14   **Abstract**

15   This article presents the first attempt to date moraines in the Dinaric mountain karst using

16   cosmogenic ^{36}Cl surface exposure dating technique. Twenty samples were collected from moraine

17   boulders from two sets of the lowest and largest lateral moraines on the Velež (1965 m asl) and

18   Crvanj mountains (1920 m asl) in Bosnia and Herzegovina. The dated lateral-terminal moraine

19   complexes, spanning elevations from ~980 to 1350 m asl, are up to 2.7 km long and rise more than

20   100 m above the valley floor. The moraine boulders yielded ^{36}Cl ages spanning from Oldest Dryas for

21   Velež (14.9 ± 1.1 ka) to Younger Dryas for Crvanj (11.9 ± 0.9 ka), considering the average age of the

22   two oldest samples from each lateral moraine as the most representative time of moraine

23   emplacement. The dated moraines mark the largest extent of glaciers in both study areas, which

24   have been reconstructed to ~ 28 km^2 for Velež and ~24 km^2 for Crvanj, having a mean equilibrium

25   line altitude at 1388 m and 1541 m, respectively. Under modern precipitation values, which account

26   for ~2000 mm, the temperature depression between 8 and 10 °C is required to sustain the

27   palaeoglaciers with reconstructed equilibrium line altitudes. Glaciers of similar size with such low

28   equilibrium line altitudes during the Lateglacial have not been reported until now for the Balkan

29   Peninsula. It is very likely that the boulder ages reflect complex exhumation and denudation

30   histories, which at this point do not allow obtaining more precise moraine chronologies for the study

31   areas. Nevertheless, this article delivers new data on the extent and timing of Quaternary glaciations

32   in the Mediterranean mountains, where records of glacier fluctuations seem to be asynchronous

33   amongst different areas. It is clear that dating moraines with cosmogenic ^{36}Cl surface exposure

34   dating in carbonate lithologies in areas of high precipitation like the Dinaric karst, remains

35   challenging.

1. Introduction

The Dinaric Mountains is more than 650 km long mountain chain flanking the eastern Adriatic coast. It is characterised by a karst landscape with high-elevated plateaux, reaching the highest elevations in the central-southern belt (Čvrsnica – 2228 m asl (above sea level), Maglič - 2386 m asl, Durmitor – 2522 m asl, Prokletije - 2694 m asl). The highest parts of the Dinaric Mountains were glaciated during Pleistocene (Cvijić, 1899) and even today few small glacial remnants still exist in the Durmitor and Prokletije mountains (Gachev et al., 2016). Hence, this area is characterised by a combination of karst and glacial landscape (Telbisz et al., 2019; Žebre and Stepišnik, 2015).

Pioneer studies on past glaciations in the Dinaric Mountains were conducted at the end of the 19th century, focusing on the area of Montenegro and Bosnia and Herzegovina (e.g. Cvijić, 1899; Grund, 1902; Penck, 1900). Extensive monographs and scientific papers from that time hold detailed descriptions of glacial landforms and even reasonably precise geomorphological maps. In the 20th century the research on palaeoglaciations continued also in other Dinaric areas (e.g. Habič, 1968; Liedtke, 1962; Riđanović, 1966; Šifrer, 1959) with several interruptions owing to wars and political instabilities. These turbulent past events have left a great impact also on the recent state of knowledge on past glaciations in the Dinaric Mountains since majority of areas still remain undated (e.g. Krklec et al., 2015; Milivojević, 2007; Milivojević et al., 2008; Petrović, 2014) and without any detailed sedimentological and stratigraphic research. Nevertheless, it is not only the landmine contamination that prevents more detailed studies, but also dating glacial deposits in carbonate areas, with high precipitation gradients and hence important denudation rates (Levenson et al., 2017 and references therein), is still very challenging.

A number of techniques can be applied to date moraines and outwash deposits in carbonate environments, including U-series, luminescence, radiocarbon (^{14}C) and TCN (terrestrial cosmogenic nuclide) dating. U-series dating can be used to date secondary carbonates that are found cementing moraines and the practical range of this technique is ~350 ka (Hughes et al., 2013). The method relies

64   on several assumptions and criteria, where special care should be taken to ensure that samples are

65   from distinct crystal horizons and show no evidence of re-crystallisation and open-system behaviour

66   (Smart, 1991). Although the U-series method can provide only the age of the cement growth,

67   therefore lacking the precision needed to constrain the timing of moraine deposition, it was found to

68   be useful for bracketing moraines within certain glacial cycles in some of the Mediterranean

69   mountains (Hughes et al., 2011, 2010, 2006). Luminescence dating is often used to date outwash

70   sands and the upper age limit may extend up to 500 ka (Wallinga and Cunningham, 2015), but the

71   method is hardly applicable to carbonate environments owing to the lack of quartz and feldspars in

72   deposits (Krklec et al., 2015). Nevertheless, the method was successfully applied to some of the

73   carbonate-dominated landscapes in the Mediterranean, where smaller amounts of quartz were

74   present in outwash due to the limited exposures of non-carbonate bedrock in the glaciated

75   catchments (Bavec et al., 2004; Lewin et al., 1991). Although radiocarbon dating has a limited

76   chronological range (<50 ka) (Hughes et al., 2013), it has been shown to be a very robust method for

77   dating Last Glacial Maximum (LGM) moraines (e.g. Monegato et al., 2007) or other Late Pleistocene

78   glacial sequences even in limestone-dominated environments (e.g. Nieuwendam et al., 2016; Ruiz-

79   Fernández et al., 2016). However, in karstic terrains, this technique is commonly restricted either by

80   material availability in moraine matrix or by the hard-water error when applying the technique in

81   moraine-dammed lakes or bogs. Cosmogenic surface exposure dating with ^{36}Cl is an established

82   method for dating moraines (Dunai, 2010; Gosse and Phillips, 2001) and has been successfully

83   applied in carbonate environments elsewhere (e.g. Gromig et al., 2018; Pope et al., 2015; Sarıkaya et

84   al., 2014; Styllas et al., 2018). However, karst denudation rates limit the ^{36}Cl exposure dating

85   technique to be applied on carbonate lithologies that are exposed to extremely wet environmental

86   conditions, if they are older than ~40 ka (Hughes and Woodward, 2017).

87   Despite several methodological and physical obstacles such as landmines, it is important to obtain as

88   much data as possible on the glacial extent and chronology from the Dinaric Mountains and wider

89   Balkan area in order to better understand the temporally (a)synchronous maximum phase of

4

90   glaciation in the Mediterranean (Hughes and Woodward, 2017) and the past and present changes in

91   atmospheric circulation influencing the Mediterranean region. The coastal Dinaric Mountains receive

92   one of the highest precipitation amount in Europe today (Crkvice weather station - MAP (mean

93   annual precipitation) ~ 5000 mm) and this seemed to be true also for the cold stage climates since

94   according to the present state of knowledge one of the lowest equilibrium line altitudes (ELAs) in the

95   Mediterranean were located in this area, showing a strong west-east gradient associated with

96   westerlies (Hughes and Woodward, 2017). The Balkan area is also considered one of key areas for

97   assessing the environmental and population history of Europe since it has been argued that this

98   region served as a Lateglacial refugium for humans, animals and plants (Pilaar Birch and Vander

99   Linden, 2018).

100   Although geomorphological evidence for palaeoglaciations in some of the Bosnia and Herzegovina

101   Mountains has already been recognized in the 19th century (Cvijić, 1899), Bosnia and Herzegovina is

102   considered as one of the main black spots in the Dinaric Mountains from the glacial chronological

103   point of view, as there are no quantitative age data and detailed sedimentary analyses until today. In

104   this paper we focus on the glacial chronology of the Velež and Crvanj mountains. Velež Mountain was

105   recognized as glaciated for the first time by Grund (1902, 1910) in the early 20th century. In this very

106   exact and advanced study for his time, considering the available topographic maps and other field

107   instruments, Grund presented the geomorphological map of the northern side of Velež, including a

108   detailed description of glacial features. He also estimated the snow line for the north-facing

109   palaeoglaciers to be between 1350-1500 m asl. This area has been long time forgotten until 2015,

110   when the glaciokarst phenomena were studied by Žebre and Stepišnik (2015). On the contrary, the

111   Crvanj Mountain has never been studied before from a palaeoglaciological point of view. Therefore,

112   the aims of our research are (a) to present the geomorphological and sedimentological evidence for

113   glaciation on the Velež and Crvanj mountains, (b) to constrain the timing of the largest recognized

114   glacier extent on Velež and Crvanj by applying the cosmogenic ^{36}Cl surface exposure dating technique

115   for the first time in the Dinaric Mountains, (c) to reconstruct palaeoglacier dimensions and related

116   palaeo-ELAs, and (d) to critically evaluate a relevance of the obtained cosmogenic ages in the light of

117   regional geomorphological and climate context.

