22 Running title: Microgeographic genetic structure of chickadees

23

24 Word Count: 5342

25 **Abstract**

26 Variation in landscape features influence individual dispersal and as a result can affect both
27 gene flow and genetic variation within and between populations. The landscape of British
28 Columbia, Canada, is already highly heterogeneous due to natural ecological and geological
29 transitions, but disturbance from human mediated processes has further fragmented
30 continuous habitat, particularly in the central plateau region. In this study, we evaluated the
31 effects of landscape heterogeneity on the genetic structure of a common resident songbird, the
32 black-capped chickadee (*Poecile atricapillus*). Previous work revealed significant population
33 structuring in British Columbia which could not be explained by physical barriers, so our aim
34 was to assess the pattern of genetic structure at a microgeographic scale and determine the
35 effect of different landscape features on genetic differentiation. A total of 399 individuals
36 from 15 populations were genotyped for fourteen microsatellite loci revealing significant
37 population structuring in this species. Individual and population based analyses revealed as
38 many as nine genetic clusters with isolation in the north, the central plateau and the south.
39 Moreover, a mixed modelling approach that accounted for non-independence of pairwise
40 distance values revealed a significant effect of land cover and elevation resistance on genetic
41 differentiation. These results suggest that barriers in the landscape influence dispersal which
42 has led to the unexpectedly high levels of population isolation. Our study demonstrates the
43 importance of incorporating additional landscape features when interpreting patterns of
44 population differentiation. Despite taking a microgeographic approach, our results have
45 opened up additional questions concerning the processes influencing dispersal and gene flow
46 at the local scale.

47 **Introduction**

48 Dispersal and gene flow are crucial for maintaining population connectivity and species
49 persistence, while also preventing population differentiation and species divergence. The
50 heterogeneity and patchiness of landscapes can influence the ability of an individual to
51 disperse between populations. If dispersal is restricted by barriers in the landscape, the
52 resulting decrease in population connectivity can lead to discrete, isolated groups. Over time,
53 these isolated groups may experience reduced genetic diversity and become genetically
54 distinct (Baguette and Van Dyck, 2007). Landscape genetics offers new approaches to
55 explicitly test the influence of landscape elements on genetic structure to identify barriers
56 corresponding to structured populations (Manel *et al.*, 2003, Holderegger and Wagner, 2008;
57 Sork and Waits, 2010; Manel and Holderegger, 2013).

58 Large physical structures (e.g. mountain ranges and large water bodies) as well as
59 stretches of unsuitable habitat are obvious barriers to dispersal and subsequent gene flow. The
60 influence of barriers can vary within and among species so it is important to be able to
61 identify the specific factors influencing genetic differentiation of target groups prior to
62 implementing management strategies (With *et al.*, 1997). For example, using a landscape
63 genetics approach, Frantz *et al.* (2012) found that motorways influenced genetic structuring in
64 red deer (*Cervus elaphus*), but not wild boars (*Sus scrofa*); as a result, considering
65 fragmentation effects of motorways would be primarily targeted at conservation efforts on
66 only the former species. The effects of landscape features can also vary across a species
67 range, as in the ornate dragon lizard (*Ctenophorus ornatus*), where land clearing was
68 associated with genetic differentiation in one area, but not another (Levy *et al.*, 2012).
69 Smaller, less conspicuous structures or environmental variables, such as microclimate, may
70 also influence gene flow. Through landscape genetics, effects of multiple factors on

71 contemporary patterns of genetic structure can be examined across different spatial scales and
72 across species with varying dispersal capabilities, allowing us to better understand how
73 organisms interact with their environment, and how they may respond to future environmental
74 change.

75 In current landscapes, habitat fragmentation from natural and human-mediated
76 processes can influence the potential for animals to disperse and thus affect the spatial
77 distribution of genetic variation at both large and small geographical scales. Contemporary
78 factors such as insect outbreaks (e.g. mountain pine beetle *Dendroctonus ponderosae*) and
79 habitat degradation (e.g. forestry operations, agricultural conversion) have reduced population
80 connectivity by removing suitable breeding/dispersal habitat (Martin *et al.*, 2006). For
81 instance, a combination of already-restricted range of the northern spotted owl (*Strix*
82 *occidentalis caurina*) in the Pacific North West coupled with the removal of dense, late
83 successional forest has left the species federally threatened (COSEWIC, 2008; Blackburn *et*
84 *al.*, 2003; Yezerinac and Moola, 2006).

85 British Columbia (Canada) has a complex climatic and vegetation history following
86 the Last Glacial Maximum (26.5 – 19 thousand years ago). When this is combined with
87 broad-scale climatic gradients (i.e. moisture, temperature and topography - Meidinger and
88 Pojar, 1991) in the province, the result is major regional transitions that create rich and
89 heterogeneous landscapes (Gavin and Hu, 2013; Figure 1). The province contains six
90 ecozones and 14 biogeoclimatic zones (see Figure 10 in Meidinger and Pojar, 1991). A major
91 longitudinal moisture gradient formed by the Coastal Mountains is characterised by dominant
92 maritime moist conifer forest in the west, transitioning to sagebush steppe in the rain-shadow
93 of the south central interior, to mixed conifer and pine forest in the east. The interior regions
94 are further influenced by a latitudinal gradient with increasing summer moisture from south to

95 north. This results in desert steppe in the south transitioning to subboreal and boreal spruce
96 forest in the north. This natural heterogeneity is further increased by high levels of habitat
97 fragmentation resulting from current forestry and agricultural practices occurring within the
98 province.

