urban highway cross-sections in the Salt Lake City area.

Figure 2. Location of field test sites with respect to Salt Lake City, Utah.

Figure 3. Equipment layout and topography of Layton site.

grass. The toe of the slope midway up the area is poorly drained and is wet throughout the year.

Figure 4 shows a photographic view of the Layton site from the measuring flume, WL-1, facing northerly and looking up the drainage area. The center of the northbound traffic lane of I-15 forms the west boundary of the drainage while the top of the sideslope on the right side of the picture forms the east boundary. Water from the drainage flows through the flume, WL-1, and free falls into the drainage grate inlet in the foreground.

Measuring equipment

Runoff is measured by a 90° bobbed tailed cutthroat flume shown in Figure 5, using a Belfort 5-FW-1 water level recorder on 12 hour rotation to record the water stage. This flume was developed by Skogerboe et al. (1967) at the Utah Water Research Laboratory. The rating table for the cutthroat flume is shown in Table 1. The cutthroat flume passes all types of debris with a minimum of interference and has about the same one percentage error on the small and large flow measurements. Debris was the principal problem on the Chicago and Baltimore watersheds. However, no debris difficulties have been experienced with this flume.

Rain gages. Rain gages L-1, L-2, L-3, L-4, L-5, and L-6 are 6 inches per traverse, weighing, recording rain gages, of Belfort 5-780 type (see Figure 6) and are set for 24 hours per rotation on an 8-day, mechanical clock. If the data on these charts are reduced on the electronic digitizer, intensities for time intervals as short as one minute and depths of 0.01 inch may be digitized. Rain gage L-7 is also a Belfort 5-780 type, but the clock is 192 hours per rotation to assure assigning the rains to the proper day and time of day.

Rain gages SL-1, SL-2, SL-3, SL-4, SL-5, and SL-6 are 6-inch capacity Truchek rain gages (Weather Measure P567). (See Figure 7.)

Temperature. Temperature is measured to 1° F by using a bimetallic temperature sensor obtained from Science Associates No. 156 (Figure 8) and recorded on a thermograph equipped with a 7-day rotation mechanical clock.

Wind. Wind velocity (speed and direction) is sensed at a single location near the center of the drainage area with a R. M. Young No. 6404 field recording wind set (Figure 9). The sensor measures wind speeds between 1.2 and 50 mph to about 2 percent accuracy and their directions to 16 points.

Figure 4. A view of the Layton site looking up the drainage channel—the paved portion and the cut slopes both drain toward the center and through the measuring flume.

Figure 5. Bobbed tailed cutthroat flume used to measure the runoff at the Layton site.

Figure 6. Typical weighing recording rain gage for measuring precipitation at the Layton site. The instruments at its base are the recorders for wind and soil moisture.

Figure 7. The Truchek rain gage.

Figure 8. The air temperature sensor used at both the Layton site and Parleys site.

Figure 9. The wind speed and direction recorder used at the Layton site.

Soil moisture. Soil moisture is sensed at three soil depths—3 inches, 9 inches, and 18 inches—with Delmhorst plaster of paris blocks recording on an Esterline Angus minigraph 0-1MA recorder at one-fourth inch per hour chart speed. The sensing circuit is shown in Figures 10 and 11. The stepper rotates the readings successively from the depths 3 inches to 9 inches, from 9 inches to 18 inches, and back to 3 inches.

Parleys Site

Layout

The equipment layout and the topography of the Parleys site is shown in Figure 12. As mentioned previously, this site is composed of the two drainage areas, as shown in Figure 1. Site number 1 with an area of 23,529 square feet (351.50 x 66.94) drains from the top of the sideslope to the pavement edge. The runoff from this area is gaged with a 2-foot, 90° V-notched, bobbed tailed cutthroat flume, PW-1 (Figure 13), identical to that gaging the Layton site. The rating table (Table 1) also applies. Water in the flume is also sensed with a float and a Belfort 5-FW-1 water level recorder with the clock set for 12 hours per rotation. This area is well covered with a stand of crested wheat grass, but there are some small rills, as old erosion scars, which presently seem to be stabilized. The soil is a sandy loam with some silty clay lenses but of very loose, poorly aggregated structure.

Site number 2 draining 23,812 square feet (339.11 x 70.22) is the asphalt-paved northbound traffic lane of I-215. A curb forms the west boundary of the drainage with water from above being intercepted at the south grate inlet. The water from the roadway is discharged into the north grate inlet (Figure 14) where it is gaged. The water falls through the grill onto a flash plate which directs it into the upstream throat of an acute angled, 2 foot, V-notched cutthroat flume (PW-2) (Figure 15). The water level is sensed with a helical wound electrical depth sensor (Figure 16) and remotely recorded on an Esterline Angus minigraph recorder mounted between the guard rails in the median. This chart moves 1 inch per hour. The grate inlet and meter box are shown in the photograph in Figure 14. The rating table for flume PW-2 is shown in Table 2. The throat angle of this flume was of necessity made more acute than 90° to allow it to fit the grate inlet box and still have the required capacity. Some small quantities of debris have been observed to collect in the upper end of this flume such as pieces of automotive grill work, bolts, etc., but there is no evidence of sufficient accumulations to disturb the flow lines. The electronics are the principal problem with this flume and the calibrations must be checked weekly to ensure accurate time and depth.

