**Abstract** – We examine the characteristics and functionality of conjugated polymer thin-films, based on blends of poly(9,9-dioctylfluorene-2,7-diyl-co-bis-N,NN'-(4-butylphenyl)-bis-N,N'-phenyl-1,4-phenylenediamine) (PFB) and poly(9,9-dioctylfluorene-2,7-diyl-co-benzothiadiazole)(F8BT), using a spray-coating deposition technique suitable for large areas. The morphological properties of these blend films are studied in detail by Atomic Force Microscopy (AFM) methods, showing that favourable results, in terms of layer deposition rate and uniformity, can be achieved using a 5:1 blend of o-dichlorobenzene and chlorobenzene as the solvent medium. A photoluminescence quenching efficiency of above 80% is also observed in such blend films. As a feasibility study, prototypical photovoltaic devices exhibit open circuit voltages of up to 1.0V under testing, and solar power conversion efficiencies in the 0.1-1% order of magnitude; metrics which are comparable with those reported for spin-coated cells of the same active blend and device architecture.

**Keywords** – Polymer blends, Polymer films, Conjugated Polymers, Deposition methods, Structures

## INTRODUCTION

1  
2 Large-area mass production techniques for organic optoelectronics, such as solar  
3 photovoltaic cells and LEDs, still represent a significant scientific and engineering challenge.  
4 In most cases, polymer electronic devices are laminar, which means that the molecules are  
5 printed or otherwise applied as thin films on foils or surfaces; spin-coating is perhaps the  
6 easiest and best studied route to producing efficient organic solar cells at the present [1]. This  
7 opens a wide field of applications, such as displays [2], electronic paper [3] or photovoltaic  
8 systems [4]. However, because of its different character, new manufacturing processes have  
9 to be developed, though techniques originally invented for printing or painting can be  
10 advanced. A current research area is, for example, the use of screen printing in order to  
11 produce photovoltaic devices [5].  
12  
13  
14  
15  
16

17 Here, we explore spray-coating via conventional airbrush equipment as a possible  
18 production technology for bulk-heterojunction organic photovoltaic (OPV) cells. Further to  
19 recent reports on Fullerene-based cells by Susanna *et al.*, Lidzey *et al.* and others [6], we  
20 study all-polymer (polymer-polymer) OPVs. In particular, the influence of key experimental  
21 parameters on layer deposition rate and uniformity, the detailed thin-film morphology  
22 (characterizing the roughness of films, the nature of the “coffee-stain” structures, the nature  
23 of any micron-scale phase separation), and the photophysical properties of the blend system  
24 (e.g. photoluminescence quenching). Furthermore, the steps to produce prototypical  
25 photovoltaic devices using spray-coating are described and the devices are characterized and  
26 compared.  
27  
28  
29  
30  
31

32 The morphological properties of these F8BT/PFB blend films are studied in detail by  
33 Atomic Force Microscopy (AFM), showing that favourable results, in terms of layer  
34 deposition rate and uniformity, can be achieved using a 5:1 blend of o-dichlorobenzene and  
35 chlorobenzene as the solvent medium. A photoluminescence quenching efficiency of above  
36 80% is also observed in such blend films. The resulting devices exhibit open circuit voltages  
37 of up to 1.0 V under testing, and solar power conversion efficiencies in the range of 0.1-1%;  
38 metrics which are comparable with those reported for spin-coated OPVs of the same active  
39 layer and device architecture [7]. Importantly, the spray-coating methods described here are  
40 highly scalable in nature, in a way that techniques such as spin-coating and vacuum  
41 deposition are not; hence, offering a genuinely different engineering paradigm.