99 To determine how these natural and anthropogenic factors influence population
100 structure, we conducted a microgeographic landscape genetic assessment of a common
101 resident songbird, the black-capped chickadee (*Poecile atricapillus*) in British Columbia. Our
102 previous work identified population genetic structuring in central British Columbia, but the
103 sampling regime and range-wide scale of the study meant that smaller geographical barriers
104 were less noticeable (Adams and Burg, 2015). Here, a fine-scale transect sampling approach
105 allowed for a more detailed examination of the landscape patterns and processes influencing
106 population genetic structuring and a larger number of microsatellite markers were used to
107 better capture the spatial distribution of genetic variation (Runde *et al.*, 1987; Selkoe and
108 Toonen, 2006). The study area is comprised of a number of different habitats and
109 environmental conditions, so studying genetic variability in a non-migratory species with
110 limited dispersal potential will allow us to investigate the role of habitat heterogeneity on the
111 ecology and evolution of populations. The aims of the study were to identify where the
112 genetic breaks occur and to evaluate the processes driving differentiation. This led to three
113 main hypotheses; 1) fine scale population genetic differentiation will be evident in the black-
114 capped chickadee due to the inclusion of additional sampled populations and microsatellite
115 loci; 2) given the level of topographical and climatic variability found within the province,
116 dispersal and gene flow are influenced by landscape features and environmental variables, and
117 3) habitat fragmentation resulting from anthropogenic disturbance (e.g. forestry and
118 agriculture) isolates populations in central and southern British Columbia.

119

120 **Materials and Methods**

121 *Study Species*

122 The black-capped chickadee is a resident songbird, common throughout most of North
123 America with a range that covers a large and complex geographical area. Black-capped
124 chickadees are an important study species because they are generalists and thrive in a variety
125 of environmental conditions, although they prefer mixed deciduous and coniferous woodland
126 (Smith, 1993). If specific landscape processes are found to have a negative impact on
127 chickadees, this would indicate that other species (particularly specialists) may also be
128 affected. As primary cavity nesters, chickadees are dependent on advanced decaying trees or
129 snags in mature forests. Their diet requirements also vary seasonally with a preference for
130 mixed berries, seeds and insects in the winter in comparison to a completely insectivorous diet
131 during the breeding season (Runde *et al.*, 1987). Although chickadees do reside and breed in
132 disturbed areas, studies have found these low quality habitats negatively affect reproduction
133 (Fort *et al.*, 2004a), territoriality (Fort *et al.*, 2004b), song output (van Oort *et al.*, 2006), song
134 consistency and perception (Grava *et al.*, 2013a) and song structure (Grava *et al.*, 2013b) in
135 this species. Elevation and the presence of other chickadee species (e.g. mountain
136 chickadees) can also influence their distribution and habitat preference (Campbell *et al.*,
137 1997). Collectively, this information highlights the importance of a number of factors related
138 to habitat quality (e.g. mature, dense woodland) on species persistence.

139

140 *Sample collection*

141 We included samples from seven populations collected as part of our previous study (i.e.
142 FtStJ1, PG, NWBC, NBC, BCR, SAB1 and SAB2; Table 1; Adams and Burg, 2015). We

143 collected additional samples during the 2012 breeding season using a transect-based approach
144 along HWY 16, the main east-west corridor in north-central British Columbia. Birds were
145 captured using mist nets and call playback, and samples of blood (< 100 µl from the brachial
146 vein) and/or feathers were obtained from each individual. This resulted in approximately 20
147 individual birds sampled from each of an additional six locations (i.e. HAZ, HOU, FF, FrL,
148 CLU and FtStJ2; Table 1). Where possible, sampling sites were confined to a 10 km radius.
149 Feather samples were also obtained from two more populations: Vancouver (VAN) and
150 Kelowna (KEL). With all individuals combined, sampling took place over ten breeding
151 seasons (2003 – 2010, 2012 and 2013) and a total of 405 individuals from 15 populations
152 were collected (Figure 1; Table 1; Supplementary Table S1). Each bird was banded with a
153 numbered metal band to prevent re-sampling and all blood/ feather samples were stored in
154 95% ethanol and, on return to the laboratory, stored at -80°C.

155

156 *DNA extraction and microsatellite genotyping*

157 DNA was extracted from blood ethanol mix (10 µl) or feather samples using a modified
158 Chelex protocol (Walsh, 1991). Each individual was genotyped for 14 polymorphic
159 microsatellite loci (Supplementary Table S2) and DNA was amplified for all loci (including
160 new loci Pij02, VeCr05 and CTC101) using the same two-step annealing PCR conditions
161 outlined in Adams & Burg (2015); the exception was for Pij02, where the two-step annealing
162 temperatures were adjusted from 50°C and 52°C to 52°C and 54°C. All procedures following
163 DNA amplification were conducted as in Adams and Burg (2015).

164 Most individuals were successfully genotyped for all 14 variable microsatellite loci.
165 Seven populations were missing genotypes for locus PmanTAGAn45, four populations for
166 Ppi2, two populations for Titgata02, and two populations for Pij02. All analyses were carried

167 out with and without these four loci to determine if missing data influenced levels of observed
168 population differentiation. In addition, we conducted analyses with and without the feather
169 sampled populations (KEL and VAN) as the DNA extracted from feathers were of lower
170 quality which resulted in missing data and created the potential for genotyping errors from
171 low amplification success for some loci.

172

173 *Genetic analyses*

174 Genetic diversity

175 A total of 399 individuals remained after removing those genotyped for ≤ 5 loci. Errors
176 within the data (i.e. input errors, allelic dropout, stutter and null alleles) were assessed in
177 MICRO-CHECKER v2.2 (van Oosterhout *et al.*, 2004). Allelic richness was calculated in
178 FSTAT v2.9.2.3 (Goudet, 2001) and tests for deviations from Hardy-Weinberg equilibrium
179 (HWE) and linkage disequilibrium (LD) were performed in GENEPOP v4.0.10 (Raymond
180 and Rousset, 1995; Rousset, 2008) using default Markov chain parameters (100 batches, 1000
181 iterations and 1000 dememorisation steps). Both observed and expected heterozygosities
182 were calculated in GenAlEx v6.5 (Peakall and Smouse, 2012) to determine the levels of
183 population genetic diversity. Lastly, levels of significance were adjusted using the modified
184 False Discovery Rate (FDR) correction (Benjamini and Yekutieli, 2001).