Measuring equipment

Rain gages. Rain gages P-1, P-2, P-3, P-4, P-5, and P-6 (Figure 6) are Belfort 5-780 dual traverse, 6

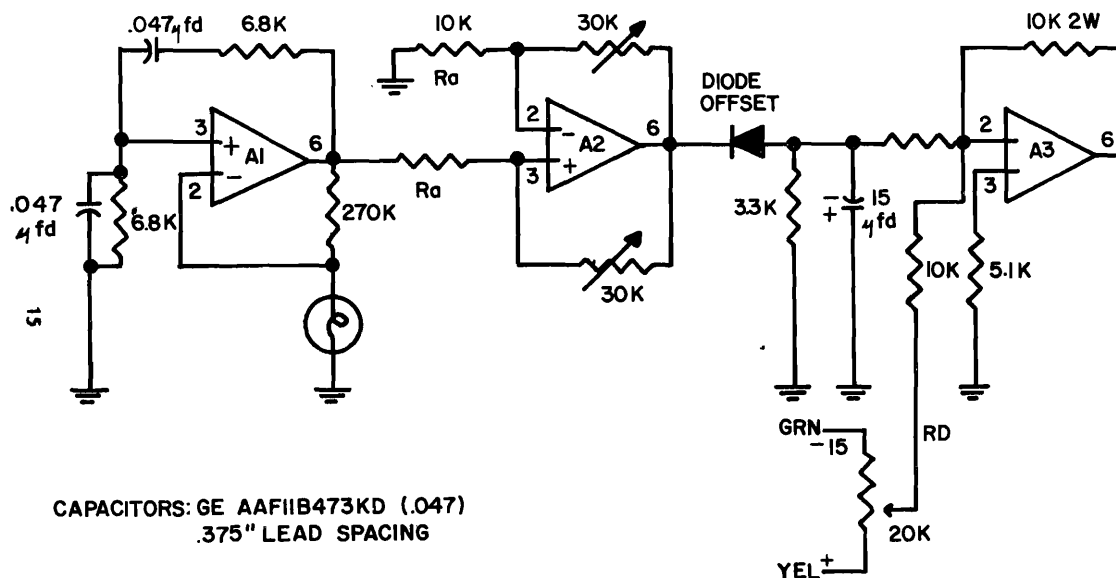

Figure 10. Soil moisture measuring circuit.