## EXPERIMENTAL

### Spray coating of polymer blends

49  
50  
51  
52  
53  
54 When prehistoric man invented the first airbrush by using reed or hollowed bones for their  
55 cave paintings, they already realized the capability of uniform and large-area colour layers in  
56 comparison to finger or brush paintings. Although this technology has been developed a lot  
57 since those ancient times, the basic principle is still the same; air with a certain pressure is  
58  
59  
60  
61  
62  
63  
64  
65

1 used to nebulize paint and accelerates the droplets towards a surface. The paint itself can  
2 basically be any liquid and therefore also solutions of dissolved polymers used for organic  
3 optoelectronics.  
4

5 For the spray-coating experiments a double-action, siphon-feed airbrush gun type 128  
6 produced by Wiltec was used. The airbrush has a working pressure range from 1 to 3.4 bar  
7 and a nozzle diameter of 0.35 mm. Double-action refers to the feature that a single lever is  
8 used to control both air pressure and paint flow rate. Furthermore, the airbrush is siphon-feed,  
9 which means that the solution is drawn by the air pressure from a cup underneath the gun.  
10  
11

12 Following on from literature reports of suitable solvents [7,8], o-Dichlorobenzene  
13 (DCB), chlorobenzene (CB) and toluene (all from Sigma-Aldrich) are used for this work. All  
14 parts of the airbrush are known to be resistant against these solvents. The conjugated  
15 polymers used in the preparation of photovoltaic blends, namely poly(9,9-dioctylfluorene-  
16 2,7-diyl-co-bis-N,NN'-(4-butylphenyl)-bis-N,N'-phenyl-1,4 phenylene-diamine) (PFB) and  
17 poly(9,9-dioctylfluorene-2,7-diyl-cobenzothiadiazole) (F8BT) were obtained from  
18 Cambridge Display Technology Ltd,<sup>1</sup> and are illustrated in Figure 1.

21  
22

## 23 **Working Principle**

24 A schematic view of the airbrush and spray-coating set-up is depicted in Figure 1. The basic  
25 working principles of an airbrush relies both on Bernoulli's principle, which states that an  
26 increase in the speed of a gas or fluid causes a decrease in pressure, and the nebulization of  
27 liquids by an increase in surface energy. Significant for the size of the droplets produced by  
28 nebulization is the mass flow ratio between the pressurized gas and the solution passing the  
29 mixing point. A higher ratio leads to smaller droplets; this can be regulated via a lever on the  
30 gun. Compressed gas from a gas bottle or compressor enters the airbrush through a valve  
31 opened by pressing the lever. The gas passes a bottleneck, which leads to an increase in  
32 speed. The reduction in air pressure caused by the propelled gas draws the solution out of the  
33 cup and to the mixing point, which is at the tip of the gun needle. At this point the  
34 nebulization of the paint takes place, as the surface energy of the solvent increases, producing  
35 small droplets.  
36  
37  
38  
39  
40  
41  
42

43 Initially, the influences of the different parameters as the spraying process have to be  
44 studied, in order to allow production of regular, uniform, and reproducible films. Relevant  
45 parameters are the nozzle-substrate distance (see Fig.1), the gas pressure, the flow rate and  
46 the substrate temperature. In these reports, compressed nitrogen gas (N<sub>2</sub>) is used to supply the  
47 airbrush. Early experiments with liquid propellants showed that the air stream coming out of  
48 the airbrush also contains small amounts of the propellant, which can lead to an unwanted  
49 transfer of propellant onto the substrate.  
50  
51  
52  
53

## 54 **Distance and Pressure**

---

55  
56  
57 <sup>1</sup> These materials were characterized as follows- F8BT; Mn = 81k, Mp = 174k, polydispersity (PD) = 2.6,  
58 photoluminescence quantum-yield (PLQY) = 82%. PFB; Mn = 39k, Mp = 162k, PD = 4.5, PLQY = 27%.  
59

1 The effects of the nozzle-substrate distance ( $d$ ) and the air pressure ( $p$ ) are significantly  
2 interdependent. On the one hand, a minimum air pressure is necessary to allow the  
3 nebulization of the polymer solution. Using a higher pressure also decreases the size of the  
4 droplets, which leads to a more regular film. However, if the air pressure is too high, the  
5 droplets will be blown away once they hit the substrate, leading to a non-contiguous  
6 “splatter” pattern. A greater nozzle-substrate distance prevents this, but increases the area  
7 covered by the airbrush and will therefore lead to a higher wastage of material. Furthermore,  
8 a short distance leads to a wet, irregular film, whereas a too high distance leads to a dry,  
9 dusty film, because the solvent droplets evaporate on their way to the substrate. By numerous  
10 trial runs, an ideal distance of  $d = 17$  cm with an  $N_2$  pressure of  $p = 1.4$  bar was empirically  
11 determined.  
12  
13  
14  
15