185

186 Population genetic structure analyses

187 We used multiple approaches to gain insight into the genetic structure of the black-capped
188 chickadee. We used two clustering methods: GENELAND v4.0.0 (Guillot *et al.*, 2005a) and
189 STRUCTURE v2.3.4. (Pritchard *et al.*, 2000). Both use Bayesian models to assign
190 individuals to genetic clusters by maximising HWE and minimising LD, but differ in the way

191 they use spatial information. STRUCTURE relies solely on genetic data (with the option of
192 predefining populations with location priors) whereas GENELAND incorporates individual
193 spatial coordinates.

194 Implemented in the program R v 3.1.3 (R Development Core Team, 2015),
195 GENELAND was run in two steps following the recommended protocol of Guillot *et al.*
196 (2005a, b). First, we ran the program for ten replicates for each K (1 – 10) using the
197 correlated allele frequencies and null allele models and 100,000 McMC iterations, a thinning
198 interval of 100 and a maximum rate of Poisson process of 399 (equal to the sample size). The
199 uncertainty attached to spatial coordinates was fixed to 20 km (i.e. the precision of our sample
200 locations; 10 km radius) and the maximum number of nuclei in the Poisson–Voronoi
201 tessellation was fixed to 1197 (three times the sample size). The number of clusters (K) was
202 inferred from the modal K and the run with the highest mean posterior probability. A second
203 run was then conducted with the inferred K fixed and all parameters left unchanged to allow
204 individuals to be assigned to clusters. To determine the robustness of this model,
205 GENELAND was run multiple times with different parameters (e.g. with and without the
206 correlated allele frequencies and null allele models; and 50,000, 100,000 and 200,000 McMC
207 iterations).

208 STRUCTURE was run with the admixture model, correlated allele frequencies (Falush
209 *et al.*, 2003) and locations as priors (locpriors). To determine the optimal number of clusters
210 (K), we conducted ten independent runs (100,000 burn in followed by 200,000 McMC
211 repetitions) for each value of K (1-10). Results were averaged using STRUCTURE
212 HARVESTER v0.6.6 (Earl and vonHoldt, 2012) and both delta K (ΔK ; Evanno *et al.*, 2005)
213 and $\text{LnPr}(X|K)$ were used to determine the true K . Any populations with individuals showing
214 mixed ancestry (e.g. 50% Q to cluster 1, and 50% Q to cluster 2) were rerun individually with

215 two populations representing each of the two clusters involved in the mixed ancestry to
216 determine correct assignment. This is important to check because as K increases above the
217 true K value, Q values will often decrease and split clusters (Pritchard *et al.*, 2000). This
218 splitting of populations must be clarified prior to additional testing. Finally, if multiple
219 populations were assigned to the same genetic cluster, those populations were rerun to test for
220 additional substructure using the same parameters as the initial run, but only to a maximum of
221 five runs for each K value. Pairwise F_{ST} values were then calculated in GenAEx v6.5 to
222 investigate the degree of genetic differentiation among the predefined populations. We also
223 calculated D_{EST} (Jost, 2008) in SMOGD v1.2.5 (Crawford, 2010), an alternative measure of
224 diversity that accounts for allelic diversity and is shown to measure genetic differentiation
225 more accurately than traditional F_{ST} when using polymorphic microsatellite markers (Heller
226 and Siegmund, 2009). We compared measures of D_{EST} and F_{ST} to determine the true level
227 of genetic differentiation. Since the theoretical maximum of 1 for F_{ST} is only valid when
228 there are two alleles, population wide F'_{ST} , standardised by the maximum F_{ST} value, was
229 calculated in GenAEx v6.5. To further assess genetic structure among populations, we
230 carried out a Principal Coordinate Analysis (PCoA) using both F_{ST} and D_{EST} in GenAEx
231 v6.5.

232

233 *Landscape genetics*

234 Parameterization of landscape variables

235 To assess the functional connectivity among populations, we evaluated four competing
236 models: 1) the null model of isolation by geographical distance (or IBD; Wright, 1943), 2)
237 isolation by elevation resistance, 3) isolation by land cover resistance and 4) isolation by
238 combined elevation and land cover resistance (i.e. both land cover and elevation raster layers

239 were combined into one resistance layer, termed ‘land-elevation’ herein). Pairwise resistance
240 distances were calculated among all sampling sites using spatial datasets and an eight
241 neighbour connection scheme in CIRCUITSCAPE v4.0 (McRae, 2006). This method is based
242 on circuit theory and uses resistance distances to assess all possible pathways between two
243 focal points (or populations) to better map gene flow across the landscape and measure
244 isolation by resistance (IBR).

245 Categorized land cover and digital elevation maps (DEM), circa 2000, were obtained
246 from GEOBASE (www.geobase.ca) and resistances to habitat types were assigned using
247 ArcMap, ESRI® (Table 2). Land cover data were categorised into six cover types. The lowest
248 resistance values were assigned to suitable chickadee habitat known to facilitate dispersal (i.e.
249 forest cover, particularly broadleaf and mixed forests) whereas other land cover types were
250 classified as being moderately permeable (i.e. coniferous forest, shrubland and grassland), or
251 completely impermeable (i.e. unsuitable habitat which included agricultural land and water) to
252 dispersal (Table 2). For elevation, five different ranges were assigned resistance values based
253 on elevations where chickadees have previously been observed. For example, low resistances
254 were given to low elevation ranges (< 1500 m), whereas higher resistance values were given
255 to higher elevations where chickadees are rarely observed (> 1500 m) (Table 2). The program
256 outputs a cumulative ‘current map’ to portray the areas where resistance to gene flow is either
257 high or low. Populations SAB1 and SAB2 were excluded from these analyses as geo-
258 referenced coordinates were outside the spatial extent of the data. Given the size of our study
259 area, all resistance surfaces were based on a 2 x 2 km resolution.