118

119   **2. Regional setting, geology and climate**

120   The Velež and Crvanj mountains (43° 15'–43° 30' N and 17° 55'–18° 20' E) are located in the central

121   Dinaric Mountains in southern Bosnia and Herzegovina between the Mostar basin to the west and

122   Nevesinjsko polje to the south (Figure 1). The central mountain crest of Velež reaching elevations

123   above 1700 m asl is approximately 12 km long and oriented in a NW-SE direction. The highest peak is

124   Botin with 1965 m asl. On the other hand, the Crvanj Mountain has a plateau shape top with the

125   highest elevations in its western part, where the peak of Zimomor reaches 1920 m asl.

126   The Velež Mountain is an overthrust of the Cretaceous shallow water carbonates over the Tertiary

127   and Cretaceous sedimentary rocks (Hrvatović, 2005). The north-facing slopes, where majority of the

128   research took place, are predominantly composed of Cretaceous limestone and dolostone. The

129   Crvanj Mountain exhibits very similar geological features. Central part of the mountain is an

130   overthrust of Triassic and Jurassic dolostones, with beds of limestone containing chert, overlying

131   Jurassic and Cretaceous limestone (OGK, 1981, OGK, 1970). Owing to the prevalence of carbonate

132   lithology, a well-developed karst aquifer functions within both areas. Subsurface drainage is oriented

133   towards springs at the Nevesinjsko polje and other deep-entrenched valleys around the mountain,

134   thus the vadose zone reaches depths of at least few hundred metres.

135   The study area is situated in a transition zone between the Mediterranean and continental climate,

136   having characteristics of a warm temperate climate, fully humid, with cool summers (Cfc) according

137   to the Köppen-Geiger climate classification (Kottek et al., 2006). Precipitation is well distributed

138   throughout the year owing to the moisture coming from the Adriatic Sea (west) and the effect of

139   orography. At Nevesinje (891 m asl), MAP over the period 1961-1990 was 1795 mm (Data courtesy

140   Federal Hydrometeorological Institute, Sarajevo), while MAP at higher elevations is likely to be

141   higher; it was estimated to be up to 2000 mm (Vojnogeografski institut, 1969). The mean annual air

142   temperature (MAAT) at Nevesinje is 8.6 °C with the warmest month being July (18 °C) and the coldest

143   January (-0.9 °C).

144

145   Figure 1: (a) Study area and the topography of Mediterranean region after the mountain belts from

146   Kapos et al. (2000) and (b) a close up of the southern Bosnia and Herzegovina. The study areas of the

147   Velež and Crvanj mountains are located between Mostar basin to the west and Nevesinjsko polje to

148   the south.

149

150   **3.   Methods**

151   3.1 Geomorphological mapping

152   Field geomorphological mapping was carried out between 2012 and 2015. Topographic maps in a

153   scale of 1:25.000 were used for mapping, while basic geological maps in a scale of 1:100.000 (OGK,

154   1981, OGK, 1970) were useful for giving a general support on the geological setting of the study area.

155   With the exception of the northwestern area of Velež and northern part of Crvanj that are situated

156   close or in the minefields (http://www.bhmac.org), the rest of the study area was examined in detail

157   although the north-facing slopes of Velež below 1400 m asl are densely forested and therefore not

158   easy to map. The interpretation of the spatially documented landforms on the field was supported by

159   the sedimentological description of some outcrops, commonly exposed as road cuts or abandoned

160   gravel pits. Standard field procedures (e.g. sedimentary structures, colour, clast size, distribution and

161   roundness) and lithofacies codes following Evans and Benn (2004) were used for sediment

162   description.

163   3.2 Cosmogenic nuclide dating

164   Cosmogenic [36]Cl surface exposure dating was used to infer the depositional ages of the moraines in

165   the Velež and Crvanj mountains. The length of time that the boulder has been exposed on the

166   moraine surfaces can be estimated by this method (Davis and Schaeffer, 1955; Dunai, 2010) via

167   cosmogenically produced isotopes such as [36]Cl, [10]Be and [26]Al. Here, we used the [36]Cl because all

168   lithologies, especially the carbonates, are suitable for the production mechanism of [36]Cl.

169   Dating with [36]Cl depends on the interactions between cosmic rays and nuclides in rocks. When rocks

170   are exposed at or near surface, cosmic ray particles, which are secondary fast neutrons, thermal

171   neutrons and negative slow muons start to bombard and interact with three main nuclides (^{40}Ca, ^{39}K

172   and ^{35}Cl) to cause formation of cosmogenic [36]Cl. Therefore, measured [36]Cl concentrations in rocks can

173   be used to quantify the time-length of boulder exposition (Gosse and Phillips, 2001; Owen et al.,

174   2001).

175   <u>3.2.1 Sample collection and chemical preparation</u>

176   We collected 20 samples for cosmogenic [36]Cl dating from the top of the boulders on the crest of the

177   moraines. The boulders were selected according to their positions on the crest, stability, size and

178   preservation indicators; such imbedded large enough boulders on moraine crests were preferred.

179   We concentrated on the largest moraines that were reasonably away from the minefields; hence

180   safe enough to accomplish the fieldwork. We sampled on both right and left lateral moraines,

181   targeting same number of samples from each lateral moraine. Only the largest glacial boulders with a

182   stable position on the moraine crests have been taken into account. A hammer and chisel were used

183   to take samples from upper few centimetres of the boulders and thicknesses of the samples were

184   recorded (Table 1). Shielding of surrounding topography was measured by inclinometer from the

185   horizon at each sample location (Gosse and Phillips, 2001). Sample locations were recorded by a

186   hand-held GPS. Elevations data are also based on the GPS measurements except for BU samples,

187   which are from topographic maps.

188   The rock samples were prepared at Istanbul Technical University (ITU) Kozmo-Lab

189   (http://www.kozmo-lab.itu.edu.tr/en) according to procedures described in Sarıkaya (2009). First,

190   samples were crushed and sieved to appropriate grain size (0.25-1 mm). Then they were leached

191   with deionized water and 10% HNO_3 to remove secondary carbonates, dust and organic particles.

192   Spiked (^{35}Cl enriched) samples were digested with excess amount of 2 M HNO3 in 500 ml HDPE

193   bottles (Sarıkaya et al., 2014; Schlagenhauf et al., 2010). ~10 ml of 0.1 M AgNO3 solution was added

194   before the digestion to precipitate AgCl. Later, isobar ^{36}S was removed from the solution by repeated

195   precipitation of $BaSO_4$ with addition of $Ba(NO_3)$ and re-acidifying with concentrated HNO_3. Final

196   precipitates of AgCl were sent to the ANSTO, Accelerated Mass Spectrometer (AMS) in Sydney,

197   Australia for isotope ratio measurements given in Supplementary Table S1.

198   Major element concentrations were determined with inductively coupled plasma emission

199   spectrometry (ICP-ES) and trace element concentrations with inductively coupled plasma mass

200   spectrometry (ICP-MS) at the Acme Lab (ActLabs Inc., Ontario Canada) to provide the total element

201   concentrations (Table 2). Total Cl was calculated by isotope dilution method (Desilets et al., 2006;

202   Ivy-Ochs et al., 2004) after AMS analysis (Table 2).

203   3.2.2 Determination of ^{36}Cl ages

204   The CRONUS Web Calculator version 2.0 (http://www.cronuscalculators.nmt.edu) (Marrero et al.,

205   2016a) was used to calculate sample ages. Cosmogenic ^{36}Cl production rates of Marrero et al.

206   (2016b) [56.3 ± 4.6 atoms ^{36}Cl (g Ca)-1 a-1 for Ca spallation, 153 ± 12 atoms ^{36}Cl (g K)-1 a-1 for K

207   spallation and 743 ± 179 fast neutrons (g air)-1 a-1] were used using the time-dependent Lifton-Sato-

208   Dunai scaling (also called "LSD" or "SF" scaling) (Lifton et al., 2014). We used 190 μ g-1 a-1 for slow

209   negative muon stopping rate at land surface at sea-level high-latitude (Heisinger et al., 2002). Lower

210   Ca spallation production rates suggested by Stone et al. (1996) or Schimmelpfennig et al. (2011) will

211   make our ages 7-10% older. Spallation and negative muon capture reactions are responsible for the

212   main production of ^{36}Cl (>95% for Mt. Velež samples and ~60% for Mt. Crvanj samples), with lesser

213 contributions from thermal neutron capture reactions by ^{35}Cl (5% for Mt. Velež samples and 40% for

214 Mt. Crvanj samples). The chemical data (Table 2) and all other essential information including the ^{36}Cl

215 concentrations and scaling factors to reproduce resultant ages is given in Table 3 and Supplementary

216 Table S1.

217 All surface exposure ages include corrections for thickness and topographic shielding. We reported

218 both zero-erosion and erosion corrected boulder ages (from 10 to 60 mm ka^{-1} of bedrock weathering

219 assumed) and preferred to use the 40 mm ka^{-1} erosion corrected age, because the study area is

220 located in one of the highest precipitation regions of Europe, and boulder surfaces show up to

221 several cm deep solution grooves. Snow correction factor for spallation reactions of 0.9539 was

222 applied to all samples based on snowpack of 25, 100, 100, 100, 50, 25 cm of snow on Nov, Dec, Jan,

223 Feb, Mar and Apr on top of boulders. Snow thicknesses were estimated based on meteorological

224 data from the Nevesinje weather station (Data courtesy Federal Hydrometeorological Institute,

225 Sarajevo).

226

227 Table 1: Sample locations, attributes and local corrections to production rates.

228

229 Table 2: Geochemical and isotopic analytical data.

230

231 3.3 <u>Glacier and climate reconstruction</u>

232 3.3.1   <u>Glacier geometry</u>

233 A digitized geomorphological map of glacial features together with 20 m digital elevation model was

234 used in the glacier geometry reconstruction. The glacier's extent was established using the field

235 geomorphological evidence such as trimlines and lateral-frontal moraines. Then, the reconstruction

236 was carried out by producing theoretical glacier surface profiles using the Profiler v.2 spreadsheet

237 developed by Benn and Hulton (2010). We have largely followed the procedure presented in Žebre

238   and Stepišnik (2014), which is based on similar principles as the newly developed semi-automated

239   GlaRe GIS tool (Pellitero et al., 2016). Software ArcGIS 10.3.1 and a predefined *Topo to Raster*

240   interpolation method was used for calculating the ice surface with 50 m contour intervals.