### 16 **Flow rate and Film Formation**

17  
18 In order to increase the reproducibility of the sprayed films, the air pressure was regulated  
19 directly at the gas bottle, so that the airbrush lever is only used to adjust the solvent rate. The  
20 actual flow rates were typically 10s of microlitres per second using a gas pressure of  $p = 1.4$   
21 bar, with a correlation between the viscosity of a solvent (see Table 1) and the flow rate. A  
22 relatively volatile solvent such as toluene facilitates suction and the jet formation during the  
23 spraying process and leads to a higher flow rate. On the other hand, a viscous solvent like  
24 DCB leads to a lower flow rate. By adding a less viscous component (i.e. CB), the flow rate  
25 may be increased again.  
26  
27  
28  
29  
30

31 When selecting a suitable flow rate for spray-coating, it has to be considered that a  
32 higher flow rate reduces the required spray duration, but also increases the droplet sizes,  
33 which leads to a more irregular film. In order to solve this problem, the process of film  
34 formation on the substrate has to be first considered. As soon as a droplet hits the substrate,  
35 the solvent evaporates and leaves the dissolved polymer material behind. The evaporation  
36 process of a droplet is difficult to describe, depending on many parameters, but it is  
37 essentially based on equilibrium between the liquid phase of the droplet itself and the  
38 surrounding vapor phase. A good way to therefore control the drying time is the temperature,  
39 since higher temperatures accelerate the evaporation process. The minimum temperature  
40 required for a film consisting of single and independent droplets depends on the flow rate and  
41 the boiling point of the solvent (see Table 1). In a test experiment, the substrate was heated  
42 on a thermostat-controlled hot plate and the minimum temperature necessary for an  
43 immediately dry substrate after a spray duration of 10 seconds was determined (see Table 1).  
44 Again, toluene with the lowest boiling point requires the lowest temperature, and DCB with  
45 the highest boiling point, the highest temperature. By adding a fraction of CB the minimum  
46 temperature decreases slightly.  
47  
48  
49  
50  
51  
52  
53

### 54 **Film thickness**

55  
56 The thickness of the resulting thin-film is dependent on the solvent, the polymer  
57 concentration and the spray duration. To rationalize the potential number of experimental  
58  
59  
60  
61  
62  
63  
64  
65

1 parameters, the polymer blend has been fixed to a 1:1 mass ratio of PFB:F8BT and an overall  
2 polymer concentration of 5 mg ml<sup>-1</sup>, hence in the approximate range used in refs 7 and 8. The  
3 hot plate was set to the corresponding substrate temperatures shown in table 1. In order to  
4 comply with the standardizations in the previous section, the substrates were sprayed on in  
5 intervals of 10 seconds, and after each interval the substrates were dried for 30 seconds. We  
6 observe an almost proportional relationship between spray duration and layer thickness, as  
7 measured using absorbance spectroscopy and then by comparison with extinction co-  
8 efficients from the literature [9], showing that new layers are actually sprayed on top of  
9 previous layers instead of only dissolving them. No significant effects of de-wetting of the  
10 deposited layers were observed. Table 1 shows the resulting film thickness deposition rates  
11 for the solvent media used in this study.  
12  
13  
14  
15

16 Importantly, UV-vis absorption characterisation of these films indicates that the  
17 desired 1:1 ratio of the blend components is retained in the coating process (see Fig. 1d).  
18 Indeed, the extinction coefficients at around 400 and 470 nm, associated with PFB and F8BT  
19 respectively, are matched for all the thicknesses studied.  
20  
21

22 The photomicrographs of spray-coated films in Figure 2 show similar structural  
23 characteristics for each of the different solvent media used; films made of dried droplets with  
24 typical sizes of 10s of microns. Based on the size of these “coffee stain” structures and the  
25 rapid evaporation of the drops upon impact, we can estimate droplet sizes of 10-25 µm with  
26 DCB:CB as the solvent medium and 20-50 µm with toluene. This would be consistent with a  
27 so-called *fine atomisation* regime from comparable literature reports involving direct Phase  
28 Doppler measurements.[10] For all solvents, the overlap of several droplets and almost no  
29 combining of droplets into larger ones is clearly visible. A more detailed analysis, using AFM  
30 measurements, is reported in the *Results* section.  
31  
32  
33  
34  
35