260

261 Landscape effects

262 We implemented a linear mixed-effect modelling approach based on the maximum-likelihood
263 population-effects (MLPE) model (Clarke *et al.*, 2002) using the ‘lmer’ function in the
264 package ‘lmer4’ v1.1.8 (Bates *et al.*, 2015) in R v 3.1.3 (R Development Core Team, 2015).
265 This approach is superior to the Mantel test to identify the landscape variable(s) which best
266 explain population genetic differentiation. This is because these tests are often described as
267 having low statistical power (Legendre and Fortin, 2010) and, more importantly, fail to
268 account for non-independence of each pairwise observation within the distance matrix (Yang,
269 2004).

270 Nine predefined models were used to test for effects of different landscape variables
271 on both estimates of pairwise genetic distance (i.e. F_{ST} and D_{EST}). When fitting MLPE
272 models, the ‘lmer’ function was modified so the random factor would account for multiple
273 memberships (i.e. two individual populations for each pairwise distance) following van Strien
274 *et al.* (2012). Explanatory variables were centred around their mean, and parameter
275 estimation was performed with the residual maximum-likelihood (REML) criterion (Clarke *et*
276 *al.*, 2002). For each parameter estimate 95% confidence intervals were calculated. Models
277 satisfied the assumptions of normality and constant variance, and showed no evidence of
278 multicollinearity. In landscape genetics, a common technique is to use the Akaike Information
279 Criterion (AIC) for model selection (Storfer *et al.*, 2007). However, use of REML precludes
280 the use of AIC; therefore we used the marginal R^2 statistic developed by Nakagawa and
281 Schielzeth (2013) in the R package, MuMIn v 1.14.0 (Barton, 2014), to select the best fitting
282 and most parsimonious model (*c.f.* van Strien *et al.*, 2012).

283

284 **Results**

285 *Genetic structure*

286 Genetic diversity

287 Among all loci and populations, the total number of alleles ranged from 3 – 46 alleles
288 (Supplementary Table S2). Observed heterozygosity at each site and across all loci ranged
289 from 0.584 (KEL) to 0.683 (SAB1, followed closely by SAB2 at 0.681), and expected
290 heterozygosity ranged from 0.572 (KEL) to 0.717 (FtStJ1; Supplementary Table S3).
291 Accounting for differences in sample size, allelic richness ranged from 2.42 (PG) to 2.79
292 (FtStJ1 and FF; Table 1). Eleven of the fifteen populations contained at least one private
293 allele (Table 1); FtStJ1 contained the highest number of private alleles (PA = 11) followed by
294 NBC and SAB2 (PA = 5). Null alleles were detected at a low frequency for a number of loci
295 and were not consistent across populations with the exception of two loci: VeCr05 (0 – 25%)
296 and Cupμ28 (31 – 71%). We found a large difference between observed and expected
297 heterozygosities across populations for locus VeCr05 (H_o : 0.185, H_e : 0.306), but not for
298 Cupμ28 (H_o : 0.485, H_e : 0.502, Supplementary Table S3). Exclusion of VeCr05 and/ or Cupμ28
299 did not alter the results, and so all 14 loci were included in the final dataset. Thirteen
300 deviations from HWE (Supplementary Table S3) and two pairs of loci in disequilibrium were
301 identified after corrections for multiple tests. All deviations were the result of a heterozygote
302 deficit. Significant LD was found between loci Titgata02 and CTC101 ($P \leq 0.001$) within
303 FtStJ1 and between loci Escu6 and Titgata02 ($P \leq 0.001$) within SAB1. As LD was not
304 consistent across populations and genotypes showed no association, it is possible that LD is
305 the result of a type 1 error. Results were not substantially affected after removing either the
306 underrepresented loci or the feather sampled populations (see summary statistics in
307 Supplementary Table S4).

308

309 Population genetic structure analyses

310 The two clustering analyses failed to converge on the total number of genetic clusters (K),
311 however a number of groupings were similar across analyses. A hierarchical STRUCTURE
312 analysis inferred seven genetic clusters (Supplementary Figure S1a) using both mean log
313 likelihood ($\Pr(X|K) = -17544.9$) and ΔK (Supplementary Figure S1b). A larger number of
314 groupings was found in GENELAND; eight runs suggested $K = 9$ and two runs suggested $K =$
315 10. As the highest posterior probability was for $K = 9$ (-958) we took this as being the true
316 estimation of K . For population membership and boundary graphs see Supplementary Figure
317 S2. The genetic clusters included single populations (BCR, CLU, FtStJ1, NBC, NWBC, and
318 PG), as well as groups of populations (KEL and VAN, SAB1 and SAB2, and all remaining
319 populations; Figure 1). Five of the groupings were identical to those identified in
320 STRUCTURE (BCR, NWBC, PG, FtStJ1 and VAN+KEL; Supplementary Figure S1). The
321 distinction of PG and FtStJ1 is concordant with patterns observed in our previous study
322 (Adams and Burg, 2015).

323 Pairwise F_{ST} and D_{EST} values showed a significant positive correlation ($R^2 = 0.692$, P
324 = 0.003). Pairwise F_{ST} values ranged from 0.009 to 0.316 (Table 3) and after corrections for
325 multiple tests, 86 of the 105 tests were significant indicating a high level of genetic
326 differentiation among populations. Similar levels of population structure were detected using
327 D_{EST} which ranged from 0.005 to 0.329 (Table 3). Overall F'_{ST} was 0.240 (Supplementary
328 Table S5).

329 Distinct clustering of populations in PCoA was only found using D_{EST} values. The
330 first principal coordinate analysis with all 15 populations resulted in clear separation of
331 populations KEL and VAN from all other populations, as well as differentiation from each
332 other, with the first two axes explaining 50.59% and 17.04% of the variation (Figure 2a)
333 respectively. Isolation of KEL and VAN is concordant with GENELAND. It is important to

334 note that these two populations contained some missing genotype information. Since PCoA is
335 sensitive to missing data, we removed KEL and VAN from analyses to identify additional
336 structure. Concordant with some of the patterns observed in GENELAND, we see separation
337 of PG as well as NWBC and BCR (Coordinate 1 = 31.05%, Coordinate 2 = 19.93%; Figure
338 2b).