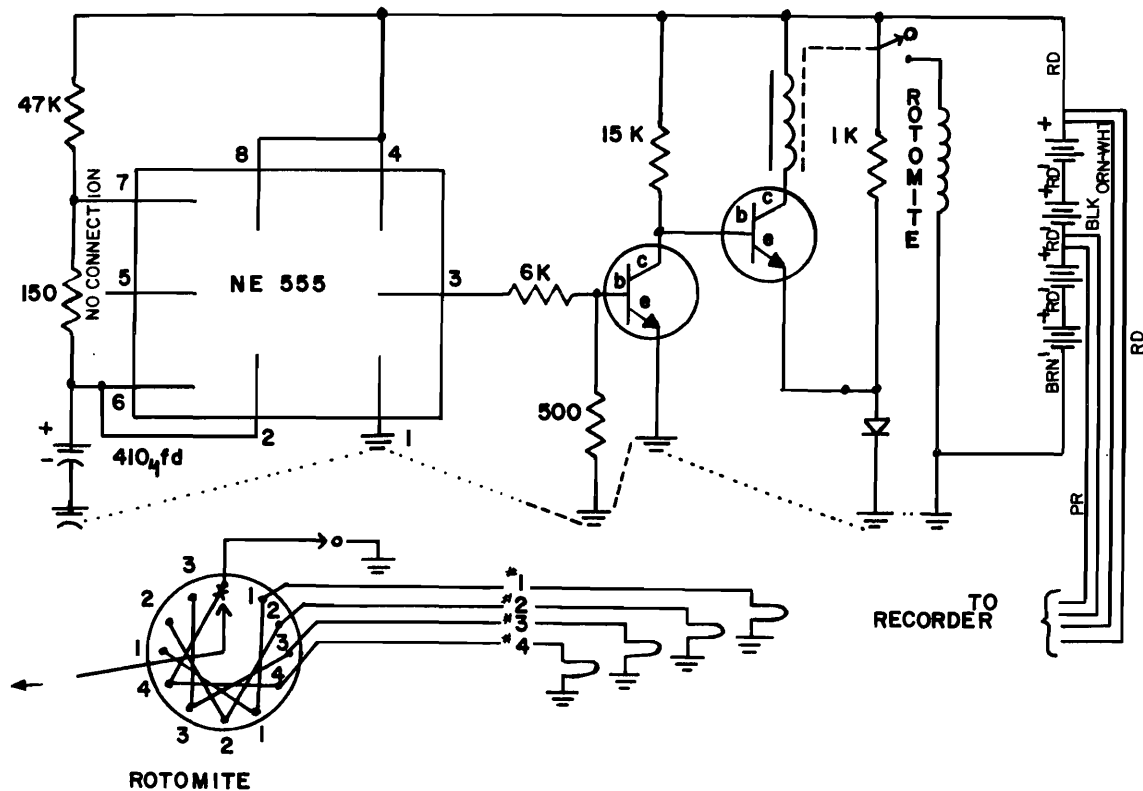

Figure 11. Switching system used to sense three soil moisture depths in sequence.

inches per traverse, weighing recording gages with the chart drives set for 24 hours per rotation. P-7 is the same Belfort 5-780 gage except that the chart drive is set for 192 hours per rotation. Rain gages SP-1, SP-2, SP-3, SP-4, SP-5, and SP-6 (Figure 7) are Truchek type gages (Weather Measure no. 567) the same as at the Layton site.

Temperature. Temperature is measured to 1°F with bimetallic temperature sensor (PT) and recorded on similar equipment to that at the Layton site (Figure 8).

Wind. Wind velocity is sensed to about 2 percent accuracy on equipment (PW) similar to that at the Layton site (Figure 9).

Soil moisture. Soil moisture is sensed and recorded on equipment (PM) similar to that at the Layton site (Figures 10 and 11).

Water level sensor for inlet flume. Circuitry for this water level sensor may be seen in Figure 17. The helical wound resistance coil is a 100 ohm per inch Beckman SM 350 helipot wire, bent in a U shape and mounted so as to be stable inside of a one inch PVC

perforated pipe (Figure 15). The four holes are only at the bottom and are one-fourth inch diameter to still the turbulent water as it falls into the flume. This pipe is mounted on the upstream wall of flume PW-2, as shown in Figure 15.

Data Collection and Reduction

Because mechanical recording systems were used in the field, all recorders required service at least once a week, regardless of whether or not there were storms. The collected data were reduced as follows:

Nonelectronic charts

The analog data on each chart are digitized on a Hewlett-Packard 9864A digitizer. In the Hewlett-Packard digitizer the analog trace of the chart record is traced with a cursor. This automatically tests any changes in slope which differ more than 10 percent and records them. The programs then reduce the data to an output form depending on which parameter is being read.

- EXPLANATION:
- COTTONWOOD FLUME
 - RECORD RAIN GAUGES
 - TRUCK RAIN GAUGES
 - DRAINAGE
 - METEOROLOGICAL
 - MOISTURE SENSOR
 - TEMPERATURE SENSOR
 - ANEMOMETER
 - WATER LEVEL RECORDER

SCALE 1" = 100'

I-215 PARLEYS CANYON

Figure 12. Equipment layout and topography of Parleys site.

Figure 13. Bobbed tailed cutthroat flume and view downstream from PW-1 at Parleys site number 1.

Precipitation charts

The precipitation data are output as intensity for each time period whose slope does not differ more than plus or minus 10 percent.¹ Thus, the output is digitized into a form ready to plot directly on a histogram or convert directly to isopluvial maps, or standard time increments.

Runoff charts

Water level charts are digitized to read in time intervals in minutes and fractions, and depths in hundredths of a foot at the beginning and ending of each time interval. The data are in a form to directly enter the rating table to obtain either the intensity or direct flow hydrograph.

¹Ten percent is the amount of leeway required to ignore vibrations due to wind and traffic on a precipitation gage chart.

Inlet flume

The nature of the chart on this sensor is such as to render automatic reduction difficult since the reference base line shifts and differences must be read as well as the paper being pressure recorded. These were read with a scale directly in hundredths of an inch at each time interval. The rating table (Table 2) was entered with this reading to get the hydrograph intensities.

This sensor could and should be improved by means of more stable electronics and a recorder with a wider chart which records on paper suitable for electronic digitizing.

Problems associated with data collection

Many problems have been encountered during data collection. Some of them were readily corrected

Figure 14. A view of the curb inlet and electronics used to gage the runoff from PW-2 at the Parleys site number 2.

ADJUST R_1 AT MINIMUM OUTPUT (IS 20in. OF WATER)
ADJUST R_2 AT MAXIMUM OUTPUT (IS 0in. OF WATER)
NOTE: THE RECORDER IS READING FULL-SCALE AT 0in. OF WATER.

Figure 17. Salt Lake City inlet flume depth measuring system, Parleys site.

in situ, but others could not be done without changes in the instrumentation systems. Such problems and their possible remedies are discussed in the following:

Rain gages. Calibration of the precipitation gages was checked at monthly intervals to be sure the depths recorded were correct. Each week the time was checked by watch and any differences recorded on the chart as part of the observer's notes.