### 36 **Photovoltaic device preparation**

37 It had been found that thick layers with little loss of material and moderate substrate  
38 temperatures can be achieved using a 5:1 mixture by volume of DCB and CB, hence this  
39 solvent medium was use in the production of prototypical solar cells (see Figure 1c), with all  
40 other spraying parameters maintained as previously described.  
41  
42  
43  
44

45 The quartz glass substrates were pre-coated with an ITO layer (from Psiotec). The  
46 PEDOT:PSS layer is deposited via spin-coating; for this, PEDOT:PSS (Sigma-Aldrich) is  
47 diluted 1:2 in deionized water. 25 µl of solution is applied onto the substrate, before spin-  
48 coating for 50 seconds at around 5,500 rpm. Afterwards the PEDOT:PSS layer is annealed  
49 and baked under inert nitrogen flow at 230°C for 30 minutes. Because of the hygroscopic  
50 character of PEDOT:PSS, the F8BT:PSS active layer was then deposited by spraying within  
51 an hour. The Aluminum electrode is thermally evaporated using an Edwards E306  
52 evaporator, evacuated to a pressure of less than 2 x 10<sup>-5</sup> mBar. Devices are then immediately  
53 legged, using standard metal cramps, in preparation for electrical testing. Whilst the working  
54 area of these devices was limited to 0.64 cm<sup>2</sup> by the area of the ITO substrates used, it should

be noted that we were readily able to evenly coat much larger substrate areas of up to 10s of cm<sup>2</sup> with the sprayed active layer.

The output characteristics of the produced solar cells were examined within a home-made “dark box”. The cells were mounted on a sample holder inside the box. The light from a 50 Watt (max) halogen lamp outside the box, powered by a regulated Kenwood PD35-10 power supply, was shone through a close-able shutter onto the cell. The distance between light source and sample holder was fixed at 10 cm, and the measured light flux onto the device was 1,600 lux, at a measured colour temperature of ~3,000 K. The entire area of the devices (as defined by the electrode overlap area) was uniformly illuminated. The cells were connected to a Keithley 6430 sub-femtoamp remote source meter via a remote pre-amplifier, in order to record the I-V characteristics of devices.

## RESULTS

### Polymer Blend Morphology

Atomic force micrographs (AFM) of 1:1 F8BT/PFB films, as spray-coated from various solvent media (DCB, toluene, and DCB:CB 5:1), are shown in Figure 2. These measurements confirm that films are made of dried droplets with typical sizes of 10-50 μm. When projected in a 3D relief view, the AFM images show “coffee-stain” structures with walls and flat centres, as shown in Figure 3. In all three cases, the flat centres show a good flatness uniformity; typically with height variation of only a few nm, as shown in the line height-profiles. However, the coffee-stain walls give more pronounced height variation. In the blends sprayed from DCB/DCB:CB the walls may be up to 10 microns wide and 100 nm high; for toluene, walls appear less pronounced with widths of a few microns and heights of 20-40 nm. Commensurately, it can be seen from Table 2 that the films sprayed from toluene have a rather lower roughness, as analyzed over a representative 40 x 40 μm area. In all case, the film coverage appears to be complete, with few gaps between the droplets being in evidence.

These micrographs show no obvious large-scale phase separation of blend components, in a fashion which is similar with comparable spin-coated films using chlorinated solvents (e.g. chloroform), but in contrast to those spun from (e.g.) xylene [11]. Upon focusing the AFM measurements onto smaller (100 x 100 nm) areas, using specially designed low frequency tips for soft matter samples (ND-MDT, Scanwel Ltd), we observe some nanoscale structure. Figure 4 shows a micrograph taken on an area within a droplet centre, and indicates some evidence of directional structuring. This may be a phenomenon associated with the radial flow of material as droplets are deposited on the substrate and then spread outwards, as the solvent is rapidly removed. The effect such nano-structuring would have on the functioning of such a photovoltaic blend is unclear, and this issue merits future

1 investigation, possibly with the use of Kelvin Probe scanning microscopy, in order to resolve  
2 the different components of the polymer blend in terms of their electronic states [12].