339

340 *Landscape genetics*

341 MLPE models were ranked based on marginal R^2 (Table 4). For F_{ST} , the best fitting model
342 included land-elevation (R^2 (mar) = 0.879; Table 4a), whereas for D_{EST} the model with the
343 highest R^2 included both land-elevation and geographical distance (R^2 (mar) = 0.711; Table
344 4b). All variables in the best models had a positive effect on genetic distance. Over all
345 models, those including either land cover or land-elevation as explanatory variables produced
346 consistently high R^2 values for both F_{ST} (≥ 0.874) and D_{EST} (≥ 0.660). The effects of
347 geographical distance and elevation varied across all models. Only once was there a
348 significant effect of the parameter elevation (model 7 for D_{EST}), and although geographical
349 distance was significant in all models for D_{EST} , (including the top two models) for F_{ST}
350 geographical distance was significant in only two of the nine models. This may be explained
351 by the different properties of the response variables (i.e. F_{ST} is based on allele frequencies
352 whereas D_{EST} is based on allelic diversity) and emphasizes the importance of comparing
353 measures of genetic distance. D_{EST} corrects for sampling bias and as the sample sizes varied
354 between sites, this may explain the differences between the two. The effect of geographical
355 distance on D_{EST} was consistent across all models, and suggests an isolation by distance
356 (IBD) effect. Meanwhile, land cover and land-elevation had a clear significant effect on all
357 models and across both measures of genetic distance. This suggests that while the combined

358 effect of both land cover and elevation resistances on genetic distance is significant,
359 ultimately, land cover resistance is the largest factor contributing to variation in population
360 genetic differentiation.

361

362 **Discussion**

363 *Fine-scale genetic structure of the black-capped chickadee*

364 Populations of black-capped chickadees in British Columbia are spatially structured from
365 restricted population connectivity as supported by individual based (Bayesian clustering
366 analyses), population based (F_{ST} , PCoA) and landscape based analyses (CIRCUITSCAPE and
367 MLPE modelling). Intensive sampling and additional microsatellite loci used in this study
368 resulted in a finer resolution of observed genetic structure. Here, nine genetic clusters were
369 inferred in comparison to four clusters in our previous study (Adams and Burg, 2015) and
370 population genetic differentiation was observed in all regions of British Columbia from the
371 north (NWBC) to the interior (CLU, NBC, FtStJ1, PG) and in the south (VAN and KEL,
372 BCR).

373 Despite their vagility and generalist behaviour, black-capped chickadees are a highly
374 sedentary species, showing strong aversion to crossing gaps in suitable habitat and this
375 characteristic appears to have a significant impact on dispersal across fragmented landscapes
376 (Desrochers and Hannon, 1997). Population genetic structure is an expected evolutionary
377 consequence of species inhabiting fragmented landscapes (Shafer *et al.*, 2010), especially in
378 species with restricted dispersal (Unfried *et al.*, 2012) like black-capped chickadees.
379 Spontaneous and highly irregular, large distance movements (i.e. irruptions) are observed in
380 juveniles (Weise and Meyer 1979), and occasionally in adults (Brewer *et al.*, 2000), and adults
381 will sometimes move down from high altitude localities in response to severe weather

382 conditions or food availability (Campbell *et al.*, 1997). However, black-capped chickadees
383 rarely disperse long distances; although a maximum dispersal of 2000 km was recorded for
384 one bird in a recapture study on 1500 individuals; less than 2% of birds dispersed more than
385 50 km from banding locations, and over 90% remained in the location they were initially
386 banded (Brewer *et al.*, 2000). Distances between adjacent populations in this study are within
387 the potential dispersal range, yet genetic differentiation was observed between populations
388 separated by both small (e.g. ~30 km between FtStJ1 and FtStJ2) and large (e.g. ~390 km
389 between PG and HAZ) distances (Figure 1). The observed patterns suggest that at smaller
390 geographical distances, other factors such as habitat heterogeneity and fragmentation resulting
391 from both natural and anthropogenic causes may be influencing dispersal and gene flow.

392

393 *Effects of landscape features on genetic differentiation*

394 A landscape genetic approach revealed the complexity of black-capped chickadee population
395 structuring from just two spatial datasets (elevation and land cover), which highlights the
396 importance of incorporating landscape level data into studies of gene flow in addition to using
397 traditional measures of IBD. Despite the relatively weak resolution of model based analyses,
398 both land cover (suitable forest cover) and elevation (low- mid elevation valleys) appear to be
399 important factors in explaining the observed patterns of genetic differentiation in black-
400 capped chickadees. The models that included land cover combined with elevation (land-
401 elevation) best explained genetic differentiation for F_{ST} and D_{EST} in two separate analyses,
402 but it is likely that land cover is the most influential factor (Table 4). As forest generalists,
403 dispersal for black-capped chickadees is largely dependent upon the availability of woodland
404 corridors (Bélisle and Desrochers 2002, Desrochers and Bélisle 2007). For example,
405 differences in forest cover can be observed between genetically differentiated populations in

406 Fort St. James (FtStJ1 and FtStJ2). Timber harvesting of the abundant lodgepole pine (*Pinus*
407 *contorta*) significantly reduces the amount of suitable forest in the south (FtStJ2) in
408 comparison to the north (FtStJ1) where the forest is managed and protected from logging
409 (Fondahl and Atkinson, 2007).