Another problem that should be remedied before future data are taken is the gaps in the areal coverage of precipitation sensors in the medians. This could be greatly alleviated by putting more Truchek or other gages in locations where recorders would not be suitable either because of their being a hazard to traffic or vice versa.

Runoff measurement. One problem encountered in the measurement of runoff from the paved areas subject to heavy traffic was the lack of any measurements of water splashed away from area subject to gaging. The water on the east lane was splashed to the area draining through gage PW-1 and the water from the lane nearest the median was splashed across the curbing into the median which was not gaged. The net result of all the splashing during peak traffic periods was loss of a large portion of the water gaged by PW-2 and some supplementing of the water gaged by PW-1.

At Layton site the loss of water from the traffic lane is not obvious since the traffic lanes and cut slope both drain through gage LW-1 and the only water loss is that splashed into the median by traffic in the adjacent lane.

Inlet flume. Calibration of the inlet water level recorder was checked frequently by dipping the sensor in a cylinder of water of known depth and the recorded depth and measured depth compared.

Time synchronizing. Time blips were used to synchronize the timing on precipitation and water level equipment. The circuits for this timer are shown in Figure 18. Great difficulty was experienced in keeping this equipment operating because the exposed wires between the sensing equipment were such an easy target for vandals and chance encounters with highway maintenance equipment. If this synchronizer is to be used, the wires should be placed either underground or in the curved portions of guard rails, etc.

Soil moisture measurements. In areas such as these two sites, drought can persist for sufficient lengths of time that soils may become air dried. Research by Fletcher (1960) has shown that infiltration decreases both directions from near the wilting percentage. Normally only the zones above the wilting percentage are considered as antecedent moisture, but each moisture content is significant in the runoff process.

Temperature measurement. Temperature exerts its influence on the runoff process (Fletcher, 1949) through surface tension, viscosity, and wettability. The influence for one arid area amounted to 1.35 percent increase in runoff per degree centigrade raise in temperature.

Wind measurement. Wind up or down a drainage may either inhibit or enhance runoff rate particularly from the paved areas. With boundaries of the drainage being as flat as in the present sites, cross winds or up or down winds can actually blow water on or off of the basin. In addition, the rainfall catch is profoundly affected by winds in excess of 20 miles per hour.