### 3 **Photoluminescence Quenching**

4  
5  
6 In their pristine state, the polyfluorenes generally exhibit a high luminescence quantum yield  
7 efficiency, when photoexcited [13]. The fluorescence intensity can be decreased by  
8 quenching processes, for example by internal conversion or energy/charge transfer of the  
9 excited state to other molecules (quenchers). This is particularly interesting for photovoltaic  
10 devices, as such a quenching of the photoluminescence is indicative of the ionisation of  
11 electron-hole pairs at heterojunction interfaces; these carriers do not recombine if the charges  
12 are extracted from the device, and they therefore do not generally re-emit a photon. Hence,  
13 we expect that the photoluminescence of a solar cell decreases with an increasing charge  
14 separation efficiency; so we can thus calculate the photoluminescence quenching (PLQ)  
15 efficiency, which reveals how efficiently electron-hole pairs are separated and charge carriers  
16 are extracted from the devices without recombination. The PLQ can be simply defined by the  
17 ratio of dissociated electron-hole pairs to the number of photons absorbed by the material. In  
18 order to account for the other non-radiative pathways available to the photo-generated pairs  
19 (excitations), this measurement is then referenced to the emission from a pristine F8BT film of  
20 known quantum yield efficiency and absorption cross-section.

21  
22  
23  
24  
25  
26  
27  
28 The PLQ efficiencies of several spray-coated films, based on different solvents and  
29 spray durations, were examined. The devices were made of a 1:1 blend of PFB and F8BT  
30 with a polymer concentration of  $5 \text{ mg ml}^{-1}$  in either toluene, DCB or a 5:1 blend of DCB and  
31 CB. The solutions were sprayed on quartz glass substrates in 1, 2 or 3 intervals of 10 seconds  
32 duration, as before. A film made of F8BT only, with a concentration of  $2.5 \text{ mg ml}^{-1}$  in a 5:1  
33 DCB:CB blend, was used as reference. A standard experimental setup for measuring the  
34 PL/PLQ efficiency was used [14], with a 488 nm Argon ion laser source of a few mW used to  
35 excite the samples. Because the absorption of F8BT is much higher at a wavelength of 488  
36 nm than that of PFB, we can thus use the pristine F8BT-only film as our reference standard  
37 and treat PFB as the quenching agent.

38  
39  
40  
41  
42  
43 The PLQ efficiencies for blends sprayed from the 3 solvent media, for a range of  
44 optically inferred film thicknesses, are shown in Table 3. We expect differences in the degree  
45 of PL quenching using different solvents, because the blend micro-/nano-structures should  
46 depend on the film formation and the characteristics of the solvent; the length-scale of the  
47 phase separation between PFB and F8BT and its comparison to exciton diffusion lengths,  
48 being of particular importance to charge separation efficiency. However, we would have  
49 expected that the PLQ should not critically depend on the film thickness. The results in fact  
50 show some random variation with thickness, whereas the solvent medium seems less critical,  
51 suggesting no significant changes in the phase separation between PFB and F8BT. McNeill *et*  
52 *al.* [15], report a PLQ of 0.95 for spin-coated devices based on PFB and F8BT without  
53 annealing and a decrease of PLQ to 0.70 for devices annealed at  $160^\circ\text{C}$ . Considering that the  
54  
55  
56  
57  
58

1 spray-coated devices were produced at temperatures of up to 100°C, thus resembling an  
2 annealing step, the PL quenching of spin-coated and spray-coated devices is similar.

### 3 **Photovoltaic Cell Performance**

4  
5  
6 Typical I-V characteristics for prototypical photovoltaic cells are given for a range of  
7 active layer thicknesses in Figure 5. The measured open circuit voltages ( $V_{oc}$ ) for the  
8 produced devices are in the range of 0.5 to 1.0 V, showing a generalized trend of increasing  
9  $V_{oc}$  with increasing thickness, as inferred in Figure 5c. It is expected that  $V_{oc}$  will be  
10 influenced by the nature of the electrodes, but not usually by the layer thickness. In particular,  
11 there may be sensitivity to slight variations in the ambient conditions (temperature, relative  
12 humidity etc.) during the active-layer deposition.