410 Populations were sampled on either side of a distinct mountain (Pope Mountain;
411 approximately 1400 m elevation) and large water body (Stuart Lake) which may act as
412 connectivity barriers. Elevation may therefore be a significant factor, as black-capped
413 chickadees are often associated with low-elevation riparian corridors in British Columbia, and
414 tend to be replaced ecologically at higher elevations by mountain chickadees (*Poecile*
415 *gambeli*) (Foote *et al.*, 2010). Low resistance dispersal routes also corresponded to areas of
416 low elevation (i.e. within the central plateau and to the south; Figure 3). Black-capped
417 chickadees frequently breed between 270 m and 1500 m elevation with the highest elevation
418 recorded at 2300 m in British Columbia (Campbell *et al.*, 1997). As black-capped chickadees
419 are forest dependent and found at lower elevations, it is not surprising that the lack of forest
420 cover and high elevations would impede gene flow. The same two landscape features are
421 important in facilitating black bear (*Ursus americanus*) dispersal in northern Idaho (Cushman
422 *et al.*, 2006).

423 Differences in land cover and elevation may reflect multiple biogeoclimatic zones
424 across the region; characterised by variation in climate, topography and vegetation. As our
425 populations are distributed across a number of these zones, it is possible that habitat
426 discontinuity is playing a bigger role in genetic differentiation, than physical geographical
427 barriers. For example, genetic differentiation in the north (NWBC) could be explained by
428 local environmental conditions. NWBC is situated within the boreal-black and white spruce
429 biogeoclimatic zone, characterised by long, extremely cold winters and short, warm summers,

430 and is isolated from other sampling sites by the Skeena and Omineca Mountains. To the south
431 of NWBC, there is a sharp transition from boreal-black and white spruce to Engelmann
432 spruce-subalpine fir to interior cedar-hemlock (Parish, 1995). The Engelmann spruce-
433 subalpine fir zone occupies the highest forested elevations in British Columbia. Our
434 landscape analyses revealed high pairwise resistance values (results not shown) between
435 NWBC and nearby populations for both elevation and land cover, suggesting limited
436 dispersal. This is also evident from both CIRCUITSCAPE (Figure 3), where there are little to
437 no connections between NWBC and nearby populations, and the effect of IBD on pairwise
438 D_{EST} values (Table 4b). Our resistance map of elevation (Supplementary Figure S3a)
439 supports isolation of NWBC. Therefore high variability in habitat and climatic conditions
440 combined with high elevations and large geographic distances may explain the genetic
441 differentiation of this population, as when gene flow is low, isolated populations may adapt to
442 local environmental conditions as a result of divergent selection pressures (Cheviron and
443 Brumfield, 2009). However, it is important to note that many neighbouring populations to
444 NWBC have not been sampled and so these observations could be a function of sampling
445 regime rather than specific landscape effects. To confirm these speculations, more robust
446 sampling in and around this area is necessary.

447 Genetic clustering of KEL and VAN was supported by high, yet non-significant
448 pairwise F_{ST} (0.316). Black-capped chickadee subspecies delimitations by size and
449 colouration might explain this grouping; VAN birds are grouped within the Oregon subspecies
450 (*P. a. occidentalis*); KEL birds within the Columbian subspecies (*P. a. fortuitus*) and all other
451 populations in this study within the larger-sized long-tailed subspecies (*P. a. septentrionalis*)
452 (Smith, 1991). While we expected to see reduced gene flow between KEL and VAN because
453 of the presence of two prominent north-south mountain ranges bisecting the two sampling

454 sites, there were inconsistencies among analyses (i.e. differentiation was indicated by F_{ST} and
455 PCoA analyses, but not by Bayesian clustering analyses). It is possible that low valleys
456 within the Coastal Range act as important corridors to dispersal between these two
457 populations. The genetic status of KEL and VAN, however, will require validation with
458 additional sampling.

459

460 *Dispersal in fragmented landscapes*

461 Loss of genetic diversity from habitat loss can impede a species' ability to adapt to changes in
462 their environment, and lead to reductions in reproductive fitness and population size
463 (Frankham, 1995; Haag *et al.*, 2010; Woltmann *et al.*, 2012; Finger *et al.*, 2014). As such, loss
464 of forests within low- to mid-elevation areas from both natural and anthropogenic processes
465 could have a significant impact on chickadee dispersal, and thus on the health of chickadee
466 populations. One reason for reduced dispersal in fragmented habitats is predation risk. Both
467 St Clair *et al.* (1998) and Desrochers and Hannan (1997) found that black-capped chickadees
468 are less willing to cross gaps of > 50 m of unsuitable habitat. In areas of central British
469 Columbia where logging and other activities have fragmented chickadee habitat, dispersal
470 would be restricted. The size and abundance of cut-blocks from forestry activities may be
471 restricting dispersal; however, explicit testing at an even smaller spatial scale is required.
472 Unexpectedly, our resistance map (Figure 3) displayed a large area in the central plateau
473 (between FrL and CLU) where movement is impeded. This area corresponds to an area of
474 increased agriculture which could explain differentiation of CLU in GENELAND analyses as
475 well as lower observed allelic diversity and observed heterozygosities (FF, FrL and FtStJ2;
476 Tables 1 and S3).

477 Natural contributors to habitat fragmentation may also explain patterns of genetic
478 structure observed here. Bark beetle outbreaks have been observed in western Canada since
479 the 1900s (Swaine, 1918). Current outbreaks are spreading quickly with warmer/milder
480 winters facilitating their expansion across western Canada. The mountain pine beetle
481 outbreak has destroyed huge portions of mature pine forests throughout British Columbia,
482 particularly in the central plateau region within elevations of 800 and 1400 m (Safranyik and
483 Wilson, 2006). Habitat loss could be leading to high levels of population isolation here,
484 particularly in low-mid elevation forested valleys which serve as dispersal corridors. In fact, a
485 number of populations within this region are showing signs of reduced genetic diversity,
486 particularly the PG population ($H_o = 0.594$, $H_e = 0.669$; Table 1), suggesting that some
487 populations may be experiencing a bottleneck as a result of restricted gene flow. Thus,
488 despite being common, widely distributed and of little conservation concern (IUCN Red List),
489 isolated chickadee populations may be undergoing microevolutionary processes which may
490 eventually lead to local adaptation.