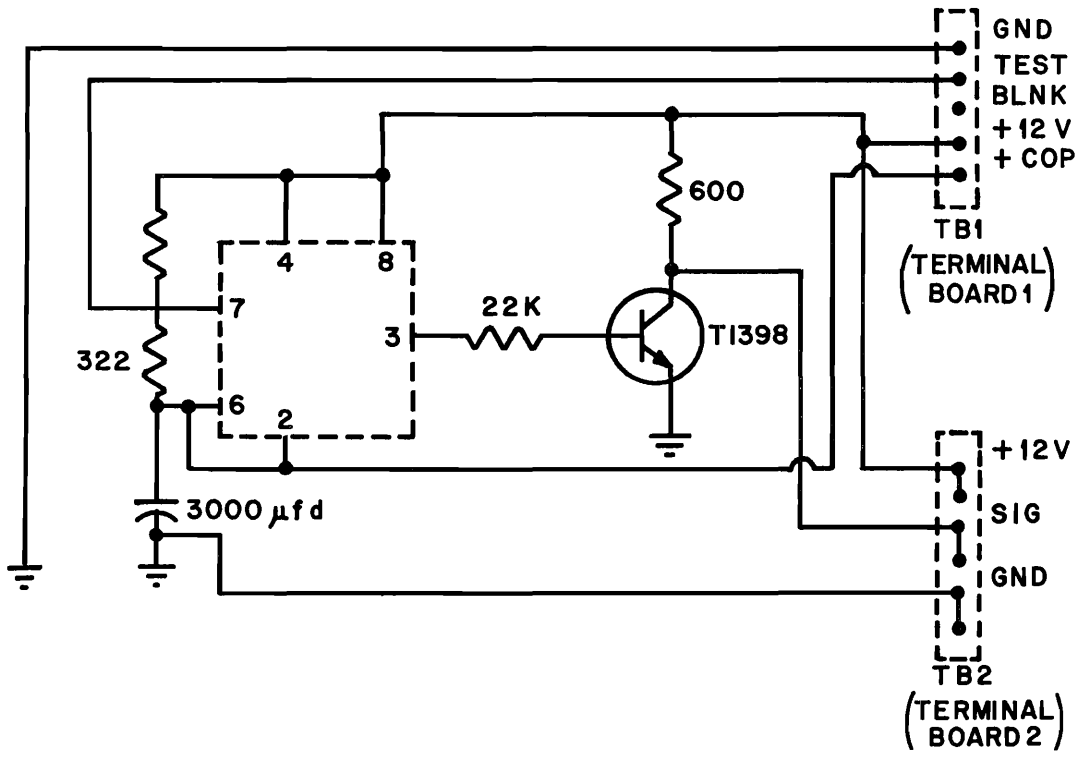

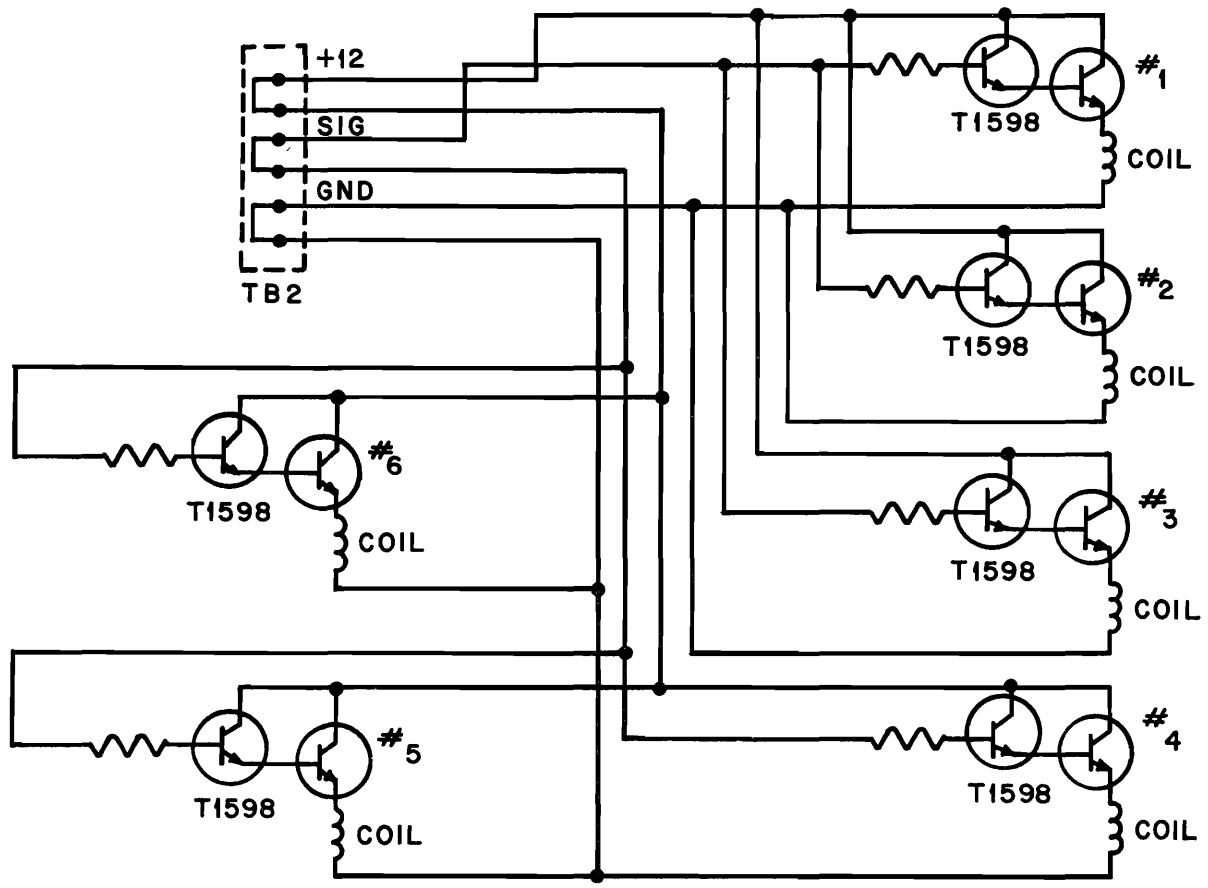

Figure 18. Schematic drawing of time synchronizer at both sites.

FIELD MEASUREMENTS

The field measurements are reported by each site beginning with precipitation, followed by runoff in a detailed fashion with temperature, wind, and soil moisture presented as summaries for periods of precipitation only.

Layton Site

Precipitation data

Precipitation data, time periods for constant units of intensity (or total in the case of nonsignificant storms), the accumulated depth and the intensity during the aforementioned time periods with periods of no record shown from the first measured rain at the site on June 23, 1972, through the first snowfall in October 1972 and beginning again after snowmelt, the first of April, through snowfall in November 1973. Observations are being continued through the thunderstorm season of 1974 and will be reported at a later date.

The rainfall depth and intensity for each of seven recording gages are given in Table 3 and the Truchek gage rainfall depths are given in Table 4.

Runoff data

The first runoff measured at the Layton site did not occur until September 1972 even though the station was in operation from April on. The runoff is tabulated in the chronological order of rainstorm events which occurred between snowmelt (April) and snowfall (November) in 1972 and 1973. In Table 5, for each event the rate of flow in cubic feet per second is tabulated against date time. Observations are continuing in 1974 and will be tabulated separately.