13  
14  
15  
16 The short circuit current  $I_{sc}$  of devices are also displayed in Figure 5c, as functions of  
17 active layer thickness. The  $I_{sc}$  values can be normalized to a short circuit current density  $J_{sc}$   
18 by dividing by the size of the active area (in our case 64 mm<sup>2</sup>); this gives  $J_{sc}$  values in the  
19 range of 1 to 5  $\mu\text{A}/\text{cm}^2$ . In an idealized bulk heterojunction system [16],  $I_{sc}$  should increase  
20 with an increasing layer thickness, as the optical absorption and exciton generation rate rises.  
21 However,  $I_{sc}$  should decrease again for large thicknesses, because of the longer transport  
22 distances of charge carriers to the electrodes. In the present case, there is a general trend for  
23  $I_{sc}$  to increase quite sharply with decreasing thickness, down to the thinnest measured devices  
24 ( $\sim 50$  nm), which is likely indicative of relatively short carrier transport lengths within the  
25 active layer. Calculating the series resistance of cells by the usual method ( $V > V_{oc}$  regime)  
26 yields values in the range of 1 - 10  $\text{k}\Omega.\text{cm}^2$  (taking device area into account), and fill-factors  
27 (as usually defined, derived from figure 5b) are typically of order 0.3 to 0.4; both of these  
28 indicators imply a limit to the absolute power conversion efficiencies achievable with the  
29 present design and layer-deposition protocols.

30  
31  
32 To ascertain the performance of these prototypical OPVs, the power conversion  
33 efficiency  $\eta$ , which is defined as  $\eta = P_{\text{MaxPowerPoint}}/P_{\text{Incident Light}}$ , was calculated in each case.  
34 Correction is also made for the light source being of a lower colour temperature than the  
35 standard photopic function as provided by the International Commission on Illumination  
36 (CIE) [17]. The average value of  $\eta$ , over >10 samples, was 0.12%, with the highest measured  
37 value being 0.25%. We can make a comparison with the spin-coated devices of McNeill et  
38 al., where  $\eta$  values of around 1% have been previously reported in F8BT:PFB and 1.5-2% in  
39 alternative blend systems such as polythiophenes/poly(phenylene-vinylenes) [7,15]. It should  
40 be noted that these values are also limited by the non-ideal matching of the lamp spectrum to  
41 the F8BT/PFB action spectrum, which is predominantly in the blue/green end of the visible.

42  
43  
44 Without illumination, a photovoltaic cell should behave like a normal rectifying  
45 diode; enabling cells in reverse bias to operate as photodetectors, as long as the dark current  
46 is not too high [18]. However, film morphology has been previously shown to have an  
47 influence on the dark current behavior of organic solar cells. For example, Green *et al.* [8],

1 describe the negative effect of roughness and pinholes between the contacts on the dark  
2 current behavior, and an increase for smoother and annealed devices. For unstressed devices,  
3 measured in the dark-box as before, dark current densities are in the range of 100 nA/cm<sup>2</sup>.  
4 The measurements suggest a dependence of the dark current on the layer roughness, because  
5 spray-coated devices show higher reverse leakage currents than analogous spin-coated ones.  
6 Additionally, devices which were annealed after depositing the active layer for 10 minutes at  
7 180°C, usually exhibited a slightly reduced reverse leakage current.  
8  
9

10 A final issue to consider is the stability/longevity of devices in their present ambient  
11 conditions and un-encapsulated state. Current-voltage characteristics of the best-performing  
12 spray-coated OPVs were re-measured after a period of 7 days after production. Typically, a  
13 decrease in I<sub>sc</sub> and maximum power by factors of up to 5 were observed. Similar behavior  
14 was experienced by K. Kawano *et al.* [19], when they examined the degradation of MDMO-  
15 PPV: PCBM solar cells with and without PEDOT:PSS layer as a function of atmospheric  
16 conditions. They describe the water absorption of PEDOT:PSS due to its hygroscopic  
17 character, producing inhomogeneities and the formation of insulating patches in the planar  
18 devices.