241   3.3.2   <u>Equilibrium Line Altitudes (ELA)</u>

242   The equilibrium line altitude (ELA) of the reconstructed palaeoglaciers was determined by applying

243   the area altitude balance-ratio method (AABR) (Osmaston, 2005). The accumulation-area ratio (AAR)

244   method, which is the most widely used approach for the palaeo-ELA reconstruction, is becoming

245   increasingly replaced by the AABR method, which is also more reliable, provided that the correct

246   balance ratio is applied (Rea, 2009). The principle of the AABR method is that the total annual

247   accumulation above the ELA exactly balances the total annual ablation below the ELA under

248   equilibrium conditions (Benn and Gemmell, 1997). The advantage of this method is that explicitly

249   accounts for both glacier hypsometry and mass balance gradients (Benn and Gemmell, 1997). The

250   method gives the best results for the clean glaciers (Benn and Lehmkuhl, 2000) where most of them

251   will have the balance ratio between 1.5 and 3.5 (Osmaston, 2005). A representative balance ratio for

252   maritime mid-latitude glaciers is 1.9 ± 0.81 (Rea, 2009), which we applied for calculating the ELA of

253   palaeoglaciers on the Velež and Crvanj mountains. A GIS tool developed by Pellitero et al. (2015) was

254   used to facilitate the ELA calculations of individual valley, cirque and outlet glaciers. The latter were

255   separated by subdividing the ice field into sectors of individual glacier entities (Cowton et al., 2009;

256   Hughes et al., 2010). The local ELA of an individual mountain is represented as a mean ELA of the

257   entire group of glaciers. The ELA of each glacier was also estimated with the AAR method using a

258   ratio of 0.6, which is believed to be representative of valley and cirque glaciers (Benn and Evans,

259   1998; Nesje and Dahl, 2000; Porter, 1977). This allowed crosschecking the ELA results calculated with

260   the AABR method.

261   3.3.3   <u>Temperature-melt simulations</u>

262 For a better understanding of the relationship between glaciers and climate as well as an additional

263 consideration of the age-dating results, we used a simple degree-day model (Brugger, 2006; Hughes,

264 2008), which calculates the amount of accumulation required to sustain glaciers. The inputs required

265 for the model are mean annual temperature range and mean annual temperature. The latter is

266 distributed over a sine curve to produce daily temperature means using the following equation

267 (Brugger, 2006):

268
$$T_d = A_y sin(2\pi d/\lambda - \phi) + T_a$$

269 where T_d is the mean daily air temperature, A_y is the amplitude of the yearly temperature (½ of the

270 annual temperature range), d the day of the year (1–365), λ is the period (365 days), ϕ is the phase

271 angle (taken as 1.93 radians to reflect the fact that January is the coolest month) and T_a is the mean

272 annual air temperature.

273 The annual accumulation required at the ELA to balance melting is equal to the sum of daily

274 snowmelt, using a degree-day factor (Hughes et al., 2010). In our study we used the mean degree-

275 day factor for snow of 4.1 mm day^{-1}°K^{-1}, which is representative of most glaciers and also in

276 accordance with values reported in the literature (e.g. Braithwaite, 2008; Braithwaite et al., 2006).

277 Snowmelt at the palaeo-ELAs on the Velež and Crvanj mountains was then reconstructed under

278 different temperature regimes, using the climate data from Nevesinje (891 m asl) for the period

279 1961-1990. Mean annual temperature at this station was depressed by 4-15 °C in 1 °C intervals and

280 then extrapolated to the mean palaeo-ELAs on Velež and Crvanj using the modern environmental

281 lapse rate of 0.65 °C/100 m. The model was run using two different mean annual temperature

282 ranges: the modern one (18.9 °C) and 150% of the modern range (28.35 °C). The latter reflects the

283 possibility that palaeoclimate might have been more continental, since the sea level in the Adriatic

284 basin was approximately 115 m lower at 20 ka, 100 m lower at 16 ka, and 60 m lower at 12 ka

285 (Lambeck et al., 2011). Nevertheless, the above-described procedure allowed obtaining a range of

286 temperature-accumulation predictions and better understanding of the palaeoclimate needed to

287 sustain glaciers in the study areas.

288

289 **4. Results**

290 4.1 <u>Glacial geomorphology</u>

291 4.1.1   <u>Velež Mountain</u>

292 The palaeoglacial landscape of the Velež Mountain (Figure 2a), with an emphasis on the glaciokarst

293 features, was previously mapped by Žebre and Stepišnik (2015). The south-facing slopes exhibit

294 minor glacier remodelling of the surface with only three cirques present below the highest peak

295 Botin (1965 m asl). The cirque`s floors are situated between 1620 and 1790 m asl. A thin cover of

296 glacial deposits is present on the cirque rims, while no glacial traces can be observed in lower

297 elevations. On the contrary, the north-facing slopes are steep cliffs characterized by a series of

298 cirques (Figures 3a and 3b) and extensive glacial deposition down to 950 m asl. Cirque floors on the

299 northern side of Velež are situated much lower in elevation (between 1400 and 1500 m asl) from

300 those on the south. Below cirques are polished limestone pavements and arêtes in between

301 individual glacial valleys. Less than 5 km from the main mountain crest lateral-terminal moraine

302 complexes occur at an elevation between 1300 and 1200 m.

303 We mapped 5 large lateral moraine pairs that are up to 2.7 km long and rise more than 100 m above

304 the valley floor. Other two smaller moraine complexes are 1.1 km long and no more than 50 m high

305 (Figure 2a). Moraines extend down to a minimum altitude of 940 m asl, where they are coupled with

306 outwash fans. Breach-lobe moraines, formed by the glacier cutting through the main lateral

307 moraines, are present on the external parts of some lateral-terminal moraine complexes, which are

308 believed to be deposited by moraine-dammed glaciers, typical for the karst areas (Žebre and

309 Stepišnik, 2015). Moraines occur also approximately 1 km up-valley of the outermost limits of

310 glaciation and some 100 m higher. They are much smaller, indicating an evident shrinkage of glaciers

311 especially in ice thickness. In most valleys of the Velež Mountain, left- and right-lateral moraine

312 couples are common (Figure 2a). We did not recognize more than two clear sets of lateral moraines.

313 The third set is usually present only on the rim of some cirques.

314 Lateral moraines are composed of a diamicton (Dmm) characterized by a sandy-silty matrix and

315 subangular to subrounded cobble-to boulder sized clasts of Cretaceous limestone and dolostone.

316 Common boulders of ~1 m in diameter are scattered along the moraine crests, although those up to

317 3 m can be also found (i.e. sample BU16-06). Further down moraines two larger areas of outwash

318 deposition are present below 1000 m asl. The meltwaters from the glacial valleys west of the peak

319 Botin were directed towards the Donje Zijemlje karst depression (Figure 3c), while those from the

320 valleys east of the highest peak were running off towards Nevesinjsko polje. However, a bifurcation

321 of meltwaters below glaciers in the karst underground system is not excluded. Outwash fans are

322 slightly inclined, from 1.5° in the proximal zones to only 0.5° in the distal zones. They consist of

323 horizontally bedded, clast-supported gravels with rare sandy lenses (Gh). The clasts are subrounded

324 to rounded Cretaceous limestone and dolostone. Average size of the clasts is from 1 to 7 cm,

325 attaining a maximum of 17 cm.

326

327 Figure 2: (a) Geomorphological map of glacial landforms on the Velež Mountain. (b) Samples for ^{36}Cl

328 cosmogenic nuclide dating were collected from the Budijevača lateral-terminal moraine complex.