Temperature data

The minimum and maximum temperature (°F) during each runoff event beginning with the first runoff event at the Layton site on September 5, 1972, until snowfall after November 5, 1972, and

beginning again after snowmelt in April 1973 are tabulated in Table 6. There are no apparent temperature relations with respect to rainfall-runoff events, but no detailed analyses were made.

Wind data

The maximum and minimum wind speeds and mean direction of the wind during the runoff events at the Layton site are given in Table 7. There was customarily a veering in wind direction at the beginning of precipitation events.

Soil moisture data

Soil moisture samples were taken at three depths, from 0 to 6 inches, from 6 to 12 inches, and from 12 to 24 inches during 1973. Electrical resistance moisture sensors were also installed at depths of 3, 9, and 18 inches. The moisture samples served as calibration points for the recorder.

The soil moisture ranged from well above field capacity following rains before equilibria to just above air dry on the surface to wetting percentage at the lower depths. The moisture measurements are shown in Table 8.

Parleys Site

Precipitation data

Precipitation data, time of beginning and ending of each change in intensity, and the accumulated depth and intensity of these times are given for the rainy season of 1972 and 1973 in Table 9. The Truchek rain gage data are given in Table 10. Records began with the first rain after snowmelt on June 23, 1972, and continued until snowfall on November 7. The 1973 records began after snowmelt on April 14, 1973, and continued until snowfall after November 25, 1973. Records continued in 1974, and will be compiled at a later date. Truchek gages were read at the time the recording gages were serviced.

23 Sept.	10.97	6.67	8.60
18 Nov.	14.78	11.84	10.61

Runoff data

Runoff was measured at two locations on the Parleys site. The first PW-1 flume measures only the

runoff from the east sideslope of I-215 plus that derived from traffic splash from the north bound east traffic lane. The second location PW-2 flume measures only the runoff from the north bound traffic lanes remaining after traffic splash.

The dates, times of beginning, times of flow beginning, rate changes, flow rates, and end of runoff for PW-1 flume are given in Table 11. The same data for PW-2 flume are given in Table 12.

Temperature data

The maximum and minimum temperatures observed during all of the runoff events with the dates and times of these events are given in °F in Table 13 for the Parleys site.

Wind data

Wind at the Parleys site was measured in the median near PW-2 flume in contrast to the location on the Layton site which was on the east cut slope.

The maximum and minimum speed and direction of wind that occurred during the 1972 and 1973 runoff events are shown in Table 14 for the Parleys site.

Soil moisture data

The soil at the Parleys site is so highly variable that considerable noise exists in the soil moisture data. The soil moisture data in 1973 are tabulated in Table 15 at the beginning of each of the runoff events. Soil moisture measurements were not conducted in 1972 because of delay in installation of soil moisture blocks.

HYETOGRAPHS AND HYDROGRAPHS FOR MAJOR STORMS

For comparison, hyetographs and the corresponding hydrographs for major storms producing flows greater than an arbitrary 0.025 cfs at the gage are plotted. There were about 10 major storms on each site. Ten major storms at Layton site are shown in Figures 19 through 28 and those at Parleys site are shown in Figures 29 through 38. The year 1972 was very dry and no measurable storm was recorded until late in the summer. The first major storm occurred on September 5, 1972, at both sites. A comparison of the hyetographs and hydrographs reveals that a similarity in pattern exists among the hyetographs and hence the corresponding hydrographs plotted at each site. Physiographically both sites are in the same Salt Lake City region but in different portions of the region so they are somewhat different. These differences manifest themselves in precipitation and runoff patterns measured at both sites.

Runoff from the highway watershed at Layton site, as shown in Figure 1(a) is composed of two overland flows, one from an impervious roadway and the other from a grass-covered sideslope. The two overland flows meet at a gutter where storm water collects from both sides and flows downstream to the inlet. At Parleys site, on the other hand, these areas are two different watersheds: Parleys site number 1 is a sideslope with a gutter and Parleys site number 2 is a four-lane roadway with a curb gutter as shown in Figures 1(b) and 1(c), respectively. An inspection of Figures 29 through 38 reveals that runoff rate from the roadway appears many times higher than that from the sideslope. Such a big difference in the runoff rate between the roadway and the sideslope is probably caused by the substantial amount of precipitation lost to infiltration, grass interception, and depression storage on the sideslope. It is conceivable that precipitation from storms of mild intensity and short duration may be entirely depleted by interception and infiltration.

In view of relatively small portion of the total runoff from the sideslope at Parleys site, the inlet hydrographs at Layton site for most of the rainfall events with the exception of prolonged ones, can be said to be contributed mostly by runoff from the roadway. A question may arise, however, as to the accuracy of the hydrographs measured, especially during traffic hour storms. As mentioned previously, the splash from traffic appeared to be a sizable

portion of runoff lost from the roadway. Adding to this problem was the electronic instability of the water level recorder for the inlet flume at Parleys site number 2. Because of these two main sources of problems, some of the runoff discharges at Parleys site number 2 such as occurred on October 4, 1972 (Figure 31), April 29, 1973 (Figure 32), and July 19, 1973 (Figure 33), could not be measured.