## 26 DISCUSSION

27  
28 Whilst the performance metrics of the OPV devices reported here approach the same  
29 order of magnitude as that reported for spin-coated cells of the same active blend and device  
30 architecture, they are clearly significantly below that of many state-of-the-art organic solar  
31 cell exemplars from the literature [20]. It is anticipated that better control of the  
32 environmental factors of production and storage would give better, more stable devices than  
33 the prototypes described here. Also, the relatively low-cost and high-availability of the  
34 polyfluorenes make them attractive for this kind of exploratory work on developing spray-  
35 coated polymer blend films. Applying this knowledge towards the use of advanced low-  
36 bandgap materials would allow spray-coated OPVs with better solar spectral matching  
37 properties to be exploited.  
38  
39  
40  
41  
42  
43

44 An interesting comparison may also be drawn with recent reports of OPV cell  
45 fabrication using inkjet-based technologies [21]. Indeed, the typical characteristics of the final  
46 films, such as the size of deposited droplets and the levels of surface roughness, are  
47 somewhat comparable. Both of these technologies offer some advantages, as viable  
48 alternatives to spin-coating for optoelectronics applications [5]. Inkjet certainly offers a route  
49 to structures not accessible with spin coating, such as patterned grids or electrodes; whereas  
50 for very high material throughput (whilst still achieving reduced material loss) and large-area  
51 deposition, spray-coating is likely to be the more favorable of the two methods. Indeed, such  
52 pros-and-cons might also be considered to exist in comparison with other state of the art film  
53 forming methods for OPVs, such as roll-to-roll printing methods. [22]  
54  
55  
56  
57  
58  
59

1 As a future direction of this work, we are currently examining the possibilities of  
2 using the related “electro-spraying” method [23] for depositing OPV active layers. This is  
3 another reported method of deposition for thin films, which also enables the deposition of  
4 delicate and fragile molecules, in a precise and controllable fashion, in both atmosphere and  
5 vacuum. One could envisage multilayers (thickness-dependent compositions) of “small  
6 molecule” film-forming semiconductors; such as PCBM or oligomeric donors [24], with  
7 whole new regimes of polymer blend morphology are possible, as compared with spin-  
8 coating or Langmuir-Blodgett techniques. In both conventional spray-coated and  
9 electro-spraying, the very rapid solvent removal will allow compositional control, but with  
10 better ordered structures than the amorphous forms typical of traditional vacuum-sublimation  
11 materials used in organic electronics, such as the oligo-acenes [25].

## 18 CONCLUSIONS

19  
20  
21 A spray-coating method has been employed in the production of all-polymer (polyfluorene)  
22 blend thin-films. Detailed studies of the influence of key experimental parameters on layer  
23 deposition rate and uniformity, the detailed thin-film morphology (including AFM) studies  
24 characterizing the roughness of films, the nature of the “coffee-stain” structures, the nature of  
25 any micron-scale phase separation (or lack thereof), and the photophysical properties of the  
26 blend system (e.g. photoluminescence quenching), are reported. These characterizations of  
27 the deposited blend films show them to be of suitable characteristics for potential use in  
28 photovoltaic cells. As an important feasibility step, the resulting prototypical photovoltaic  
29 devices exhibit open circuit voltages of up to 1.0V under testing, and solar power conversion  
30 efficiencies in the 0.1-1% order of magnitude range; metrics which are comparable with key  
31 analogues reported using methods of spin-coating for the active layer deposition. In the light  
32 of this, and of other very recent reports, [26] we propose that such spray-coating methods  
33 hold great potential as an approach to the challenges presented by the scale-up and large area  
34 mass fabrication of OPVs.

44 within the quadrant defined by short-circuit current ( $I_{sc}$ ) and open-circuit voltage ( $V_{oc}$ ). (c)  
45 The variation of  $I_{sc}$  (circles) and  $V_{oc}$  (crosses) as a function of active-layer thickness. Linear  
46 trendlines are added as a visual aid.