329 The samples ID`s along with the ages (ka) corrected for 40 mm ka^{-1} of erosion are presented in (b).

330

332 parts and moraines entirely covered by forest below them. (b) The easternmost cirque on the Velež

333 Mountain, which hosted a small valley glacier during the maximum glacial phase. (c) The

334 westernmost outwash fan filling the floor of Donje Zijemlje karst depression.

335

4.1.2   <u>Crvanj Mountain</u>

337   The western slopes of the Crvanj Mountain (Figure 4a) were remodelled by limited extent of a cirque-

338   type glaciation. A complex of three cirques (Figure 5a) with northwestern exposition are present below

339   the highest peak Zimomor (1920 m asl). The cirque floors are situated at an elevation span of 1430-

340   1480 m asl. Up to 10 m high moraine ridges are located inside and below the cirques between 1400

341   and 1500 m asl. Three km long, deeply entrenched gully starts below glacial deposits and terminates

342   in the apex of the large outwash fan, covering the northern part of Nevesinjsko Polje.

343   Central part of the mountain is a wide-ranging plateau, having surface slightly sloping eastwards. Major

344   part of the plateau area is made of dolostone that appears to be glacially moulded, showing rounded

345   hills slightly elongated in the direction of glacier flow, and few dolines and polished pavements. Only

346   limited patches of glacial till can be found on the plateau, whereas on the eastern and southern slopes

347   of Crvanj glacial till appears in the form of large lateral moraines. The northern sector of the mountain,

348   where glacial deposits are also to be expected, has not been examined on the field due to the presence

349   of minefields. Since the area is completely overgrown by a forest, it was neither possible to confirm

350   the presence of moraines by means of remote sensing data.

351   A pair of lateral moraines and minor recessional moraines on the south-facing slopes extend between

352   1180 and 1400 m asl. In between the main lateral moraines, a gully is carved in bedrock, and after

353   approximately 3 km of length it terminates in the outwash fan on Nevesinjsko Polje. The largest

354   moraines that were also sampled (Figure 4b), are present on the eastern slopes of Crvanj at an

355   elevation range of ~1000-1350 m asl. Lateral moraines are no more than 1.5 km long and rise up to

356   150 m above the terminal moraine depression, where a lake is present (Figure 5b).

357   Till building these lateral moraines appears as a diamicton (Dmm) with sandy-silty matrix and angular

358   to subrounded clasts (Figure 5c). The lithology is more diverse as in the case of the Velež moraines.

359   Limestone and dolostone clasts show greater roundness compared to sandstone clasts (Figure 5d),

360   which are often striated. Gravel- to boulder sized clasts prevail within examined outcrops, while scarce

361   boulders, not exceeding 1.5 m in height, can be observed on the crests of moraines. Outwash deposits

362   in the Crvanj area have not been examined in detail due to a lack of outcrops.

363

364   Figure 4: (a) Geomorphological map of glacial landforms on the Crvanj Mountain. (b) Samples for [36]Cl

365   cosmogenic nuclide dating were collected from the Jezero left and right lateral moraines. The

366   samples ID`s along with the ages (ka) corrected for 40 mm ka^{-1} of erosion are presented in (b).

367

368   Figure 5: (a) Northern cirque below the highest peak of the Crvanj Mountain. (b) The sampled left

369   and right lateral moraine with a lake in between and (c) glacial till exposed in a road cut (d) with

370   striated sandstone clasts.

371

372   4.2 [36]Cl exposure ages

373   We collected a total of 20 glacial boulder samples from Velež and Crvanj mountains for [36]Cl

374   cosmogenic nuclide dating purposes (Table 1). The sampled moraines belong to a group of the lowest

375   moraines in both study areas and therefore mark the largest extent of palaeoglaciers that can be

376   recognised on the basis of geomorphological evidence.

377   Denudation rates of carbonate rocks can be very high and are believed to increase with increasing

378   MAP (Levenson et al., 2017; Ryb et al., 2014). The data from several carbonate terrains around the

379   world show denudation rates of the order of 40 (± 20) mm ka^{-1} for areas with mean annual

380   precipitation similar to that of Nevesinje (Levenson et al., 2017), while similar denudation rates (30-

381   60 mm ka^{-1}) were recently measured also in the Mediterranean karst (SE France) (Thomas et al.,

382   2018) independently of the precipitation amount. Thus, 40 mm ka^{-1} was used as the most

383   representative erosion rate for the correction of all sample ages in this study.

384   Reported age uncertainties were given at the 1-sigma level (i.e., one standard deviation), which

385   include both the analytical and production rate errors. The cosmogenic ages of boulders, and thus

386   the age of moraines represent the beginning of glacier retreat i.e., change in the equilibrium

387   conditions of the glacier mass, or stationing of the glacier on a terminal point.

388   4.2.1   <u>Velež Mountain glacial chronology</u>

389   Ten samples (Figure 6) were collected from the crest of one of the largest and best developed lateral-

390   terminal moraine complexes on the Velež Mountain, located in the Budijevača Valley (Figures 2b, 7a

391   and 7b). The sampled lateral-terminal moraine complex on Velež appears at 1300 m asl and after 2.7

392   km terminates at 980 m asl. It rises up to 130 m above the lake, which is located in between the

393   moraine complex. The lithology of all boulders that were collected from this moraine complex is

394   limestone, showing high concentrations of CaO (~55%) and very low K_2O and Cl (12.9-37.5 ppm), thus

395   the main production mechanism (>95%) is spallation of Ca (Table 2, and supplementary Table S1).

396   Five boulders from the right lateral moraine of Budijevača Valley yielded [36]Cl ages of 14.1 ± 1.8 ka

397   (BU16-01), 7.8 ± 0.9 ka (BU16-02), 10.9 ± 1.4 ka (BU16-03), 8.8 ± 1.1 ka (BU16-04) and 9.0 ± 1.0 ka

398   (BU16-05). Boulders from the left lateral moraine gave ages of 15.7 ± 2.1 ka (BU16-06), 9.0 ± 1.0 ka

399   (BU16-07), 6.3 ± 0.6 ka (BU16-08), 10.7 ± 1.3 ka (BU16-09) and 11.5 ± 1.4 ka (BU16-10) (Table 3).

400

401   Figure 6: Photos of the sampled boulders and their cosmogenic ages based on 40 mm ka-1 bedrock

402   erosion rates on the Velež Mountain.

403

404   None of the measured ages is more than twice the standard deviation away from the mean of the

405   surface exposure ages in a data set (Figure 8); therefore, no statistical outliers can be identified.

406   However, the biggest and tallest two boulders (BU16-01, BU16-06) gave the oldest ages (14.1 ± 1.8

407   ka and 15.7 ± 2.1 ka, respectively) among the group of samples taken from this moraine complex,

408   which indicates the exhumation caused by erosion of the moraines is likely to have a great influence

409   on the age of samples. Assuming that inheritance is not a relevant process due to the position and

410   characteristics of the moraine, then the oldest ages are likely to best estimate the true depositional

411   age.

412   Therefore, the oldest two samples representing the best estimate of the age of the landform, give

413   ages of 14.1 ± 1.8 ka (BU16-01) for the right lateral moraine and 15.7 ± 2.1 (BU16-06) for the left

414   lateral moraine. These average ages of 14.9 ± 1.1 ka indicate the Oldest Dryas glaciation in the Velež

415   Mountain.

416

417   Figure 7: (a) GoogleEarth image and (b) an aerial photo of the Budijevača lateral-terminal moraine

418   complex. Sampling locations are marked with yellow points in (a), white dotted lines in (b) are

419   moraine crests and blue arrowed line is the direction of the glacier flow. Note the height (130 m) of

420   the moraine in (b).

421

422   Figure 8: Cosmogenic ^{36}Cl ages of the boulders from right- (RL) and left-lateral (LL) moraines of (a)

423   Mt. Velež and (b) Mt. Crvanj. Upper panels show the individual sample ages with 1-sigma

424   uncertainties, and the lower panels show the probably density functions (PDF) of the samples.

425   Average age of the oldest two samples (indicated by thick black PDF curves) from both data sets

426   were shown and assigned to the age of the landforms.

427

428   4.2.2   Crvanj Mountain glacial chronology

429   We also collected 10 samples (Figure 9) from a pair of lateral moraines on the western slopes of the

430   Crvanj Mountain (Figure 4b). The sampled pair of lateral moraines stretches between 1350 and 1120

431   m asl and stands approximately 150 m above the lake area. Boulders are of different carbonate

432   lithologies with prevailing seven dolostone and three limestone boulders. Dolostone samples

433 (samples from CR16-01 to CR16-06 and sample CR16-08) have lower concentrations of CaO (26.51-

434 43.59%), but much higher concentrations of Cl (155.7-450.0 ppm) compared to limestone samples

435 (samples CR16-07, 09 and 10) (Table 2), which make the low energy neutron capture reactions via

436 ^{35}Cl an important part of the production mechanism of ^{36}Cl (about 40% of total ^{36}Cl production)

437 (supplementary Table S1).