Seven Belfort rain gages, in addition to six Truchek rain gages, were installed for each site on drainage area of less than 0.1 square miles. Despite such dense precipitation measuring points on the areas, the amount of precipitation recorded varies from one gage to another, especially under low intensity storms (see Figures 23 and 25). Sometimes, there was even no record of rain at some gages for the same rainfall event. For example, Table 16 shows that no measurable rain was recorded at gage L-4 on May 25-26, 1973, at Layton site (Figure 25), at gage P-5 on October 4, 1972, at Parleys site (Figure 31), at gages P-1, P-2, and P-3 on August 16, 1973, at Parleys site (Figure 34), and at gages P-1 and P-5 on October 8, 1973, at Parleys site (Figure 37). Because a calibration check on the rain gages was made on a monthly basis and mechanical clocks were checked every week, it is unlikely that the variability of rainfall data recorded was caused by a malfunction of the gages and recorders.

The nature of temporal and spatial variations in storm patterns over the urban highway watersheds manifested itself on the rainfall data recorded. Despite the complexity in storm patterns, as shown in Figures 19 through 38, the inlet hydrographs in response to the major storm inputs at Layton site look very similar to each other, namely all suddenly rise to the peak and then gradually taper off in the receding stage. The longer base of the hydrographs at Layton indicates the basin lag to be longer than at either Parleys watershed and the more complicated pattern of flow sequencing by the timing of the flow from the pavement to the central gutter and from the sideslope to the central gutter where they join to continue to the gage at LW-1. An analogous hydrograph might be obtained by incrementally adding the hydrographs of PW-1 and PW-2 at the Parleys site.

A further analysis of the hyetographs and hydrographs is not attempted in this report, but will be made, if necessary, in the other phase of research.

EVALUATION OF WATERSHED RETENTION

Watershed retention may be evaluated with the same accuracy as streamflow or precipitation from an event on the drainages by first estimating the mass or accumulative retention. Beginning with the Parleys event of October 4-5, 1972, on drainage site No. 1 which drains a sideslope the next six steps may be followed:

1. Plot the mass rainfall curve for each precipitation gage beginning with the gage where precipitation first began (gage No. 3 at 7:53 PM) and continuing through gage No. 1 (precipitation at 7:55 PM). The net mass rainfall input curve is made by taking the mean at each of the 5 minute intervals from the beginning of rainfall on the first gage to the ending of rainfall on the last gage. All non-recording precipitation gages are assumed to be distributed in time the same as this mean mass curve. For the event being considered, the procedure gives 13 different curves (7 Belfort and 6 Truchek), depending on the total precipitation at each non-recording gage, representing either the mean mass time distribution curve or its actual time distribution curve.
2. Plot the mass runoff curve for the event. In the 4-5 October 1972 example there are two runoff curves (see Figure 31). The first runoff began at 8:14 PM and ended at 9:33 PM with a volume of 0.0128 acre-inches. The second runoff began at 11:15 PM on October 4 and ended at 1:14 AM on October 5, 1972, with a volume of 0.000357 acre-inches. Thus, the total volume of both runoff events corresponding to the October 4-5 rainstorm is 0.0132 acre-inches.
3. The difference in the mass rainfall volume for each 5-minute interval of precipitation is obtained by planimetering the isohyetal map for that time period and adding the total measured volumes for all time periods. This sum is the actual volume of rainfall during the storm. This volume is reduced by the volume of runoff to give the volume of watershed retention. Note that watershed infiltration is only a part of watershed retention. Factors such as evapotranspiration are too small to measure and depression storage eventually infiltrates. Interception is a true retention as was the water required to wet the watershed surface under thunderstorms.
4. Since the rain began at 7:53 PM on October 4, 1972, and ended at 12:45 AM on October 5, 1972, infiltration continued for a period of 4 hours and 53 minutes, but not at a maximum rate after runoff stopped, since after this time watershed infiltration exceeded rainfall rate. Subtracting a mass runoff of 0.024 inch from the mean mass precipitation of 0.40 inch from 7:53 PM to 12:46 AM resulted in a mass infiltration of 0.376 inch in 4 hours and 53 minutes.
5. Plot the maximum of 0.376 inch of infiltration on 3 x 5 cycle log paper at the time of 17,580 seconds and assume arbitrarily the lowest unit of infiltration or 0.001 inch infiltration in 1 second. Draw a straight line through these two points. This is the mass infiltration curve.
6. On the same sheet, plot the infiltration rates against time, as taken from the corresponding times and amounts of the mass infiltration curve. For example, at 1 second the mass infiltration is 0.001 inch so that $(0.001/1) \times 3,600 = 3.60$ inches/hour mean infiltration rate for the 1 second period. The estimated watershed infiltration decay curve for the sideslope at Parleys site No. 1 is thus plotted, as shown in Figure 39.