491

492 **Conclusions**

493 Weak population genetic differentiation is expected for common and widespread species with
494 the ability to disperse among habitat patches (i.e. bird flight), but our findings suggest that
495 variation and/or changes in the environment can impact genetic differentiation in mobile
496 species, resulting in microgeographic population structuring.

497 Dispersal and gene flow among black-capped chickadee populations appear to be
498 affected by variation in landscape topography and forest cover; features critical to chickadee
499 survival and reproductive success. Climatic differences among sampling sites may also create
500 differential selective pressures. The importance of including landscape features when

501 assessing connectivity and population differentiation is particularly relevant when identifying
502 vulnerable populations and management units, as over time isolated populations may diverge
503 through local adaptation or inbreeding. In the face of climate change, biogeographic zones
504 will change and forest tree species are under threat of shifting and narrowing distributions
505 (Hebda, 1997; Hamann and Wang, 2006; Wang *et al.*, 2012) which could in turn, have an
506 impact on black-capped chickadee populations. Changes in precipitation and winter
507 temperature have already driven shifts in the geographic patterns of abundance of bird
508 populations in western North America (Illán *et al.*, 2014).

509 Overall, when assessing patterns of genetic differentiation of populations, a smaller
510 sampling scale and the inclusion of more loci can provide additional patterns of genetic
511 structure. More importantly, incorporating both landscape features and environmental
512 variables when explaining patterns can significantly improve our understanding of how
513 species evolve in response to changes in their environment.

728 **Table 4.** Results of maximum-likelihood population effects (MLPE) model selection after accounting for non-independence of pairwise
729 distance observations. For all models, pairwise F_{ST} (a) and D_{EST} (b) values were the response variable. Models are ranked based on
730 marginal R^2 value (high to low) with the best fitting model having the highest R^2 value. For each explanatory variable included in the
731 model, values ($\times 10^{-4}$) are presented as regression slopes \pm 95% confidence interval. Values in bold indicate significant parameter estimates
732 (i.e. 95% confidence intervals which do not overlap zero). Explanatory variables not included in the model are indicated by ‘--’.

2 **Figure 1.** Sampling locations of the black-capped chickadee (*Poecile atricapillus*) in British
3 Columbia (See Table 1 for abbreviations) with inferred clusters from GENELAND ($K = 9$)
4 denoted by the patterned circles [\(and colours in the online version\)](#). The nine genetic clusters are
5 1) NWBC, 2) NBC, 3) FtStJ1, 4) PG, 5) CLU, 6) HAZ, HOU, FF, FrL and FtStJ2, 7) BCR, 8)
6 VAN and KEL, and 9) SAB1 and SAB2.

7

8 **Figure 2.** Principal coordinate analysis conducted in GenAlEx based on pairwise D_{EST} values for
9 (a) all 15 populations (coordinates 1 and 2 explained 50.59% and 17.04% of the variation
10 respectively) and (b) after removal of populations KEL and VAN (coordinates 1 and 2 explained
11 31.05% and 19.93% of the variation respectively).

12

13 **Figure 3.** Map showing the resistance grid output from CIRCUITSCAPE analyses for the
14 resistance surface of land cover and elevation combined (land-elevation) as this variable best
15 explained genetic differentiation in other analyses. A close up of the central plateau region is
16 included (bottom).

17

18 **Table 1.** Sampling location information including site abbreviation (Abbrev.), geographical
19 location (latitude (Lat) and longitude (Long)) and sample size (N). Microsatellite summary
20 statistics for each population and all loci including: observed (H_o) and expected (H_e)
21 heterozygosities, number of private alleles (PA) and allelic richness (AR).

22

23 **Table 2.** Landscape models and corresponding resistance values assigned to each cover type or
24 range in CIRCUITSCAPE analyses. Model hypotheses are also provided.

25

26 **Table 3.** Pairwise F_{ST} values (below diagonal) and harmonic mean estimates of D_{EST} (above
27 diagonal) for 15 black-capped chickadee populations based on 14 microsatellite loci. Bold
28 values indicate significance after corrections for multiple tests.

29

30 **Table 4.** Results of maximum-likelihood population effects (MLPE) model selection after
31 accounting for non-independence of pairwise distance observations. For all models, pairwise
32 F_{ST} (a) and D_{EST} (b) values were the response variable. Models are ranked based on marginal R^2
33 value (high to low) with the best fitting model having the highest R^2 value. For each explanatory
34 variable included in the model, values ($\times 10^{-4}$) are presented as regression slopes \pm 95%
35 confidence interval. Values in bold indicate significant parameter estimates (i.e. 95% confidence
36 intervals which do not overlap zero). Explanatory variables not included in the model are
37 indicated by '--'.

38

39 **Supplementary Information**

40 **Figure S1.** (a) A hierarchical STRUCTURE analysis inferred six genetic groups with additional
41 substructuring found for FtStJ1 and SAB1, as illustrated in the histograms (right). Each vertical
42 line represents one individual and the colour(s) of each line represents the proportion of
43 assignment of that individual to each genetic group. Inferred genetic groupings (coloured pie
44 charts) were overlaid onto a map for better visualisation (left). Overall population assignment

45 was verified by (b) log likelihood plots ($\text{LnPr}(X|K)$) and (c) delta K . Runs involving only two
46 populations could not be plotted.

47

48 **Figure S21.** GENELAND output including the modal number of clusters ($K = 9$), map of
49 population membership, and map boundaries for each of the nine clusters inferred.

50

51 **Figure S32.** Maps showing the resistance grid output from CIRCUITSCAPE analyses for the
52 resistance surfaces (a) elevation and (b) land cover.

53

54 **Table S1.** Details of black-capped chickadee sampled. Samples in grey were removed from
55 analyses. Sources include Burg lab (wild), and University of Northern British Columbia
56 (UNBC).