438 Six boulders were collected from the left lateral moraine that yield ages of 8.2 ± 1.6 ka (CR16-01), 9.2

439 ± 1.6 ka (CR16-02), 4.2 ± 1.0 ka (CR16-03), 8.4 ± 1.5 ka (CR16-04), 11.3 ± 2.5 ka (CR16-05) and 7.0 ±

440 1.2 ka (CR16-06) (Table 3). The samples taken from the right lateral moraine yielded slightly younger

441 ages, i.e. 7.0 ± 0.7 ka (CR16-07), 8.5 ± 1.4 ka (CR16-08), 8.3 ± 1.0 ka (CR16-09) and 12.4 ± 1.6 ka

442 (CR16-10).

443 Even in this data set the statistical outliers do not appear (Figure 8) and the largest and at the same

444 time the tallest boulder (CR16-05) gave the oldest age. We applied the same approach as for Velež

445 and chose the oldest sample from each lateral moraine as the most representative time of moraine

446 emplacement. The oldest two samples yielded ages of 11.3 ± 2.5 ka (CR16-05) for the left lateral

447 moraine and 12.4 ± 1.6 ka (CR16-10) for the right lateral moraine. The average age of two samples

448 (11.9 ± 0.8 ka) indicate the Younger Dryas stadial event in the Crvanj Mountain.

449

450 Table 3: Cosmogenic ^{36}Cl inventories, production rates, ages of boulders considering different erosion

451 rates and ages of glacial landforms using 40 mm ka^{-1} of erosion in the Velež and Crvanj mountains.

453 Figure 9: Photos of the sampled boulders and their cosmogenic ages on the Crvanj Mountain.

454

455 4.3 Palaeoglacier geometry

456 On the basis of additional field observations, we revised the palaeoglacier extent and ELA estimation

457 for the Velež Mountain, which have been previously presented by Žebre and Stepišnik (2015a).

458   However, the reconstruction of glaciers and ELAs on the Crvanj Mountain is presented for the first

459   time in this paper.

460   Geomorphological evidence indicates that during the maximum phase of glaciation the Velež glaciers

461   covered an area of approximately 28.2 km^2 (Figure 10a). The north-facing glaciers, to some extent

462   described already by Grund (1910, 1902), initiated in cirques, moved down the valleys and

463   terminated in the karst depressions north of the mountain. Eight km-wide and up to 210-m-thick

464   system of 7 interconnected valley glaciers, with a number of nunataks protruding above the ice

465   (Figure 10b and 10c), was situated below the cirque complex. Only two valley glaciers on the north-

466   facing slopes, the eastern- and westernmost ones, were disconnected from this uniform ice mass.

467   The lengths of the north-facing glaciers were between 1.5 and 5 km. The westernmost valley glacier

468   was the lowest glacier in the study area, which terminated at an altitude of 940 m asl. According to

469   the calculations made by Profiler v.2 (Benn and Hulton, 2010) the thicknesses of the ice below the

470   cirques were between 130 and 210 m. On the south-facing slopes below the highest peak Botin, only

471   two small cirque glaciers existed, covering an overall area of less than 1 km^2.

472

473   Figure 10: (a) Palaeoglacier geometry with 50 m glacier contour lines, (b) glacier extent with

474   longitudinal profiles used in glacier reconstruction, and (c) the modelled ice thickness of the Velež

475   glaciers. Numbers in (b) indicate separate valley and cirque glaciers used for the ELA calculations. For

476   the geomorphology and sampling locations refer to Figure 2a.

477

478   The Crvanj Mountain hosted a small ice field and two cirque glaciers with an overall area of 23.9 km^2

479   during the maximum phase of glaciation (Figure 11a). Four outlet glaciers, heading towards N, E and

480   S directions (Figure 11b), drained the ice field. The outlet glaciers were between 2 and 3.5 km long

481   and up to 1.5 km wide. They ended at elevations between 900 and 1200 m. The northern outlet

482   glacier might have reached lower altitudes, but owing to landmines in that area we were not able to

483   make the geomorphological investigation. The greatest ice thickness was calculated on the plateau

484   area, reaching approximately 200 m (Figure 11c). The two cirque glaciers formed on the northwest-

485   facing slopes and covered an area of 1.4 km^2.

486

487   Figure 11: (a) Palaeoglacier geometry with 50 m glacier contour lines, (b) glacier extent with

488   longitudinal profiles used in glacier reconstruction, and (c) the modelled ice thickness of the Crvanj

489   ice field. Numbers in (b) indicate separate outlet and cirque glaciers used for the ELA calculations. For

490   the geomorphology and sampling locations refer to Figure 4a.

491

492   4.4 Palaeo-equilibrium line altitudes

493   The mean ELA of palaeoglaciers on the Velež Mountain was calculated to 1388 m (σ=186) using the

494   BR ratio of 1.9 ± 0.81 (Rea, 2009) (Table 4). While the mean ELA of the north-facing valley glaciers

495   was 1292 m, on the south-facing slopes where only two cirque glaciers formed, the ELA was 434 m

496   higher. Applying the same BR ratio, the mean palaeo-ELA on the Crvanj Mountain was found at 1541

497   m (σ=46) (Table 4). The ELA of the ice field with pertaining outlet glaciers was calculated to 1476 m,

498   while the ELA of cirque glaciers was 104 m higher. Northeast oriented glaciers had in general lower

499   ELAs, which is reasonable owing to differences in solar radiation and temperatures between north

500   and south facing slopes. However, the NE-SW difference in ELA is approximately 8-times higher on

501   Velež (NE-SW ELA difference=434 m) compared to Crvanj (NE-SW ELA difference=52 m), which can

502   be explained by different morpho-climatological conditions. The morphology of the Velež Mountain

503   with steep north-facing slopes allowed the formation of valley glaciers, where the accumulation was

504   likely dominated by windblown deposition and avalanches. These two mechanisms were not as

505   pronounced on the Crvanj Mountain due to the ice field type glaciation and consequently the local

506   ELA differences were relatively small.

507   To crosscheck the ELA calculations using the AABR method, we also applied the AAR method using

508   the ratio of 0.6 (Benn and Evans, 1998; Nesje and Dahl, 2000; Porter, 1977), which is the most widely

509   accepted, but not necessarily one of the most accurate methods (and ratios) for the palaeo-ELA

510   calculations (e.g. Kern and László, 2010). The results differ insignificantly, since the mean ELA for the

511   Velež Mountain is calculated to 1392 m and for the Crvanj Mountain to 1596 m. Taking into account

512   the ELAs calculated with the AABR method, the Velež Mountain ELA is 153 m lower than the ELA on

513   the Crvanj Mountain and 204 m lower in the case of AAR method.

514

515   Table 4: The estimated palaeoELAs (in metres) for all reconstructed palaeoglaciers on the Velež and

516   Crvanj mountains (see Figure 10b and 11b for the location of each glacier). The applied method is

517   area altitude balance ratio (AABR) with a ratio of 1.9 ± 0.81, which is representative for mid-latitude

518   maritime glaciers according to empirically derived results by Rea (2009).

519

520   4.5 <u>Degree-day model outputs</u>

521   Because snowmelt equals snow accumulation at the ELA under equilibrium conditions, our melt

522   predictions using a simple degree-day model show the amount of accumulation required to sustain

523   the reconstructed glaciers (Table 5). Hypothesizing the existence of glaciers with the reconstructed

524   ELAs on the Velež and Crvanj mountains in the recent climate, the annual accumulation required to

525   offset melting would need to be 9304 and 8295 mm of water equivalent, respectively. Further

526   hypothesizing the accumulation on palaeoglaciers was similar to the modern MAP at Nevesinje and

527   the modern annual temperature range was same as today, then the temperature depression

528   between 9 and 10 °C for Velež and between 8 and 9 °C for Crvanj is required to sustain the

529   palaeoglaciers with reconstructed ELAs. This is a very rough estimation because annual accumulation

530   on glacier approximates winter and not annual precipitation, excluding local inputs from avalanching

531   and wind-blown snow. The Velež glaciers on the north-facing slopes were likely influenced by the

532   aforementioned local inputs, which makes the melt predictions further overestimated. If assuming

533   higher annual temperature range because of possibly more continental climate during glacial stages,

534   even higher accumulation is required to balance melting.

535

536   Table 5: The degree-day model outputs for the Velež and Crvanj palaeoglaciers based on the

537   reconstructed mean ELAs for each mountain (ELA Velež =1388 m, ELA Crvanj=1541 m) and modern

538   climate data from Nevesinje (891 m asl) (mean annual temperature=8.6 °C, mean annual

539   temperature range=18.9 °C, MAP=1795 mm) for the period 1961-1990 (Data courtesy Federal

540   Hydrometeorological Institute, Sarajevo).

541

542   **5.   Discussion**

543   5.1 ^{36}Cl cosmogenic nuclide dating uncertainties

544   Apart from analytical and production rate uncertainties, geological uncertainties also have to be

545   considered when interpreting exposure ages. The latter often overshadow the first two and are

546   principally subject to prior-exposure (inheritance), reworking and exhumation of boulders on

547   moraines and erosion rates. Influence of vegetation and snow cover as well as tectonic movements

548   and other geomorphological processes can also play an important role in the interpretation of

549   exposure ages. Below, we discuss in detail the most relevant uncertainties for our study area.