The same procedure may be applied to the Layton storm of October 4-5, 1972, except that it was necessary to correct it for the amount of the runoff from the roadway which occupies 1/2 of the total drainage. It had been previously observed that the roadway at Parleys site No. 2 retained 0.02 inch of water in the same period of time so the mass precipitation was reduced by this amount of retention to account for the retention of runoff by the roadway. After runoff from the roadway is determined, an estimate of the runoff from the sideslope could be made. The mass infiltration curve may be constructed similarly. The upper point on the mass infiltration curve for this event is 0.41 inch in 52,800 seconds, while the lower point can again be assigned as a mass infiltration of 0.001 inch in 1 second. The estimated watershed infiltration decay curve for the sideslope at Layton site is shown in Figure 40. Note that the curves at both sites look very similar.

Figure 39. Estimated infiltration capacity of soil on sideslope at Parleys site.

SUMMARY AND CONCLUSIONS

Hydrologic data including precipitation and runoff for two rainfall seasons in 1972 and 1973 were collected for two urban highway watersheds in the Salt Lake City area, Utah. The data are needed for the verification of a mathematical model simulating the rainfall-runoff process on typical highway watersheds. The procurement and installation of field equipment as well as the selection of two test sites were accomplished in 1971 through 1972. Only two seasons of field data could be collected to date. However, the year 1972 happened to be a season with infrequent storms. No measurable storm was recorded until late in the summer of 1972. All precipitation, runoff, air temperature, wind, and soil moisture data collected for each rainfall event are presented in this report.

Despite the arrangement of considerably dense precipitation-measuring points on each site, rainfall data collected varied from one gage to another, especially under low-intensity storms. A comparison of hydrographs plotted for major storms at Parleys site numbers 1 and 2 reveals that a substantial amount of precipitation was depleted by infiltration, grass interception and depression storage on the sideslope. The hydrographs at the Layton site in the early rising stage were judged to be constituted mainly of runoff from the roadway, but in the late receding stage contributed mostly from the sideslope.

The splash from heavy traffic during rainfall at Parleys site number 2 was observed to account for a

significant amount of runoff lost from the roadway. Unfortunately, corrective provisions were not made to measure the amount of splash. Without this measurement, it is difficult to determine the effect of splash on the inlet hydrographs. The seriousness of splash due to traffic at the Layton site was not so obvious as at Parleys site number 2 because the total runoff at Layton site consisted of those from the paved roadway, paved shoulder, and grass slope.

The most difficult problem encountered during field data collection from the highway cross-section is the traffic that not only interrupts the natural rainfall-runoff process on the roadway, but also constitutes a potential hazard to the field instruments and vice versa. To accurately compute the inlet hydrograph due to runoff from the roadway, human factors such as traffic should be taken into consideration in the mathematical modeling.

Debris plugging difficulties of the discharge-measuring flumes found in Baltimore, Philadelphia, and Chicago have not been experienced with the cutthroat flumes installed. There were also several other problems encountered during data collection and reduction. Some of them were readily corrected *in situ*, but others could not be remedied without partial or entire modifications of the field instrumentation systems. Those which should be improved were already pointed out earlier and will be summarized in the following section.

RECOMMENDATIONS

The principal future works recommended for the field phase of the project are as follows:

1. Continuance of the field data collection through a few more seasons would certainly yield valuable information on the unique rainfall-runoff process on the typical urban highway cross-sections. In order for data to be useful, a total of at least 10 seasons is required. The additional field data will be extremely important in the verification of the mathematical model and can be obtained at minimal unit cost since the capital investments have already been made.

2. A great variety of precipitation data recorded at various rain gages including Belfort and Truchek on each site with the same rainfall event certainly indicated the necessity of having more rain gages installed on each site. Apparent gaps in the areal coverage of rain gages were in the medians. A denser network of rain gages will enable plotting an isohyetal map for every storm occurring on each site and hence analyze the rainfall-runoff relationship for the typical urban highway watershed.

3. The splash from traffic appeared to be a sizable portion of many of the events at Parleys site

number 2, but not so obvious at Layton site. Most of this water could be directed back to the roadway by flashings between the guard posts of the median by the curb side and measured with trough gages on the uphill side of the traffic lane.

4. The water level sensor and recorder for the inlet flume (PW-2) at Parleys site number 2 could and should be improved by means of more stable electronics and a recorder with a wider chart which records on paper suitable for electronic digitizing.

5. Great difficulty was experienced in keeping time synchronizers at both sites operating because the exposed wires between the sensing equipment were such an easy target for vandals and chance encounters with highway maintenance equipment. The wires for the time synchronizers should be placed either underground or in the curved portions of guard rails.

6. Infiltration capacity of the sideslopes at both sites should be measured by use of an infiltrometer. The amount of interception and depression storage for various rainfall events should be determined *in situ*.