57

58 **Table S2.** Repeat type (if known), primer sequence, allele size range (bp), number of alleles (N_a)
59 and MgCl_2 concentration for each microsatellite locus used to genotype black-capped chickadee
60 individuals. * indicates new primer designed during this study.

61

62 **Table S3.** Expected (H_e) and observed (H_o) heterozygosities, total number of alleles (N_a) for 15
63 populations of black-capped chickadees at 14 microsatellite loci. Summaries are provided for
64 across loci and across populations. Bold values indicate deviations from HWE. See Table 1 for
65 sampling site abbreviations.

66

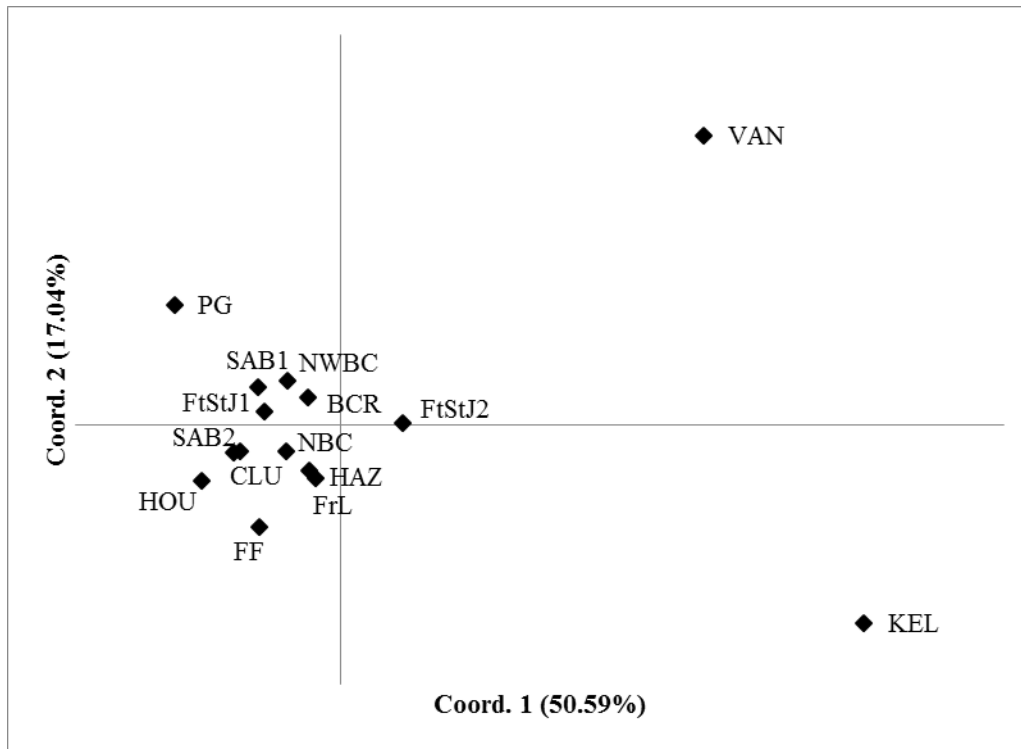

67 **Tables S4.** A comparison of the summary statistics after the removal of feather sampled
68 populations KEL and VAN and underrepresented microsatellite loci. These include a) mean
69 observed and expected heterozygosities across populations and b) loci as well as c) pairwise FST
70 values.

71

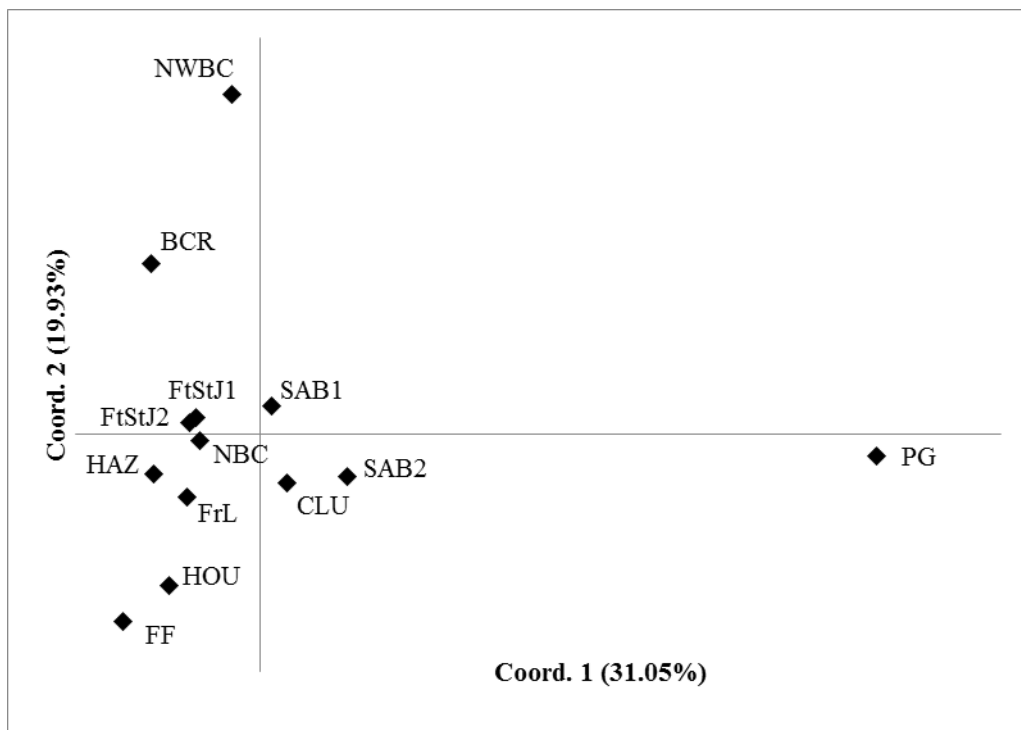

72 **Table S54.** Pairwise F'_{ST} values for 15 black-capped chickadee populations based on 14
73 microsatellite loci with significant values in bold ($P \leq 0.05$).