550   5.1.1   Moraine degradation and exhumation of boulders

551   Although moraines in karst areas dating to Last Glaciation but also to older Pleistocene glaciations

552   (e.g. Hughes et al., 2011, 2010) are believed to be well-preserved because of the absence or minimal

553   fluvial reworking, they nevertheless degrade due to karst denudation and the topography is getting

554   smoother over time. Moraine crest lowering is more pronounced in its early stage, within the first

555   few thousands of years after the moraine deposition, when majority of large boulders are exhumed

556   (Putkonen and Swanson, 2003). However, there is a substantial difference in the intensity of

557   degradation among different types of moraines. Moraines with broad and flat crests, such as

558   hummocky moraines, will degrade less than for example lateral moraines with sharp crests and steep

559   slopes (Applegate et al., 2010; Putkonen and Swanson, 2003). In our case, the dated lateral moraines

560   exhibit smooth crest morphology and few large boulders are present on their crests. This indicates

561   that their post-glacial evolution has been influenced by a relatively marked degradation. Several

562   studies highlighted the problems related to the degradation of moraines and consequently the

563   boulder exhumation, resulting in cosmogenic ages that are inconsistent with the stratigraphic order

564   of moraines (e.g. Hughes et al., 2018; Palacios et al., 2019; Roy et al., 2017; Schaefer et al., 2008). The

565   influence of exhumation is particularly evident when trying to date moraine boulders older than Late

566   Pleistocene (Hughes et al., 2018). According to the moraine degradation model (Applegate et al.,

567   2010; Putkonen and Swanson, 2003), our dated moraines are supposed to degrade in the order of

568   ~20 m since Lateglacial. Our exposure ages likely reflect a range of ages when the active degradation

569   of the surface took place, and therefore in high precipitation regions we prefer to consider the oldest

570   age within a group as the best estimation of the true depositional age. Without erosion corrections,

571   these figures are 10.5 ± 0.9 ka for the Velež, and 15.6 ± 2.3 ka for the Crvanj mountains. The oldest

572   age in both cases is represented by the tallest and overall largest boulder within the group of

573   samples, which further demonstrates that the exhumation of boulders is one of the main geological

574   uncertainties to be considered while interpreting exposure ages in similar environments. This is in

575   accordance with the analysis of a large dataset of glacial boulders, confirming that tall boulders, most

576   likely with minimum post-glacial shielding, yield higher quality exposure ages (Heyman et al., 2016).

577   5.1.2   Inheritance

578   The inheritance is the initial nuclide concentration that is already in the rock before the beginning of

579   the final exposure (Ivy-Ochs and Schaller, 2009). Therefore, one of the most important assumptions

580   of the cosmogenic surface exposure dating is that the inheritance is negligible or could be

581   determined (Schmidt et al., 2011). Several studies related to moraine boulder inheritance indicate

582   that the glacier scouring of the bedrock is a very efficient mechanism in removing the pre-existing

583   cosmogenic component (e.g. Applegate et al., 2012, 2010; Davis et al., 1999; Dortch et al., 2013;

584   Hallet and Putkonen, 1994; Heyman et al., 2011). Several studies carried out on the moraine

585   boulders in the Taurus Mountain Range of Turkey since 2008 were compiled by Çiner et al. (2017)

586   (their figure 11), who concluded that out of 183 limestone samples, only 6 boulders (3.3%) were

587   outliers attributed to inheritance; the authors hence assumed this figure close to negligible. Although

588   few cases where inheritance is reported from moraine boulders (e.g. Dortch et al., 2013), we believe

589   that given the high erosion rates of the boulders, mainly due to high precipitation in our study area,

590   any inheritance related to prior exposure would have been zeroed. We therefore neglected

591   inheritance as a factor in our age calculations.

592   5.1.3   <u>Karst denudation rate</u>

593   In karst terrains, both chemical denudation and mechanical erosion processes operate and the total

594   karst denudation rate is the sum of both processes (Ford and Williams, 2007). Chemical denudation

595   rates established within karst vary due to runoff of precipitates, temperature and partial pressure of

596   carbon dioxide in surrounding atmospheres (Gunn, 2004). The chemical denudation rates are

597   regularly calculated through monitoring of dissolved mater content in karst springs (Ford and

598   Williams, 2007; Veress, 2009). Those values are non-relevant for determining karst denudation rates

599   on exposed carbonate bedrock (e.g. karren, glacial boulders), since there is no effect of enhanced

600   dissolution in epikarst subsoil environments. Relevant methods for exposed carbonate surfaces

601   include continual in-situ measurements by means of micro-erosion meter (Cucchi et al., 1995; Furlani

602   et al., 2009; Veress, 2009). However, these are only relevant for the recent climatic conditions.

603   Results from the northern part of the Dinaric Mountains highlight significant differences, which are

604   the result of lithological control coupled with climatic setting (Furlani et al., 2009). There are

605   differences between dolomites and calcarenites ($\sim$10 mm ka^{-1}) and micritic limestones ($\sim$40 mm ka^{-1})

606   (Cucchi et al., 1995; Furlani et al., 2009). Substantial differentiations in denudation rates are a

607   consequence of climatic setting and even small climatic variations (Mediterranean and sub-alpine

608   climate) can yield double denudation rates (Furlani et al., 2009). There is a shortage of detail

609   monitoring of micro-erosion meter denudation rates in high Dinaric environments. Available data

610   from the nearby Julian Alps on micritic limestones show average denudation rate of ~40 mm ka^{-1} with

611   considerable increases (up to ~100 mm ka^{-1}) within depressions with thicker snow cover (Kunaver,

612   1979). Those results correspond, in the order of magnitude, with other values obtained with the

613   same method in similar environments (Forti, 1984; Pulina, 1974). Furthermore, recently applied

614   measurements of ^{36}Cl concentrations for establishing denudation rates in different karst terrains

615   around the world (Levenson et al., 2017) and in SE France (Thomas et al., 2018) show denudation

616   rates in the order of 40±20 mm ka^{-1}. According to Thomas et al. (2018) there is no clear connection

617   between climatic spatial gradients and denudation rates; the latter are rather influenced by the

618   surface inclination. On the Velež and Crvanj mountains we deducted denudation rate at 40 mm ka^{-1}

619   even though previous researchers in the Balkans did not apply denudation corrections in cosmogenic

620   dating (Pope et al., 2015) or used rather low rates as 5 mm ka^{-1} (e.g. Gromig et al., 2018; Styllas et al.,

621   2018) (Table 6).

622

623   Table 6: A list of different dating methods applied to glacial landforms in the Balkan Peninsula. Note

624   that calculations of ^{36}Cl cosmogenic exposure ages from Mount Chelmos and Mount Olympus are

625   based on the production rates from Stone et al. (1996) and Schimmelpfennig et al. (2011),

626   respectively. For comparison, two boulder-ages from Mount Chelmos (CH10 (11.03 ± 0.9 ka), CH11

627   (8.76 ± 0.70 ka)) (Pope et al., 2015) and two boulder-ages from Mount Olympus (TZ03 (12.44 ± 1.07

628   ka), MK12 (12.37 ± 1.07 ka)) (Styllas et al., 2018) were recalculated using the production rates of

629   Marrero et al. (2016b). The two ages from Mount Olympus were also corrected for snow and

630   erosion, using the same values as in the paper of Styllas et al. (2018). The recalculated ages are 13-

631   14% younger for Mount Chelmos and 23-24% younger for Mount Olympus with respect to the

632   published ages. [14]C ages from Snežnik were recalculated according to the IntCal13 calibration

633   (Reimer et al., 2013). Recalculated ages are marked with asterisk.

634

635   5.1.4   <u>Shielding</u>

636   Post-depositional processes such as shielding by snow, vegetation, sediment and soil can reduce

637   nuclide concentrations on boulders, resulting in underestimation of landform ages. Although most

638   studies on moraines indicate that snow cover is a second-order process (~10% or less) (Schildgen et

639   al., 2005), a relatively thick snow cover might have been present in our study area because of high

640   precipitation potentials. As Velež and Crvanj mountains are geographically close, we assumed

641   identical snow shielding acting on the sampled boulders. We estimated a snowpack of 25, 100, 100,

642   100, 50, 25 cm of snow on Nov, Dec, Jan, Feb, Mar and Apr on top of boulders and calculated that

643   the total effect of snow correction of our samples to be around 4.9% (i.e. snow correction make the

644   ages 4.9% older). Doubling the snowpack data would add another 5.4% in average.

645   Another shielding factor might be related to vegetation. The presence of forest increases boulder

646   instability in matrix-rich moraines. Trees, soil and leaf litter decrease the cosmic rays reaching the

647   rock by only a few percent (Kubik et al., 1998). However, as trees grow or fall even large boulders can

648   be toppled (cf. Cerling and Craig, 1994). Assuming that dense trees covered the study areas, as we

649   see today, one would need to consider the shielding due to the vegetation during the exposure time

650   of the boulders.

651   5.2 <u>Interpretation of [36]Cl cosmogenic nuclide dating results from the Velež and Crvanj mountains</u>

652   After taking into account all relevant cosmogenic nuclide dating uncertainties for both study areas,

653   the most probable age of the dated moraines is Lateglacial, spanning from Oldest Dryas for Velež

654   (14.9 ± 1.1 ka) to Younger Dryas for Crvanj (11.9 ± 0.9 ka). These are still to be considered as

655   minimum ages. To better understand a relevance of the obtained ages, these have been put into the

656   geomorphological and climate context.

657   According to the geomorphological evidence, the dated moraines mark the largest extent of glaciers

658   in both study areas. These have been estimated to approximately 28 km^2 for Velež and 24 km^2 for

659   Crvanj using field evidence combined with the glacier flow-line model. The ELAs have been calculated

660   to 1388 m for Velež and 1541 m for Crvanj by applying the AABR method. Glaciers of similar size with

661   so low ELAs during Younger or Oldest Dryas have not been reported until now for the Balkan

662   Peninsula; they have been recorded only in the form of cirque glaciers (e.g. Gromig et al., 2018;

663   Hughes et al., 2011, 2010; Kuhlemann et al., 2009; Pope et al., 2015; Ribolini et al., 2011, 2018;

664   Styllas et al., 2018). Smaller moraines that are present at higher altitudes compared to the dated

665   moraines in our study area (Figures 2 and 4) are in better agreement with the above-cited Lateglacial

666   moraines and their corresponding ELAs. We would also assume that the dated moraines on both

667   mountains pertain to the same glacial period, because they mark the largest extent of glaciers in

668   their respective areas, which were of similar size. These local differences in ages might result from

669   different denudation rates between dolostone and limestone lithologies, the first being dominant in

670   the Crvanj area and the last in the Velež area (supplementary Table S1). Moreover, it would be

671   unrealistic to assume that all LGM moraines would have been washed away or entirely degraded,

672   also because moraines in karst environments generally tend to be better preserved compared to

673   moraines in the typical alpine environments, where slope and fluvial processes are much more

674   intense. Thus, it is difficult to justify the Lateglacial age of the reconstructed glaciers on Velež and

675   Crvanj from the geomorphological context.

676   Temperature depressions between 8 and 10 °C are required to sustain the reconstructed glaciers

677   with pertaining ELAs according to the degree-day model simulations (Table 5) if considering the

678   accumulation on palaeoglaciers was similar or less than the modern MAP. This is in accordance with

679   the reconstructed LGM temperature drop inferred from pollen for northern Greece and central Italy

680   (Peyron et al., 1998) as well as from ELAs for the Central Dinaric Mountains (Kuhlemann et al., 2008).

681   Though some of the reported temperature depressions for the Oldest and Younger Dryas in the

682   Balkan Peninsula are even more pronounced from those at LGM, like for example pollen inferred 10-

683   14°C drop in temperature for Oldest Dryas and around 10°C for Younger Dryas in the Lake Maliq in

684   Albania (Bordon et al., 2009). This is highly unlikely, also because no such drop in temperature has

685   been confirmed elsewhere in the Mediterranean, while the Younger Dryas temperature depression

686   inferred from the distribution of relict rock glaciers in the SE European Alps has been estimated to 3-

687   4°C (Frauenfelder et al., 2001). MAAT depression of 4°C for Velež and Crvanj would result in 4807-

688   5601 mm of water equivalent (w.e.) of annual melt at ELA, which is unrealistic. However, a drop in

689   temperature of 5-6°C, which would result in 4064-4807 mm w.e. of snow accumulation required to

690   balance melting at the ELAs of the reconstructed glaciers (Table 5), might be reasonable. The modern

691   glaciers in the Pacific Coast Range with maritime climate (e.g. South Cascade glacier) having very high

692   winter mass balance (~2000-4000 mm w.e.) and MAAT at the ELA close to or even above 0°C

693   (Krimmel, 2001; Ohmura et al., 1992; WGMS, 2016), are good modern analogues to our

694   reconstructed glaciers. Nevertheless, having glaciers in the Velež and Crvanj mountains with similar

695   winter mass balance as today in the Pacific Coast Range would require substantially higher MAP than

696   today.

697   The boulder ages reflect complex exhumation and denudation history, which at this point do not

698   allow obtaining more precise moraine chronologies for the Velež and Crvanj mountains. Future work

699   is needed to better understand the exhumation and denudation processes and their influence on the

700   cosmogenic exposure dating approach in a karst landscape like the Dinaric Mountains. Both study

701   areas as well as the entire country of Bosnia and Herzegovina lack any previous knowledge on the

702   timing of glaciations, which makes the correlation of the age data very difficult. This is however a

703   new dataset and presents a relevant contribution towards better understanding of the glacial

704   chronologies in the Dinaric Mountains.

705   5.3 <u>Glacial chronologies in the Balkans and elsewhere in the Mediterranean</u>

706   Although the mountains in the Dinarides and elsewhere in the Balkan Peninsula exhibit large areas of

707   glacially modified landscape, they are still poorly represented by age data, which makes a robust

708   comparison with the Velež and Crvanj data rather difficult. The closest area with established glacial

709   chronologies are mountains of Montenegro (Hughes et al., 2011, 2010) (Table 6, Figure 12), where

710   Younger Dryas has been recorded only in the form of cirque glaciers, having ELA at 1465 m on the

711   coastal Orjen Mountain. More distant Balkan areas with existent glacial chronologies, but still

712   relevant for comparison with the Velež and Crvanj mountains, are the Šar Planina and Galičica

713   mountains in the Former Yugoslav Republic of Macedonia (FYROM), and Mount Chelmos and Mount

714   Olympus in Greece. The glacier advance in the course of Younger Dryas on the aforementioned

715   mountains is also reported as cirque glaciations, with ELAs of 2300-2400 m on the Šar Planina

716   Mountains (Kuhlemann et al., 2009), 2130 m on the Galičica Mountain (Gromig et al., 2018; Ribolini

717   et al., 2011) and 2114 m on Mount Chelmos (Pope et al., 2015). ELA for Mount Olympus was

718   estimated to 2200-2600 m for the LG1-3 Lateglacial phase, which corresponds to Younger Dryas

719   period after the recalculation of the ages using the same production rates as those applied to our

720   moraine boulders (Table 6). All the above-mentioned published ELAs have been recalculated

721   (supplementary Table S2) to the same ELA method, and hence they are entirely comparable. The

722   Younger Dryas advances in other Mediterranean mountains have been confirmed in the High Atlas

723   (Hughes et al., 2018), Taurus Mountains (Sarıkaya and Çiner, 2017), Iberian Peninsula (Palacios et al.,

724   2016) and Maritime Alps (Federici et al., 2017). While the Younger Dryas glaciers where restricted to

725   cirque areas in the High Atlas, Taurus Mountains and majority of Iberia, they reached the size of

726   short valley glaciers in the Central Pyrenees (García-Ruiz et al., 2016) and Maritime Alps (Federici et

727   al., 2017). Nevertheless, the magnitude of glaciation on the Crvanj Mountain is outstanding when

728   compared with other Younger Dryas glaciers in the Balkan Peninsula and elsewhere in the

729   Mediterranean.

730   Glaciers in the Balkan Peninsula dated to the Oldest Dryas were as well small in extent, with ELAs

731   between 2200 and 2350 m on the Šar Planina Mountains (Kuhlemann et al., 2009), 2250 m on Mount

732   Pelister (Ribolini et al., 2018), and at 2000 m on the Galičica Mountain (Ribolini et al., 2011). The

733   Oldest Dryas advance on Orjen has not been recognized by Hughes et al. (2010), but from the

734   minimum ages provided by U-series dating that show early Holocene ages (Table 6), these can be

735   interpreted in terms of Younger Dryas (as interpreted by Hughes et al. (2010) or Oldest Dryas

736   glaciation with ELA at 1465 m. The calculated ELA for Velež is extremely low (1388 m) when

737   compared with the aforementioned ELAs, even after recalculating all the published ELAs

738   (supplementary Table S2). The Oldest Dryas advance in the Eastern Mediterranean has been

739   recognized on Dedegöl Mountains, where moraines were dated to between 16.4 ± 0.7 ka and 12.0 ±

740   1.0 ka (Köse et al., 2018), while Mt. Akdağ (14–17 ka), Mt. Sandıras (13–20 ka) and Erciyes Volcano

741   (14–17.5 ka) show similar Lateglacial chronologies (Sarıkaya and Çiner, 2017). Similar ages have also

742   been reported from other Mediterranean mountains (Federici et al., 2011; Palacios et al., 2016).

743   Several marine and continental proxies from the Adriatic Sea (e.g. Combourieu-Nebout et al., 2013;

744   Favaretto et al., 2008; Rossignol-Strick, 1995) and Balkan region (e.g. Aufgebauer et al., 2012; Bordon

745   et al., 2009; Vogel et al., 2010), respectively, indicate that the Younger Dryas and Oldest Dryas were

746   cold events. However, the relative amount and source of moisture is still a matter of debate. While

747   some argue for cold and dry glacier advance during Lateglacial (Ribolini et al., 2018; Styllas et al.,

748   2018), others suggest the climate at that time was humid (Hughes et al., 2011, 2010; Pope et al.,

749   2015). Thus, understanding palaeo-precipitation sources is of major importance for understanding

750   the zonal partitioning of glacier behaviour in the Balkan Peninsula. Pope et al. (2015) suggested that

751   the moisture bearing atmospheric systems delivering winter precipitation in the west central Balkan

752   Peninsula were different from those influencing southern Greece, the first being influenced by

753   cyclogenesis in the northern Adriatic (Hughes et al., 2010) whereas the latter likely received winter

754   precipitation from a western or southern source. The position of the polar jet stream is a key factor

755   in controlling precipitation pattern in the Mediterranean as well in the Balkan Peninsula. A general

756   idea of the southern shift of the polar jet stream during LGM, which brought a southward shift of the

757   North Atlantic storm tracks to about 40°N (Hofer et al., 2012; Laîné et al., 2009), is well supported by

758   atmospheric circulation models, but how the local synoptic circulation was acting in the

759   Mediterranean area is still debatable. Recent findings suggest a southerly moisture transport across

760   the southern Mediterranean and then approaching the Alps from southward direction (Luetscher et

761   al., 2015), which is consistent with the idea of the moisture bearing atmospheric systems delivering

762   high precipitation amount, mainly during spring and autumn, to the west central Balkans. While this

763   precipitation pattern was suggested for the LGM, it might hold true also for the Younger Dryas and

764   Oldest Dryas events, likely for a shorter period and not as intense as during LGM, but still supporting

765   the idea, to some extent, of a relatively large ice masses on Velež and Crvanj during that time.

766   Moreover, the Adriatic coast during LGM and Oldest Dryas was much further south with respect to

767   the Younger Dryas (Figure 13a). This suggests that during Younger Dryas greater amount of moisture

768   was available in the low-level jet, which is the main source for the orographic precipitation in the

769   Dinaric Mountains. Even if temperatures at that time were not as low as during LGM, the available

770   moisture might have been higher.

771   It is also worth noting the role of the orographic barrier of the Dinaric Mountains in capturing (today,

772   and most likely also in the past) most of the humidity from the Adriatic Sea air masses, leaving the

773   inland part of the Balkans relatively dry (Hughes et al., 2010). This effect is reflected in a strong west-

774   east gradient in ELA, which was suggested for the last cold stage glaciers in Montenegro and Greece

775   by Hughes et al. (2011, 2010, 2006). A rise in ELA of 100 m for every 15 km inland was calculated for

776   the Montenegrin glaciers by the same authors. Similar pattern of the inland ELA rise can be

777   recognized also for the Younger Dryas and Oldest Dryas glaciers in the part of the Balkan Peninsula

778   facing the Adriatic Sea (Figure 12b and 12c), which suggests the west-east gradient in ELA was

779   characteristic throughout the Late Pleistocene. We estimated a rise in the ELA of 94 m during the

780   Younger Dryas and 77 m for the Oldest Dryas for every 15 km inland. Very low ELAs in our study

781   areas seem to be shifted further inland (Figures 12b and 12c). This pattern might be related to the

782   fact that the first orographic barriers in the Neretva catchment are located more than 50 km from

783   the Adriatic coast and that specific topoclimatic conditions controlled the ELA depression. This might

784   be the reason why the Oldest Dryas ELA on Velež would have been lower than the ELA on Orjen,

785   since the modern MAP on Orjen is more than twice as high as on Velež.

786   On some of the massifs in the Iberian Peninsula the glaciers between 17.5 and 14.5 ka deposited

787   moraines that are spatially close to the LGM moraines (Palacios et al., 2016), which seem to be the

788   case also for some of the Turkish Mountains (e.g. Sarıkaya et al., 2014, 2009). However, in the Velež

789   and Crvanj mountains we did not find any geomorphological evidence that would imply larger glacier

790   extent, but closely spaced to the one we dated. It might be true that these large lateral-terminal

791   moraine complexes are products of several glacial stages, as has been already suggested by Žebre

792   and Stepišnik (2015a), which would imply that the glaciers on Velež and Crvanj reached their Late

793   Pleistocene maximum extents well after the global LGM. This is in agreement to some extent with

794   the ages obtained in the Šar Planina Mountain (Kuhlemann et al., 2009) and Montenegrin Mountains

795   (Hughes et al., 2011, 2010), where the moraines indicative for the local LGM were dated to the

796   period following the global LGM. The cosmogenic ages from terminal moraines in the Rila Mountain

797   (Kuhlemann et al., 2013) indicate that the local LGM extent occurred in two phases, i.e. prior and

798   after the global LGM. In contrast with the records in FYROM and Montenegro, the Late Pleistocene

799   glacier maximum on Mount Chelmos was dated to 40-30 ka and thus predates the global LGM (Pope

800   et al., 2015) (Table 6). While a relatively large LGM glaciation is reported from the Rila Mountains

801   (Kuhlemann et al., 2013), with 29 valley glaciers covering an area of 430 km^2 and having ELAs

802   between 2150 and 2290 m, from the Šar Planina Mountains with valley glaciers several km long

803   having ELAs between 1900 and 2300 m (Kuhlemann et al., 2009), and from Montenegro with several

804   smaller valley and cirque glaciers with a total area of 56 km^2 and ELAs between 1456 and 1952 m

805   (Hughes et al., 2011, 2010), much smaller glaciation in the form of cirque and small valley glaciers has

806   been recognized on Mount Chelmos (Pope et al., 2015), covering less than 5 km^2 in total, with the

807   mean ELA of 1986 m.

808   The evidence for older, Middle Pleistocene glaciations, when the glaciers in Montenegro, Greece and

809   Croatia would have reached their maximum extent (Table 6), is missing in our study areas. It is

810   obvious from several studies that the timing of glaciations not only varied across the Mediterranean

811   mountains (Hughes and Woodward, 2017), but also on a regional scale across the Balkan Peninsula.

812   Although our findings seem to match to a considerable extent to the results from the Balkan

813   Peninsula and some other Mediterranean mountains, more research is needed in Bosnia and

814   Herzegovina and in the Dinaric Mountains in general to better understand the climatic controls on

815   glaciations and the asynchrony of glacier fluctuations amongst different areas. The focus of future

816   research should be on moraine build-up during several glacial stages and possible age conflicts

817   between different dating methods, as recently pointed out also by Rodríguez-Rodríguez et al. (2018).

818

819   Figure 12: (a) All locations in the Balkan Peninsula where moraines/outwash have been dated so far.

820   Base layer of mountain belts is from https://ilias.unibe.ch/goto.php?target=file_1049915, based on

821   the mountain definition by Kapos et al. (2000). Bathymetric data is from the European Marine

822   Observation and Data Network (http://www.emodnet.eu/), while the sea level data for LGM, Oldest

823   Dryas and Younger Dryas is from Lambeck et al. (2011). ELA as a function of the distance from the

824   Adriatic Sea for (b) Younger Dryas and (b) Oldest Dryas. Only areas with absolute age data are taken

825   into account.

826

827   **6. Conclusions**

828   The Velež and Crvanj mountains in the Dinaric mountain karst in Bosnia and Herzegovina were

829   extensively glaciated during the Late Pleistocene despite their low altitude (<2000 m asl). During the

830   most extensive glaciation total glacier area was 28.2 km^2 on the Velež Mountain and 23.9 km^2 on the

831   Crvanj Mountain. High karst plateaux were covered by ice fields reaching thicknesses up to 200 m.

832   Valley and outlet glaciers reached as far down as ~900 m asl, where large lateral-terminal moraine

833   complexes were deposited. Twenty glacial boulders from the largest two moraine complexes were

834   sampled and dated using cosmogenic ^{36}Cl surface exposure dating. The obtained ages correspond to

835   the Lateglacial advances, namely the Younger Dryas on Crvanj and the Oldest Dryas on Velež,

836   although the age difference in the maximum glacier extent between the two mountains might result

837   from different denudation rates. However, the magnitude of glaciation along with the equilibrium

838   line altitude and degree day model simulations are exceptional in terms of the Lateglacial evidence in

839   the Balkan Peninsula. A possible explanation for that might be an increased moisture supply during

840   Lateglacial due to larger extent of the Adriatic Sea with respect to LGM along with specific

841   topoclimatic conditions controlling the ELA depression. This paper presents the first attempt to date

842   moraines in the Dinaric mountain karst using cosmogenic ^{36}Cl surface exposure dating and is thus an

843   important contribution towards a better understanding of the timing of glaciations in the Dinaric

844   Mountains. However, dating moraines in this type of karst with high precipitation amounts remains

845   problematic owing mainly to unknown denudation rates and the magnitude of moraine degradation.
